the absorption measurements. Thus we emphasize that the calorimetric heats of absorption are the only ones that need be considered. Their internal consistency is an excellent confirmation of the estimated accuracy.

Free Energy and Entropy for Formation of Pd_2H.—The change in the standard free energy for reaction 3 can be calculated from the pressure–composition relation during the course of the reaction in which

$$\Delta F° = 2F°_{Pd_2H} - F_{H_2}° - 4F°_{Pd} = 2F°_{Pd_2H} \qquad (5)$$

Since reaction 3 represents a solution of hydrogen in palladium with the two limits being pure palladium and pure Pd_2H, the entire process can be treated thermodynamically using the conventional method for handling solutions; that is, the partial molar free energies of the components are considered

$$F°_{Pd_2H} = 2(\bar{F}_{Pd})_{Pd_2H} + 1(\bar{F}_H)_{Pd_2H} \qquad (6)$$

The free energy in the standard state of Pd_2H (which is, of course, pure Pd_2H) is thus relative to those of pure palladium and hydrogen in the ideal gas state at 1 atm. pressure. Since the hydrogen in Pd_2H is in equilibrium with hydrogen gas at the equilibrium pressure, P_{H_2}, the partial molar free energy of hydrogen in palladium hydride is given by

$$(\bar{F}_H)_{Pd_2H} = {}^1/_2F_{H_2(p)} = 0.5RT \ln p_{H_2(Pd_2H)} \qquad (7)$$

Using the Gibbs-Duhem equation, one obtains

$$(\bar{F}_{Pd})_{Pd_2H} = -0.5RT \int_{x=0}^{x=0.5} x\,d \ln p_{H_2(Pd_2H)} \qquad (8)$$

where x stands for n_H/n_{Pd}. Since the square root of the pressure follows a straight line relationship with composition at the very low concentrations of hydrogen, the integral is best evaluated in two parts: the integral of $x\,dp^{1/2}/p^{1/2}$ at low concentrations, *i.e.*, an upper limit of $x = 0.04$, and the integral $x\,d \ln p$ for the higher hydrogen concentrations. The experimental pressure–composition data used in the evaluation of the integral are taken from the isotherm of Fig. 1 which is extrapolated at low concentrations of hydrogen to coincide with the isotherm of Gillespie and Hall. Graphical integration of eq. 8 produced a value of $(\bar{F}_{Pd})_{Pd_2H} = -18.7$ cal./mole. The standard molar free energy of Pd_2H is then evaluated from eq. 6 and 7 to be $F°_{Pd_2H} = -1153 \pm 6$ cal./mole. The hydrogen

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

lation was taken as the average equilibrium pressure for the seven heat of absorption measurements in the mixed phase region. This average pressure is 18.78 ± 0.91 mm. From eq. 5, $\Delta F°_{303.16°} = -2306 \pm 12$ cal./mole.

According to the second law of thermodynamics, the entropy change for reaction 1 is

$$\Delta S° = \frac{\Delta H° - \Delta F°}{T} \qquad (9)$$

At 303.16°K., using the above calculated values for $\Delta H°$ and $\Delta F°$, $\Delta S°_{303.16°} = -23.50 \pm 0.19$ e.u.

Discussion of Results

The change of slope of the straight line obtained from the pressure–temperature relationship after heating to 75° obviously involves some change in the structure of palladium hydride which is brought about by the increase in temperature. The change is apparently permanent since the desorption energy is fixed according to the highest temperature to which the hydride has been heated. The most surprising aspect of this effect is that only 10% of the hydrogen in the palladium had not previously been heated to 80°. Most of the hydrogen in the hydride had been heated to 80° when the two desorption experiments illustrated in Fig. 1 were accomplished. This indicates that the hydrogen pressure is determined by a relatively small quantity of hydrogen which probably is located in the surface lattices of the metal and which is not in all cases in internal equilibrium with the hydrogen in the interior of the metal. This fact is explained in the third paper of this series. The fact that equilibrium pressures are indicative of only the surface hydride concentration invalidates the use of isosteric heats at low temperatures for absolute values of the heat of desorption.

Heats of absorption have been measured twice before calorimetrically, both times at 0°.[9] The ice calorimeter apparatus used in both investigations is useful only in measuring fairly rapid heats of reaction, certainly not in observing heat effects over long equilibrium times. The average of a set of almost constant values measured by Mond, Ramsay and Shields[9a] at 0° is −9362 cal. mole^{-1}. Gillespie and Ambrose[9b] found −9283 cal. mole^{-1}. The palladium blacks used by both these investigators are known to exhibit hysteresis effects when hydrogen is absorbed at low temperatures so that these values are probably too low on this account.

From the experiments of this paper, the heat of absorption in the α-phase is found to be lower than the constant heat of absorption found in the mixed α- + β-phase. Although Gillespie and Ambrose's[9b] calorimetric investigation detected no difference in the heat of absorption at low and at high concentrations of hydrogen, their isosteric heats were 6000 cal. mole^{-1} in the α-phase and 8860 cal. mole^{-1} in the mixed phases.

The fact that the several investigations give better agreement for the calorimetric heats of adsorption than for the isosteric ones must be due to the fact that they are less affected by lack of equilibrium.

As mentioned above, the fact that the calorimetric desorption heats for the mixed α- and β-phases are not constant during desorption must be due to the very great desorption hysteresis evident in the isotherm of Fig. 1. The reason for desorption hysteresis, even though absorption hysteresis does not occur, will be discussed in a following paper[10] because it involves a new mechanism which is postulated for hydrogen mobility through the metal.

Acknowledgments.—One of the authors (D. M. N.) wishes to thank the Socony Mobil Oil Company for the generous provisions of the Socony Mobil Incentive Fellowship. Thanks are due to Mr. C. W. Brouse for the construction of the gold calorimeter and to Dr. R. G. Ascah for the construction and help in the calibration of the platinum resistance thermometer.

Palladium Hydride. II. The Entropy of Pd_2H at 0°K.[1]

BY DONALD M. NACE AND J. G. ASTON

RECEIVED FEBRUARY 13, 1957

The heat capacity contribution due to the absorbed hydrogen atoms in palladium hydride at a composition of nearly Pd_2H was measured in a newly constructed adiabatic calorimeter over small temperature intervals from 16 to 340°K. A residual entropy of 0.59 ± 0.18 e.u. has been calculated from experimental data to exist at 0°K. It is concluded that Pd_2H does not approach a completely ordered state at low temperatures and so is not a true compound. The shape of the heat capacity curve indicates the probability of covalently bound hydrogen at low temperatures with a dissociation process occurring as the temperature is varied. More evidence for this model is to be given in the succeeding paper.

Introduction

If Pd_2H were a true compound, and there were no hydrogen bonding as in ice, the entropy at 0°K. should be zero. This principle has been used by Hildenbrand and Giauque[2] to establish that at low temperatures ammonium oxide and ammonium hydroxide are true compounds. By using calori-

metric heat capacities measured as a function of temperature, they calculated the absolute entropy of a system from

$$S_T = \int_0^T C_p \, d \ln T + S_0 \qquad (1)$$

where S_0 is the entropy at absolute zero. According to the third law of thermodynamics, S_0 of any substance whose atomic arrangement and quantum states correspond to a unique lowest energy state at the absolute zero is zero. In the preceding paper[3] the entropy change for the reaction at 303.16°K., $4Pd + H_2 = 2Pd_2H$, is determined as

$$\Delta S_{303.16°} = 2S_{Pd_2H} - 4S_{Pd} - S_{H_2} = -23.50 \pm 0.19 \text{ e.u.} \qquad (2)$$

The experimental heat capacities measured in this investigation were those of the gold calorimeter containing pure palladium black before and after absorption of sufficient hydrogen to form about 98% Pd_2H. Since both sets of heat capacities include the heat capacity of the gold calorimeter, only the difference between the heat capacity of the calorimeter with pure palladium and the calorimeter with palladium hydride has any real significance. If this difference in heat capacity is expressed on a molar basis of hydrogen absorbed, $\Delta C_p'$ per mole of hydrogen added can be stated to be

$$\Delta C'_p = C_p(2Pd_2H) - C_p(4Pd) \qquad (3)$$

If the entropy at 0°K. of pure palladium is zero, eq. 2 can be expressed as

$$\Delta S_{303.16°} = \int_0^{303.16°} \Delta C'_p \, d \ln T - S_{303.16°}(H_2) + S_0(2Pd_2H) \qquad (4)$$

The absolute entropy of gaseous hydrogen in the standard state has been published[4] and is 31.34 e.u. at 303.16°K. Rearranging eq. 4 and inserting the known values, the entropy of Pd_2H at 0°K. is

$$S_0(Pd_2H) = {}^1/_2(-23.50 \pm 0.19 + 31.34 - \int_0^{303.16°} \Delta C'_p \, d \ln T) \qquad (5)$$

The zero point entropy of Pd_2H can thus be calculated from the results of a study of the heat capacity contribution of a mole of hydrogen to the heat capacity of palladium when palladium hydride is formed.

If the hydrogen atoms in Pd_2H are randomly distributed at room temperature, the system on cooling under equilibrium conditions will approach a unique lowest energy state corresponding to the most ordered arrangement of the atoms. Frequently the lowest energy state is degenerate, in which case a residual entropy $k \ln O$ is retained in which O is the number of equal energy orientations possible and k is the Boltzmann constant. If the energy differences between possible arrangements are small, a residual entropy of δ will be found at the absolute zero when the temperature is lowered to a point where thermal motions are unable to orient atoms into the completely ordered arrangement. Such a situation exists for carbon monoxide, nitrous oxide and nitric oxide.

(4) H. W. Wooley, R. B. Scott and F. G. Brickwedde, *J. Natl. Bur. Standards*, **41**, 379 (1948).

The shape of the heat capacity *vs.* temperature curve necessary for the third law entropy study also serves as a clue to the origin of thermal energies in the solid. The energy content of a solid at low temperatures arises from vibrations of the atoms in the crystal, but molecules have the opportunity to increase their energy in other degrees of freedom, such as rotation of a molecular unit or vibration of atoms within a molecule, as the temperature is increased.

Apparatus.—The heat capacity measurements were carried out in a newly constructed adiabatic calorimeter designated as Calorimeter J. The gold calorimeter and the sample of palladium black which it contains are described in the preceding paper.[3] A strain-free platinum resistance thermometer inserted into this calorimeter carries the designation Pt-G-5. It was calibrated between 11.5 and 92.6°K. by comparison under adiabatic conditions with two platinum resistance thermometers which are primary standards of The Pennsylvania State University temperature scale. The two primary standards, Pt-G-8 and PT-G-12, had been calibrated against the helium gas thermometer.[5] A total of 20 resistance measurements were made in this comparison calibration. Thermometer Pt-G-5 was calibrated on the International Scale by a similar comparison against the two primary standards involving 13 resistance measurements from 92.6 to 300°K. in addition to a precise determination of the ice point resistance. The value of such a calibration on the International Scale made by comparison measurements against a primary standard is that the chance need not be taken of thermally affecting the platinum wire during calibration at the boiling point of sulfur, one of the fixed points on the International Temperature Scale. The scale below 90°K. corresponds to 90.154°K. for the boiling point of oxygen,[6] whereas the value chosen to establish the International Temperature Scale was originally 90.19°K. In this case the value 90.154°K. was used for the boiling point of oxygen and proper adjustments made.

The low temperature cryostat and adiabatic shield arrangement were designed basically like those previously described.[7-9] Details are given in a thesis.[10] Above the shield, inside the cryostat the entering gas is passed through a temperature controlled heat exchanger to bring it to the same temperature as the calorimeter. This was for use in heat of absorption measurements.

Materials.—The palladium sample and hydrogen have been described in the preceding paper.[3]

Results

It was possible to maintain perfectly adiabatic conditions for Calorimeter J above 18°K. The average time necessary for thermal equilibrium was five minutes in the liquid hydrogen region, 15 minutes in liquid nitrogen, and 20 to 30 minutes above 200°K. For 55 experimental heat capacities of the calorimeter containing pure palladium, the average deviation of the points from a smooth curve is shown in Table I.

At the conclusion of all the experimental heat capacity measurements for palladium and palladium hydride, the heat capacity of the degassed calorimeter was again determined in the region from 35 to 95°K. These ten heat capacity determinations have an average deviation of ±0.05% from the new curve but on the average are 0.06% below the original heat capacity smoothed curve.

The heat capacities of the calorimeter containing first palladium black and later palladium hydride at the composition at which the atomic ratio H/Pd is 0.487 were measured from 16 to 303°K. The experimental data are given in Tables II and III. The heat capacity contribution of one mole of hydrogen to four moles of palladium, ΔC_p, is plotted against temperature in Fig. 1. The heat capacity anomaly which occurs between 30 and 100°K. is illustrated on an enlarged scale in Fig. 2. The repeated heat capacity determinations of the degassed calorimeter are also plotted on Fig. 2 as deviations from the original empty calorimeter heat capacity curve, and the deviations have been multiplied by the same factor used to convert the palladium hydride experimental heat capacity difference to a molar basis of hydrogen. The purpose of showing these remeasured heat capacities is to illustrate that the hump cannot be due to any permanent change undergone by the palladium.

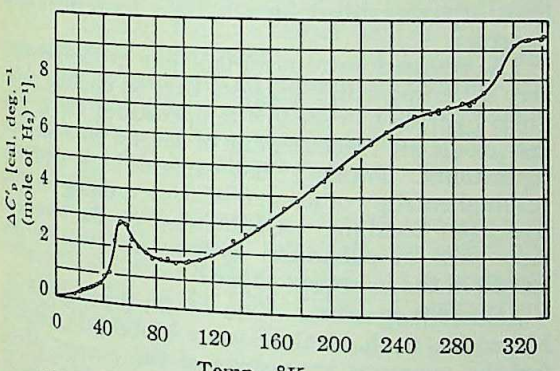

Fig. 1.—Heat capacity due to 1 mole H_2 in Pd_2H.

The heat capacities in all the temperature regions are quite reproducible for palladium hydride. The agreement among several overlapping series of runs is demonstrated in both Figs. 1 and 2. Obviously, any rearrangement of structure on change of temperature, if such occurs, proceeds rapidly since the heat capacities are reproducible regardless of the initial temperature to which the calorimeter is cooled. Based on the average deviations of the experimental heat capacities, the probable error of the $\Delta C'_p$ is about 10% at 15°K., and about 3% between 25 and 50°K., decreasing to 2% above 200°K. On integration to give entropies, the percentage error probably is decreased.

The heat capacity curve for palladium hydride above 290°K. shows a sudden rise. Heat capacities in this range are corrected for the heat of desorption of hydrogen evolved into the dead space of the calorimeter and filling line, the heat of compression of gas in the calorimeter dead space, and the change in concentration of hydrogen in the palladium. The heat of desorption for the quantities of hydrogen desorbed was assumed to be equal, but negative in sign, to the calorimetrically measured heat of absorption, −9605 cal./mole of hydrogen.

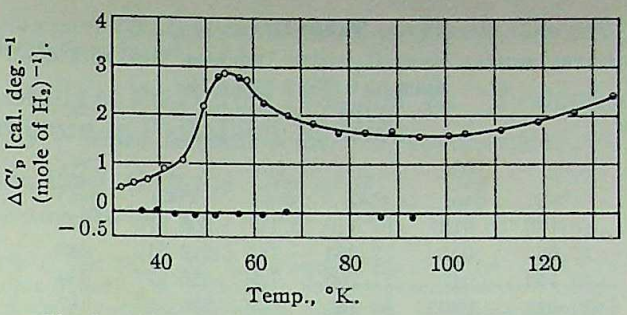

Fig. 2.—Heat capacity due to hydrogen in palladium (4 atoms): open circle, system cooled to 14°K.; half-filled circle, system cooled to 50°K. only; completely filled circles, after long pumping to remove the absorbed H_2.

65	6.316	180	10.45	300	11.68		

[a] Heat capacities at this and the following temperatures were measured after degassing of the calorimeter following all heat capacity measurements on Pd_2H.

Table IV contains a summary of the entropy change found by evaluating the integral in eq. 5. The zero point entropy can now be stated to be

$$S_0(Pd_2H) = \tfrac{1}{2}(-23.50 \pm 0.19 + 31.34 - 6.66 \pm 0.16)$$
$$= +0.59 \pm 0.18 \text{ e.u.}$$

The entropy of Pd_2H thus approaches a value of 0.59 ± 0.18 e.u. at the absolute zero of temperature. This discrepancy from an entropy of zero must be due to some degree of randomness in the arrangement of hydrogen atoms in the metal.

Discussion

The combination of bonding potentialities of unfilled inner shells of palladium and the observed exothermic release of energy when hydrogen is absorbed in palladium would certainly lead one to consider chemical bonding of some sort between

palladium and hydrogen atoms as the probable explanation for the absorption process. If such bonding does occur, the character of the metallic bond between palladium atoms is undoubtedly involved in a resonating system probably involving hydrogen bridge bonds as suggested by Rundle.[11]

The heat capacity curves of Figs. 1 and 2, in general, rise rapidly with temperature. In addition, an anomaly exists at 55°K. which is of the type commonly attributed to the beginning of molecular rotation in a covalent molecule. The 55°K. anomaly is similar to that of $(NH_4)_2O$ at about the same temperature as recently reported,[2] NH_4Cl, NH_4NO_3, $(NH_4)_2SO_4$ and CH_4 (references given in ref. 2). Rotation of the tetrahedral NH_4^+ ion and CH_4 molecule is commonly regarded as responsible for the increased energy absorption in the neighborhood of the anomaly. In the case of pure compounds, the anomaly is of the λ type, indicating that the potential barrier to rotation depends on the degree to which neighboring molecules are rotating. In cases where the coöperative interaction between neighboring molecules is not very great, the anomaly becomes less sharp. The effect of reducing the cooperation between neighboring molecules of methane is shown when methane is diluted with krypton. The λ-type anomaly[12] for pure methane is converted to a broad rounded hump for the methane in dilute solid solution with krypton.[13]

At temperatures above 55°K., the heat capacity contribution of hydrogen rises continuously at a rapid rate up to room temperature. The absence of a leveling off of the heat capacity indicates vibrational degrees of freedom present in the hydride which could be associated with molecular vibrations of covalently bound atoms. The heat capacity of pure palladium and of molecular hydrogen, or even of free protons if such could be present in the palladium lattice, would reach a constant classical limit at temperatures much lower than room temperature.

The residual entropy of 0.59 e.u. at the absolute zero of temperature suggests that on cooling palladium hydride to very low temperatures the hydrogen atoms are frozen in one of several possible configurations. Pauling[14] has explained the 0.82 e.u. residual entropy of ice at 0°K. by assuming random hydrogen bonding. A somewhat similar situation may exist in palladium hydride and will be discussed in the following paper.[15]

Acknowledgments.—One of the authors (D. M. N.) wishes to thank the Socony Mobil Oil Company for the generous provisions of the Socony Mobil Incentive Fellowship. The help of Mr. L. F. Shultz, who produced all of the refrigerants and aided in the assembly of the apparatus, was invaluable.

Palladium Hydride. III. Thermodynamic Study of Pd_2D from 15 to 303°K. Evidence for the Tetrahedral PdH_4 Structure in Palladium Hydride[1]

BY DONALD M. NACE AND J. G. ASTON

RECEIVED FEBRUARY 13, 1957

The heat capacity of Pd_2D has been measured from 15 to 152°K. and 280 to 300°K. for comparison with that of Pd_2H to verify a theoretical conclusion based on the shape of the lambda transition in the latter. For completeness certain points in the isotherm and partial molal heats of absorption of deuterium in palladium have been measured. The heat capacities of Pd_2H have been analyzed. Reasonable barrier heights and frequencies have been calculated to fit for a model based on PdH_4·7Pd at low temperatures. To explain the heat capacities above 120°K., a dissociation process is postulated which involves a decrease in the average number of hydrogen bonds as the temperature is raised. Hydrogen diffusion through palladium is conceived as a movement of hydrogen atoms by a continuous combination of (1) rotation about a parent palladium atom and (2) bonding to, and subsequent rotation about, a neighboring palladium atom. A new theory has been developed to explain the phase separation and hysteresis in the absorption isotherm.

Introduction

This is a continuation of the work reported in the two previous papers.[2,3] A lambda transition was found in the heat capacity curve of Pd_2H which is reminiscent of the type found for solutions of methane in krypton and for ammonium compounds. The effect on the lambda transition of substituting all the hydrogen in methane by deuterium has been studied by Clusius, Popp and Frank.[4] Due to the smaller zero point energy of deuterium as compared to hydrogen, the temperature of the lambda transition for CD_4 is shifted to a higher temperature. It also is split into two peaks. A comparison of the heat capacity anomaly of palladium hydride and palladium deuteride to see whether the equivalent shift and splitting occur is thus desirable. The heat capacity of Pd_2D has therefore been studied from 15 to 152°K.

As will be seen presently, it was necessary to conclude from the results that Pd_2H was essentially PdH_4·7Pd at the low temperatures. It is necessary to assume that as the temperature is raised reactions of the type

$$PdH_{2x} + Pd = 2PdH_x \qquad (A)$$

occur, giving a contribution to the heat capacity. Such reactions are essentially reactions of migrations. To substantiate this, the heat capacity of Pd_2D also was studied in the postulated temperature region of migration. In this paper, a calculation of the heat capacity curve for palladium hydride is made on the basis of this proposed PdH_4 model and correlated with the experimental data. The way in which the model explains other phenomena associated with the palladium–hydrogen system at high temperatures will be discussed.

Experimental

The adiabatic calorimeter and sample of palladium used for the heat capacity and calorimetric heat measurements is described in the preceding papers.[2,3] The deuterium used was obtained from the Cryogenic Laboratory at Boulder, Colorado (National Bureau of Standards), and reportedly contains 99.4 to 99.7% deuterium, the remaining fraction being HD.

Absorption of Deuterium by Palladium.—Seven increments of deuterium were absorbed at 30° in the palladium black sample, and the heat released by each increment was measured under adiabatic conditions. Deuterium was much slower than hydrogen in coming to pressure equilibrium during the heat of absorption measurements. In the case of hydrogen absorption, pressure equilibrium generally was reached in three to four hours, but, with deuterium, the pressure was decreasing at a rate of over 1 mm. per hour as much as seven hours after absorption. The heats, which are listed in Table I, were calculated on the basis of the temperature change after four hours of adiabatic conditions, at which time the rate of temperature change was never greater than 0.0003° per minute.

TABLE I

A. HEAT OF ABSORPTION OF DEUTERIUM AT 30°

Phase	Change in moles of D_2	Mean ratio D/Pd	Mean temp. T_m, °K.	ΔH

B. HEAT OF DESORPTION OF DEUTERIUM AT 30°

$\alpha+\beta$	0.005873	0.458	303.775	9536
$\alpha+\beta$	.004874	.425	299.733	8873

The average heat of absorption of deuterium in the mixed phase region is −8379 cal. mole^{-1} at an average temperature of 30.248°. These heats show a definite increase for each increment of gas added throughout the mixed phase region. The pressure over palladium deuteride also increased with each addition of deuterium. One month after the heats of absorption measurements were made, the equilibrium pressure over the final composition of palladium deuteride was measured, and at 35° was found to be 100 mm. instead of the value of 230 mm. observed several hours after addition. This amazingly slow equilibrium obviously has an effect on the accuracy of the heats of absorption for deuterium. The high heats of desorption compared to those of absorption shown in Table I correspond to a similar situation for palladium hydride.[3]

The temperature coefficient of the pressure of deuterium over palladium deuteride was measured

from 0 to 33° a month after the deuterium had been absorbed by the palladium. Figure 1 is a plot of log p *versus* $1/T$ at a D:Pd ratio of 0.479. The isosteric heat calculated from this straight line is 8635 cal. mole^{-1}.

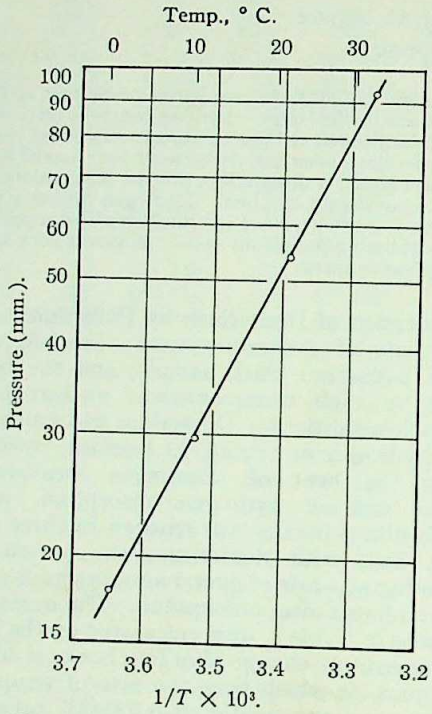

Fig. 1.—Pressure–temperature data Pd_2D.

Although calorimetric determinations of the heat of deuterium absorption in palladium never have been reported in the literature, isosteric heats above 200° have been determined before. The isosteric heat for deuterium desorption in the mixed phase region from the pressure–temperature relation of Gillespie and Downs[5] at an average temperature of 215° is 7760 cal. mole^{-1}. It is interesting to compare the isosteric heats obtained for palladium hydride and for palladium deuteride from this and the investigations of others.[5,6] The ratio of the isosteric heat, $\Delta H(Pd_2H)/\Delta H(Pd_2D)$, at 200° from the results of Gillespie and collaborators is 1.11. From this investigation, the same ratio at 30° is 1.12. The ratio of the equilibrium pressure over palladium deuteride to the pressure over palladium hydride shows an increase as the temperature is lowered. From the data of Gillespie the ratio is 2.1 at 270°, 2.4 at 250° and 2.9 at 200°. From this investigation the ratio is 4.6 at 30° and 4.8 at 20°.

The Heat Capacity Curve for Palladium Deuteride.—The heat capacities of the calorimeter containing palladium deuteride at a deuterium concentration corresponding to an atomic ratio D:Pd of 0.479 were measured from 15 to 152°K., and from 279 to 301°K. Because the time for this investigation was limited, it was not considered essential to cover the region from 152 to 279°K. The increase in heat capacity due to the deuterium is listed for each temperature in Table II. The data are plotted in Fig. 2 and Fig. 3. Agreement among overlapping runs is again evident as it was in the case of palladium hydride. The anomalous hump is again present, the temperature corresponding to the maximum value at the peak having shifted from 55.0°K. for palladium hydride to 57.5°K. for palladium deuteride. This is a 4.6% increase, while the shift from 20.4°K. for CH_4 to 21.4°K. for the first peak of CD_4 represents a 4.9% temperature increase. Although a second peak is not immediately evident in the case of palladium deuteride, the heat capacity decreases only slightly after the peak, and the two peaks may be combined in the general shape of the curve. The peak of the palladium deuteride curve is higher than that of the palladium hydride curve.

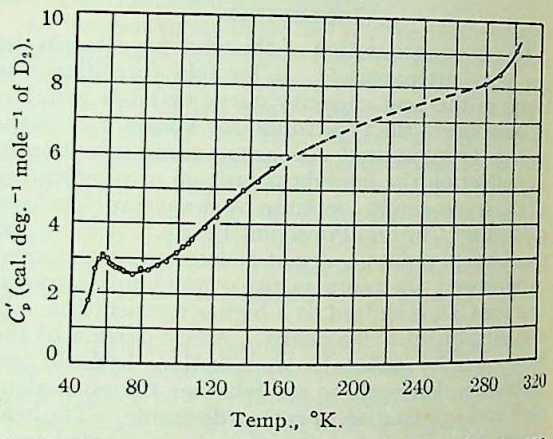

Fig. 2.—Heat capacity increase of palladium due to one mole of deuterium.

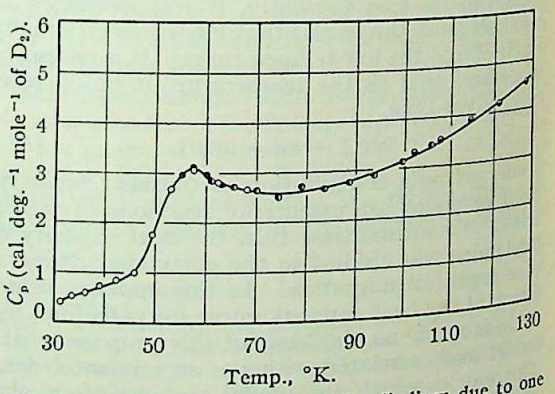

Fig. 3.—Heat capacity increase of palladium due to one mole of deuterium: open circles, cooled to 15°K.; half-filled circles cooled to 59°K., only completely filled circles, cooled to 53°K.

The second rise in the heat capacity of palladium hydride above room temperature following a leveling off of the curve also finds its analogy in the palladium deuteride curve, the temperature of the rise being considerably lower.

Theoretical Heat Capacity Curve at Low Temperatures Based on $PdH_4 \cdot 7Pd$ and $PdD_4 \cdot 7Pd$.—On the basis of the probable covalent bonding between palladium and hydrogen atoms, and the striking resemblance of the heat capacity anomaly to the cooperative rotational transition found in tet-

rahedral NH_4^+ ions and CH_4 molecules, a starting hypothesis for the molecular unit is PdH_4.

In comparing the experimental data with those calculated from any model, the former must be expressed on the basis used in the theoretical calculations. Accordingly, the experimental heat capacities from Fig. 1 of the preceding paper[2] must be calculated on the basis of one mole of PdH_4, and this can be done simply by adding the known molar heat capacity of one gram atom of pure palladium[7] to the experimental heat capacity contribution of four hydrogen atoms in palladium hydride in units of cal. per mole of PdH_4, if the theoretical calculation also neglects the excess palladium.

It now remains to define the details of the model more precisely. At the over-all composition of Pd_2H, one out of every eight palladium atoms would have four hydrogen atoms covalently bound to it according to the PdH_4 model. Also, in order to have the hydrogen atoms present in Pd_2H uniformly distributed throughout the lattices of the metal, two hydrogen atoms must be present in each palladium lattice cube since each face centered cubic palladium lattice contains the equivalent of four palladium atoms. The hydrogen atoms can satisfy both these requirements if PdH_4 molecules replaced palladium atom on four corners of each palladium lattice. If the hydrogen atoms of each PdH_4 molecule are tetrahedrally arranged about their central palladium atom, they can be directed toward the center of four different palladium lattice cubes. The two hydrogen atoms which are oriented toward the center of each cube lie at a point at which each hydrogen atom is equidistant from four tetrahedrally surrounding palladium atoms. The coöperative aspect of rotation of hydrogen atoms around adjacent corner palladium atoms is obvious. Rotation must be in phase so that only two hydrogen atoms occupy a minimum energy position in a cube at the same time. Figure 4 shows one possible arrange-

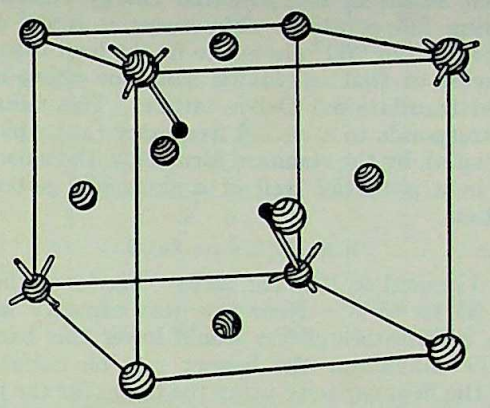

Fig. 4.—One possible arrangement of PdH_4 molecules in the palladium lattice: open circles, Pd atoms; black circles, H atoms.

ment of four PdH_4 molecule on corners of a palladium lattice cube. At the composition Pd_2H, each cube has attained this capacity of two hydrogen atoms. Based on this model and the crystallographic dimensions of the expanded palladium lattice in the β-phase, the Pd–H bond distance is 1.72 Å. and the moment of inertia of the spherical top molecule PdH_4 is 13.0×10^{-40} g. cm.^{2}.

A theoretical heat capacity curve can now be drawn for the hypothetical molecule PdH_4. This curve is drawn in Fig. 5 as the solid curve and superimposed on the experimental heat capacity data (open circles) expressed on the basis of PdH_4. The theoretical curve is composed of five contributions to the heat capacity. Curve A is the contribution of three translational degrees of freedom in the crystal based on Debye $\theta(\theta_t)$ of 275°, the value for

pure Pd. The filled circles are the experimental value for pure palladium.[7] Curve B represents the contribution of the additional three rotational degrees of freedom which would be present in the PdH_4 molecule, representing oscillations of the hydrogen atoms in the potential energy barrier restricting full rotation. The curve is based on a Debye $\theta(\theta_r)$ of 200° chosen to fit the heat capacity in excess of that calculated from the above-mentioned translational Debye lattice. This value of θ_r corresponds to a cut-off frequency (ν_m) which is associated, by the standard formula, with an oscillation in a potential well of a sinusoidal potential function.

$$V = V_0(1 - \cos 3\varphi)/2 \qquad (1)$$

with V_0 equal to 1600 cal. mole^{-1} barrier in the region 35 to 45°K. Near the heat capacity maximum coöperative effects would lower this barrier. At the maximum the barrier can be calculated from the heat capacity using the tables for the thermodynamic functions for molecules with restricted internal rotation. Curve C then represents the heat capacity curve due to a restricted rotor with V_0 equal to 390 cal. calculated from these tables. By considering that rotation becomes essentially free of hindering effects above the transition peak, the heat capacity contribution from the three rotational degrees of freedom must approach the classical limit of 3/2 R, represented in Fig. 5 as line D. Since the experimental heat capacity curve for PdH_4 increases sharply above 90°K., additional contributions must come from the nine remaining vibrational degrees of freedom in the molecule. Curve E is the vibrational contribution based on five bending frequencies, empirically set equal to 500 cm.$^{-1}$ to get the best fit with the experimental data. The assumption is made that the four stretching frequencies are too high to make a contribution. The bending frequencies are lower than the corresponding ones in methane. This is easily accounted for by lower force constants as well as the higher moments of inertia. The decreased bending frequencies of CCl_4 compared with those of methane constitute an example of the operation of both effects. The experimental curve is still increasing rather rapidly above 120°K., but the contribution of the four remaining stretching frequencies would not be expected to be the cause since they could hardly make an appreciable contribution until above room temperature. The cause of the rapid rise in the experimental curve must therefore be due to another factor. This will be discussed presently.

A corresponding treatment of the results with deuterium can be made in the same way. The results are shown in Fig. 6 which corresponds exactly to Fig. 4. The barrier to give the best fit at the peak is 475 cal. mole^{-1}, whereas the θ_r value for the torsional vibration to obtain the best fit below the peak is 235° corresponding to a ν_m of 164 cm.$^{-1}$. The value of V_0 calculated from the value of ν_m is 4480 cal. mole^{-1}. The agreement between this frequency and the 139 cm.$^{-1}$ value for ν_m for palladium hydride is illusory since the reduced mass is greatly increased with deuterium. The contribution of the five internal bending modes [illegible] arbitrarily made because once the average frequency has been set at 500 cm.$^{-1}$ for PdH_4 the value of PdD_4 is determined. The Teller–Redlich rule states that for a heavy central atom replacement of all the hydrogen by deuterium changes the frequencies inversely as the square root of two. This rule predicts quite closely the results of replacing the four hydrogens of methane by deuterium.[8]

On this basis the frequency for PdD_4 is 355 cm.$^{-1}$, and this was used in calculating the theoretical curve in Fig. 6. Inspection of Fig. 8 shows that the experimental points deviate considerably from the calculated curve on the high temperature side of the peak in a manner quite different from that of methane. The palladium hydride fits because the average frequency of the bending modes was chosen to obtain a fit, but obviously no reasonable frequency could be chosen to fit the deuterium results. The contribution for the vibration frequencies is negligible at temperatures immediately above that of the peak for any physically real frequency.

There are two *a priori* factors which would predict a higher heat capacity contribution. One of them is the possibility of a second peak in the rotational heat capacity on the high temperature side of the anomaly as has been mentioned above (as with deuteromethane); the other is that the dissociation process causing the deviation of the measured curve from the theoretical curve for palladium hydride above 120°K. is shifted to a much lower temperature. The higher barrier for palladium deuteride is most naturally attributed to its lower zero point energy.

High Temperature Model of Palladium Hydride.—The only previous heat capacity study of a transition metal hydride at low temperatures was made on tantalum containing small amounts of hydrogen.[9] The tantalum hydrides (in the α-phase) have about the same heat capacity as pure tantalum up to 100°K.; then the heat capacity rises considerably and reaches a peak at a temperature that is determined by the concentration of hydrogen. After the peak is reached, the heat capacity rapidly falls to the heat capacity of pure tantalum. The height of each peak is the same regardless of the concentration of hydrogen present if the heat capacity is expressed on a molar basis for the hydrogen. The peak occurs at 220°K., for an atomic H:Ta ratio of 0.0284; at 255°K., for a ratio of 0.0676; and at 265°K., for a ratio of 0.0958. The peaks form an envelope which is the heat capacity curve for the highest H:Ta ratio.

The rapid rise in heat capacity of palladium hydride up to room temperature in place of an expected leveling out above 150°K. may be analogous to Kelly's broad heat capacity peak. Kelly believes this anomaly is due to ordering of the dissolved hydrogen atoms (which are assumed to be free protons) as the temperature is lowered. Recent X-ray diffraction studies[10] on tantalum hydrides at low temperatures indicate that Ta_2H begins to pre-

cipitate from a homogeneous α-phase hydride when the temperature is lowered below room temperature. In view of this discovery, the energy taken up by palladium hydride as the temperature is raised probably is due to heat of dissociation. The dissociation process involves a disordering migration of hydrogen atoms from the low energy position in $PdH_4 \cdot 7Pd$ to more random arrangements throughout the lattice. Such reactions can be symbolized by

$$PdH_{2x} + Pd = 2PdH_x \qquad (A)$$

In the case of palladium hydride, the second rise in heat capacity occurring at about 290°K. may well be the stage in which reaction (A) becomes

$$PdH_2 + Pd = 2PdH \qquad (B)$$

Evidently the second rise in heat capacity near room temperature due to this cause is shifted down the temperature scale on replacement of hydrogen by deuterium. Therefore a corresponding effect would be expected for the abnormal rise just above 120°K. It is apparently this effect which is at least in part responsible for the different behavior of palladium deuteride in the high temperature side of the peak.

The Diffusion Mechanism of Hydrogen through Palladium.—The disordering process that occurs when $PdH_4 \cdot 7Pd$ is heated is thus taken to involve a redistribution of hydrogen bonds among various palladium atoms in each lattice cube. The stability of the hydrogen bond itself most likely is due to resonance forms involving hydrogen atoms which lie midway between two or more palladium atoms. The bonds themselves may be similar to the "half bonds" which Rundle proposed[11] for electronically deficient compounds. He predicted that in the case of great electron deficiency, such as occurs in transition metals, four or more atomic orbitals may be combined to give a single bond orbital of lower energy than the single atomic orbital. After it has settled into a hydride configuration, the rotating PdH_4 molecule (or lower hydrides such as PdH_2) may be thought of as being in a higher energy state with the hydrogens bonded to only one palladium atom. If rotation of the hydrogen atoms in a PdH_4 molecule (or a lower hydride) occurs, it is feasible for a hydrogen atom bridging two palladium atoms to be rotated about the second palladium atom with which it shares a common orbital. The availability of rotational energy allows a translation of hydrogen atoms from one palladium lattice to another by a combination of hydrogen atoms being first shared with and then rotated about neighboring palladium atoms.

This concept of hydrogen transfer through the metal differs from previous theories in which inexplicably free protons drift at random in the metal. The proposed mechanism is supported by two recently published discoveries. Results of a neutron diffraction study of palladium hydride at room temperature show that the most probable positions for the hydrogen atoms are on the edges of the palladium lattice cube, mid-way between the corner palladium atoms, and at the center of the cube (coördinator $\frac{1}{2}a,0,0; 0,\frac{1}{2}b,0; 0,0,\frac{1}{2}c$; and $\frac{1}{2}a,\frac{1}{2}b,\frac{1}{2}c$, respectively).[12] In the model of palladium hydride proposed in this paper, each palladium atom in the lattice is a revolving sphere with a high hydrogen probability on the surface. Four of these spheres nearly intersect at the center of the cube and at points on the edges midway between the corners; therefore, maximum intensity should be found at these positions in the neutron diffraction patterns. The nuclear magnetic resonance studies[13] of palladium hydride at room temperature by Norberg have revealed line widths which indicate rapid proton motion within the lattice. The activation energy for diffusion necessary to explain his result in terms of the free proton theory led Norberg to propose a "short circuit" diffusion mechanism consisting of diffusion along lattice imperfections. According to the present theory, the "short circuit" is formed by the resonance-rotation mechanism which arises in a natural fashion.

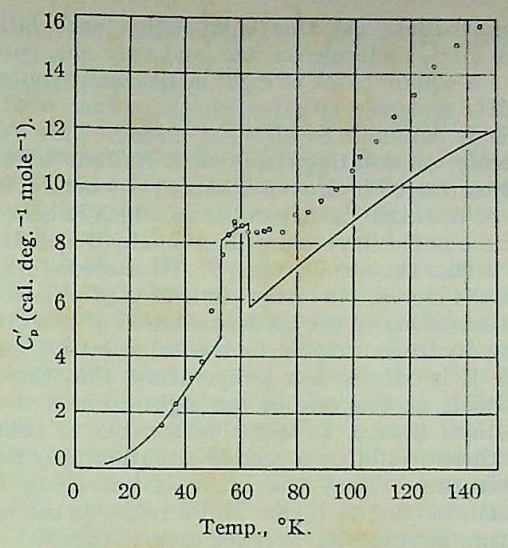

Fig. 6.—Theoretical heat capacity of PdD_4: open circles, experimental PdD_4 points; solid line, total of Debye translation, Debye torsion, rotation and Einstein modes.

Phase Separation Hysteresis.—It has been pointed out that, because the lattice is face centered cubic, for the composition Pd_2H the maximum number of hydrogen atoms that can be present in a palladium lattice cube is two. This presupposes that each hydrogen atom lies at a position equidistant from four different palladium atoms. At high temperatures where absorption isotherms are measured, PdH_4 molecules have reacted with palladium neighbors to share their hydrogen or form lower hydrides. The same number of hydrogen atoms per unit cell, on an average, are demanded by the configuration. The average is maintained by the rotation (*not necessarily free*) of each hydrogen atom around a parent palladium atom in phase with the other hydrogen atoms. At low temperatures the hydrogen atoms cluster as PdH_4 molecules on corners of the palladium lattice. This leads to the prediction of the first break in the absorption isotherm at a composition Pd_8H (H:

(11) R. E. Rundle, *J. Chem. Phys.*, **17**, 671 (1949); *J. Am. Chem. Soc.*, **70**, 1769 (1948); **69**, 1719 (1947); **70**, 99 (1948); **69**, 1379 (1947); **69**, 1327 (1947); **69**, 1980 (1947); **69**, 1719

Pd = 0.125). At this composition each lattice has a PdH_4 molecule on one, and only one, corner site. A square block of eight lattice cubes contains a PdH_4 molecule situated on the corner position which is common to all eight cubes. This PdH_4 molecule, on rotating, can orient its four tetrahedrally arranged hydrogen atoms at any instant into four of the eight lattice cubes to which it belongs. No cube could have more than one hydrogen atom in it unless the atomic ratio H:Pd exceeded 0.125. Thus the increase in lattice dimension (β-phase) has its *raison d'etre* in the accommodation of two interacting hydrogen atoms in the same lattice cube. While it is only at low temperatures that there is one PdH_4 at this one of the eight corners of the palladium lattice, it seems reasonable to believe that there would be a related situation near room temperature. Thus the break is not sharp but gradual, moving to higher H:Pd ratios as the temperature increases as observed experimentally.

From the evidence given in the first paper[2] in this series, the absorption isotherm (as distinct from the desorption process) for hydrogen in palladium black is convincingly an equilibrium isotherm. Hydrogen must be able to penetrate into all the lattices of the palladium sample, and the β-phase which is formed must be uniformly distributed. This is not true for many isotherms which have been published, such as is shown in Fig. 7

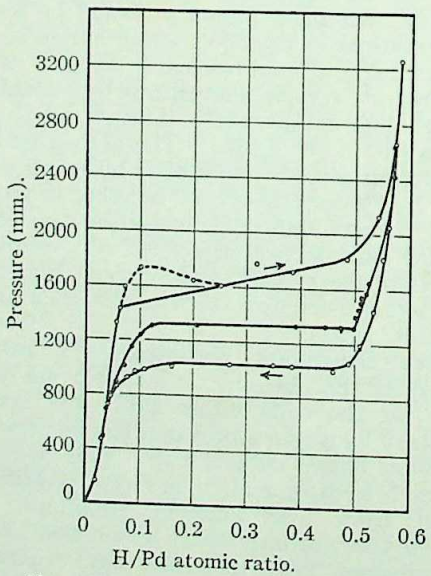

Fig. 7.—Absorption, desorption and equilibrium isotherms at 160° for hydrogen on palladium: open circles, absorption and desorption; filled circles, equilibrium.

where the hysteresis involved in a 160° isotherm[14] is contrasted with the isotherm of Gillespie and Hall at 160°.[15] The diffusion of hydrogen into palladium proceeds rapidly and without hysteresis to a composition approximately Pd_8H. Additional hydrogen absorption must form β-phase expanded lattices on the surface of the metal. The process of forming an internal β-phase expanded lattice cannot occur spontaneously by diffusion of hydrogen atoms from the surface β-phase lattices into an unexpanded α-phase cube because energy must be absorbed in order to expand the lattice. The mechanism for the formation of internal expanded β-phase lattice must involve an unstable active state and probably one in which three hydrogen atoms are present in one of the already expanded external lattices. Such a process is then followed by the rapid release of the third hydrogen atom into a neighboring α-phase lattice. Obviously the farther from the surface this process must proceed, the slower will be the approach to equilibrium.

The proposed mechanism presupposes that the condition of the surface lattices determines the hydrogen pressure over the hydride. If this is so, desorption of hydrogen from surface β-phase lattices should produce α-phase surface lattices over which the equilibrium pressure of hydrogen is abnormally low. Experimentally this is always observed, even in the case of the two true equilibrium isotherms in Fig. 1 of the first paper[2] in this series. The rapid drop in pressure on desorbing hydrogen implies that surface β-phase lattices have been depleted of hydrogen and become α-lattices. A pressure is soon reached at which a steady state is established in which hydrogen can be desorbed without further lowering of pressure. Since internal lattices must also be undergoing desorption, hydrogen atoms from internal β-phase lattices pass to β-phase lattices near the surface at a rate depending on the hydrogen concentration gradient in the internal lattice. During this rapid flow of hydrogen, the β-lattices near the surface must of necessity have an excess of hydrogen atoms in order that they may pass hydrogen on to α-lattices in the surface. When the pumping of hydrogen from the palladium hydride sample is stopped, the rate of desorption of hydrogen from surface lattices to the gas phase falls to zero. The external hydrogen pressure in equilibrium with the surface lattices will remain fixed at a value depending on the hydrogen concentration which lies entirely in α-phase surface lattices. No sort of β-lattice is possible on the surface unless the pressure is raised to that of the flat part of the isotherm, or as Gillespie and Hall have done, the temperature of the system is raised to a high enough temperature (360°) to equilibrate the system internally.

By the addition of hydrogen, partially desorbed palladium hydride can be brought back to an equilibrium condition with a pressure of hydrogen in contact with it which is again on the true equilibrium isotherm. This is in accord with the theory. Not even the total amount desorbed need be added in order to return the pressure to the equilibrium value of the two-phase region because the pressure is established by the surface lattices. This fact is a striking confirmation.

The model has been shown to be consistent with the two isotherm breaks which occur at the compositions Pd_8H and Pd_2H. The initial break in the isotherm of Gillespie and Hall[15] occurs at Pd_8H in the range 160 to 250°. The fact that the break occurs at somewhat lower hydrogen concentrations at lower temperatures can only be due to lack of

internal equilibrium. Gillespie and Perry[16] have in fact observed several abnormal 0° isotherms for which no break at all occurs.

The second isotherm break occurs at Pd_2H from 80 to 200°. The break occurs at higher hydrogen concentrations at lower temperatures possibly because of hydrogen adsorption in structural rifts and defects caused by the independent expansion of each lattice cube.

Significance of the Entropy of Pd_2H at 0°K.—In the preceding paper[2] a residual entropy of 0.59 e.u. at 0°K. was compared to the residual entropy of 0.82 e.u. for ice on the basis that random hydrogen bonding can occur in both. In ice, each oxygen atom is surrounded by four tetrahedrally arranged hydrogen atoms. In $PdH_4 \cdot 7Pd$, only some of the palladium atoms are surrounded by four tetrahedrally arranged hydrogen atoms. For ice, however, only two hydrogen atoms are covalently bound at one time to an oxygen atom while all four hydrogen atoms can be covalently bound to the central palladium atom. Just as random distribution of hydrogen atoms in ice is frozen into a false equilibrium at low temperatures, the arrangement in Pd_2H is subject to a similar circumstance. In building a model of $PdH_4 \cdot 7Pd$, many different arrangements of the PdH_4 molecules on corner lattice sites can be constructed. Actually there are five possible arrangements for the distribution in an independent lattice cube, but the cubes are not independent in the metal. The arrangement of PdH_4 molecules in one cube partially determines the arrangement in the neighboring cubes. The system is too complex to lend itself to a numerical calculation of the total number of arrangements as can be done in the case of ice. However, since each cube is equivalent to two Pd_2H molecules, the experimental value of 0.59 e.u. allows the choice of two arrangements for the PdH_4 molecules in each cubic lattice because

$$S_0 = k \ln 2^{N/2} = {}^1/_2 R \ln 2 = 0.69 \text{ e.u.} \qquad (2)$$

Comparison with Free Proton Theory.—It must be remembered that the degree of hydrogen bonding in palladium hydride is changing with temperature as indicated by the heat capacity curve. It is apparent that the covalently bonded hydrogen model at high temperatures becomes a model of interstitial hydrogen atoms vibrating and rotating relative to the palladium lattice. This assembly of hydrogen atoms, even though the hydrogen atoms share electrons with individual palladium atoms, would be indistinguishable from the model of free protons assembled in regular monolayers as considered by Lacher.[17] The straight line relation in the α-phase between hydrogen concentration and the square root of hydrogen pressure applies equally to a PdH covalently bound hydrogen model or to a free proton model. In other words, much that has been explained in the past on the basis of free protons can also be explained by the covalently bound hydrogen. Additional investigations, particularly of neutron diffractions, will have to be conducted at temperatures well below room temperature in order that the covalently bound hydrogen model be further verified.

Acknowledgments.—One of the authors (D. M. N.) wishes to thank the Socony Mobil Oil Company for the generous provisions of the Socony Mobil Incentive Fellowship. The help of Mr. L. F. Shultz, who produced all of the refrigerants and aided in the assembly of the apparatus, was invaluable.

Magnesium–Cadmium Alloys. VIII. Heat Capacities of Mg_3Cd and $MgCd_3$ between 20 and 290°. The Standard Heats, Free Energies and Entropies of Formation and the Residual Entropies[1,2]

By W. V. Johnston, K. F. Sterrett, R. S. Craig and W. E. Wallace

Received March 23, 1957

Heat capacities of $MgCd_3$ and Mg_3Cd have been measured between 25 and 270° using a new adiabatic calorimeter permitting a precision of 0.1 to 0.2% in the measurements. Experiments were performed using an intermittent heating technique in order that equilibrium heat capacities might be obtained. The data reveal a specific heat anomaly of the customary type for alloys undergoing order–disorder transitions, with peak values at 83.8 and 150.6° for $MgCd_3$ and Mg_3Cd, respectively. With the aid of the heat capacity data, the standard heats, free energies and entropies of formation of the alloys at 270°, which were reported earlier, have been corrected to 25°. The residual entropy of Mg_3Cd has been found to be 0.03 ± 0.04 e.u./g. atom and the corresponding quantity for $MgCd_3$ has been found to be 0.16 ± 0.04. The latter is in good agreement with the quantity 0.17 ± 0.01 e.u. computed statistically under the assumption that there is a random distribution of the observed number of Schottky defects over the lattice sites. Attention is directed to the large errors which can occur when the conventional continuous heating technique is used with systems undergoing configurational changes.

In Paper VII of this series heat capacity data for Mg_3Cd and $MgCd_3$ between 12 and 320°K. were presented.[3] Entropies of formation of these two substances at 270° had been determined[4] earlier by the electrochemical cell method and in

paper VII the two sets of data were used to evaluate the residual entropy of the compound $MgCd_3$. The required thermal data above 320°K. were taken from the literature. A similar calculation for Mg_3Cd was not possible at that time because of the unreliability of the heat capacity data for it above 320°K. In fact the calculation for $MgCd_3$ was not entirely satisfactory since the existing data extended only to 430°K. and an extrapolation over an interval of 110° had to be made. To permit a satisfactory evaluation of the residual entropies of these substances a new calorimeter has been built and used to determine their heat capacities between 20 and 290°. The data obtained are of additional interest in that (1) they permit reliable evaluations of the heats, free energies and entropies of formation of the two compounds at 25° and (2) they indicate for the first time the temperature dependence of the *equilibrium* heat capacities in the region where these substances exhibit thermal anomalies due to order–disorder transformations. Previous studies have consistently involved the continuous heating technique yielding *non-equilibrium* heat capacities, which for these materials differ at some temperatures appreciably from the equilibrium values.

Experimental

Apparatus.—Since full descriptions of the calorimetric equipment used may be found elsewhere,[5,6] only a brief account will be given here. The calorimeter assembly was essentially of the Southard–Brickwedde design.[7] A few departures from conventional practice were necessary because of the higher temperatures involved. Wires were insulated with glass braid (instead of Nylon) impregnated with either Teflon or a silicone resin. The sample container was very similar to that which has been used[3] in this Laboratory for several years in the study of intermetallic compounds at low temperatures. It was sealed off using a solder consisting of Pb with 5% Ag added. This proved to be more satisfactory mechanically than pure Pb which was originally used. The sample was sealed off in an enclosed container which permitted the soldering to be done under reduced pressure. About 0.1 atm. pressure of helium exchange gas was introduced. Temperatures were measured with a capsule type platinum resistance thermometer that had been calibrated by the National Bureau of Standards. Its fundamental interval was periodically redetermined during the course of the work.

Materials Used.—The samples employed were the same as had been used in the earlier work.[3] They had been stored under an atmosphere of helium while not in use. Compositions were 74.98 ± 0.04 and 24.98 ± 0.04 atomic % cadmium for $MgCd_3$ and Mg_3Cd, respectively. The masses of sample employed were: $MgCd_3$, 582.207 g. or 6.4425 g. atoms; Mg_3Cd, 252.092 g. or 5.4418 g. atoms.

Method of Measurement.—$MgCd_3$ and Mg_3Cd undergo order–disorder transitions in the temperature range covered at about 85 and 150°, respectively. Most of the heat capacity data for alloys in the order–disorder region have been obtained using the continuous heating technique. It appears that such results may in certain regions of temperature be seriously in error (10% or more) due to the failure to maintain equilibrium in the sample. Disordering requires a redistribution of atoms over the positions in the lattice and this may fail to keep pace with the changing temperature when continuous heating is used. In this event the measured heat capacity is a non-equilibrium value and is therefore not suitable for entropy calculations.

The intermittent heating technique has been employed in the present study. The sample is heated for a carefully measured interval of time of 5 to 15 minutes duration resulting in a temperature increment of roughly 5°. Temperature was then followed until it became constant,[8] if this occurred in a reasonable length of time. This was not feasible with Mg_3Cd from 35 to 60° and with $MgCd_3$ from 31 to 95°. In these ranges the temperature continued to fall for many hours after the heat input was stopped, indicating that disorder in the sample was continuing to increase. In some instances the course of the temperature–time curve was followed for 20 hr. and the sample had not reached configurational equilibrium. In these cases an extrapolated final temperature was found under the assumption that the temperature tends exponentially toward the equilibrium value, an assumption which has been justified by recent kinetic studies[9] of the order–disorder transformation in $MgCd_3$.

With Mg_3Cd the extrapolations were short and errors introduced from this source were slight. The extrapolations were not short, however, for temperatures near the order–disorder Curie point for $MgCd_3$. Equilibration was so sluggish that errors of several per cent. were possible at temperatures between 70 and 80°. Accordingly three determinations were made of the total change in enthalpy for $MgCd_3$ on heating it from 50 to 100°. It was carefully maintained at the lower temperature for a long period of time to establish equilibrium initially. Near 100° equilibration occurred in a short period of time so that ΔH for the 50° interval of temperature could be established quite reliably. The individual heat capacity determinations were then used to construct a provisional curve of C_p *vs.* T. That curve was then adjusted upward proportionally so that the integrated heat effect obtained from the curve agreed with the directly measured ΔH for the 50 to 100° interval.

Results

The data for Mg_3Cd were obtained in 10 series of measurements involving a total of 81 determinations. For $MgCd_3$ there were 11 series and a total of 71 individual measurements. It was of course necessary to have the sample at equilibrium before and after each measurement. The treatment of the sample in the after-period has been described above. The details of the thermal conditioning of the samples prior to initiating a series of measurements are too numerous to relate here.[10] In general the thermal treatment was such that the sample was as near to equilibrium as could be achieved experimentally before measurements were begun. In some instances the treatment involved a very considerable amount of time and care. For example, with $MgCd_3$ below 80° it proved necessary to maintain the sample at temperature for roughly a week for it to come to equilibrium.

Smoothed values for the heat capacities are given in Table I. Excluding the regions of slow equilibration, the precision of the measurements is 0.1 to 0.2% as judged from the scatter of points from a smooth curve.

Residual Entropies.—Entropies of formation of magnesium–cadmium alloys were reported earlier based on measurements made using the electrochemical cell method.[4,11] The entropies of formation of $MgCd_3$ and Mg_3Cd at 270° were

found to be 1.04 and 0.91 e.u., respectively.[12] Using the heat capacity data for the pure metals reported in the following paper[13] together with earlier data from this Laboratory for the low temperature region[14] one computes entropies at 270° to be 11.56 e.u. for Mg and 16.28 e.u. for Cd. From these data one calculates the entropies of $MgCd_3$ and Mg_3Cd to be 16.14 and 13.65 e.u., respectively. The data in the present paper together with previously published results[3] permit the calculation of $S_{270°} - S_{0°K.}$ for the two compounds. These entropy increments are found to be 13.54 e.u. for Mg_3Cd and 15.96 e.u. for $MgCd_3$, from which one computes the residual entropies to be 0.11 and 0.18 e.u. for the respective compounds.

For reasons which shall now be indicated the quantities so computed represent that which may be called the uncorrected values. The compounds are formed upon cooling the corresponding magnesium–cadmium solid solution, the solution being the stable form at high temperatures. Since the transitions are second order and are spread out over a temperature range, progressive reduction of the temperature of the systems results in an accompanying configurational change. For the present purpose the configuration of the system can be represented by the Bragg–Williams[15] order parameter s. As temperature approaches 0°K., s tends to unity corresponding to the situation in which each magnesium atom occupies a magnesium site in the lattice and each cadmium atom, a cadmium site. However, in practice mobility is lost before perfect configurational order is achieved, s is frozen-in at some value slightly less than unity and the compound is left with a residual entropy.

The heat capacity data for Mg_3Cd show this freezing-in of the configuration in a very striking way (Fig. 1). The C_p values rise with temperature as if they will reach the Dulong–Petit limit at about 300°K. However, at about 310°K. there is a sudden rise in C_p followed by a small maximum, after which the heat capacity rises steadily until the λ point is reached. These results indicate that on cooling the order parameter becomes frozen-in at about 310°K. On warming back up configurational changes begin to occur at that temperature and there is a sudden rise in the heat capacity. The small maximum in C_p is undoubtedly a kinetic effect. Some of the configurational contribution which should have appeared at a slightly lower temperature has been displaced upward on the curve due to the slowness of atomic redistributions at the lower temperature. This point of view is supported by the results obtained by Welber, Webeler and Trumbore[16] using the continuous heating technique. Their results obtained with a heating rate of 4 deg./min. are also shown in Fig. 1. They find a small maximum at about 370°K. and their C_p values from 325 to 355°K. are about 10% lower than the present results. It seems clear that their technique delayed full development of the configurational contribution to C_p until temperatures in excess of 360°K. were reached at which point the mobility in the solid had increased to the point that the accumulated deficit in C_p could be realized. This gave rise to their maximum in C_p.

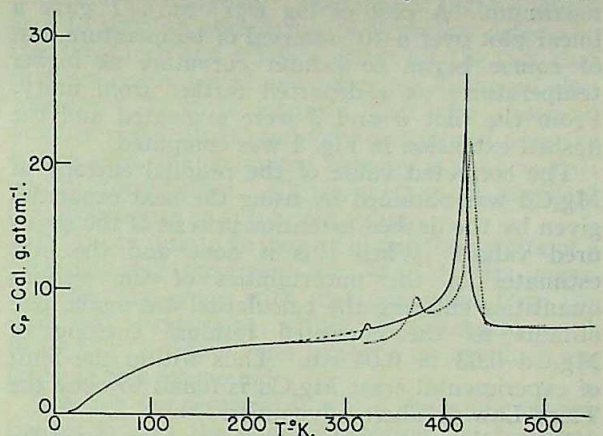

Fig. 1.—Heat capacity of Mg_3Cd: ———, this study; - - - - - -, present results corrected for frozen-in disorder (see text); ....., data of Welber, Webeler and Trumbore (ref. 16).

The dashed extension of the experimental curve in Fig. 1 shows the behavior to be expected if s had not become frozen-in. This extension has been constructed using results of theoretical treatments of order–disorder phenomena. The Bragg–Williams theory was used since results computed from their theory when s approaches unity do not differ from those obtained using more refined treatments. As s approaches unity, the configurational heat capacity C_p^c is given by the expression

$$C_p^c = \frac{\alpha}{T^2} e^{-\beta/T}$$

(12) Data are expressed throughout this paper on a per gram atom basis. These data therefore refer to the entropy change accompanying the formation of one gram atom of alloy from the component metals.

where α and β are constants. C_p^s was estimated by extending linearly the curve below the sharp rise at 310°K. so as to join the curve at 530°K. and then subtracting data taken from this curve from the experimental results above the small maximum. A plot of log $C_p^s T^2$ *vs.* $1/T$ gave a linear plot over a 40° interval of temperature, but of course began to exhibit curvature at higher temperatures as s departed farther from unity. From the plot α and β were evaluated and the dashed extension in Fig. 1 was computed.

The corrected value of the residual entropy of Mg_3Cd was obtained by using the heat capacities given by the dashed extension instead of the measured values. When this is done and the best estimates of the uncertainties of the various quantities entering the calculation are made, one obtains as the corrected residual entropy of Mg_3Cd 0.03 ± 0.04 e.u. Thus within the limit of experimental error Mg_3Cd is found to obey the Third Law of Thermodynamics.

When the unsmoothed heat capacity data[3] for $MgCd_3$ were examined, it was found that there is a sharp rise and a small maximum at about 200°K. These are smaller than the ones shown in Fig. 1 for Mg_3Cd and had escaped notice at the time of the original publication. A procedure similar to that which was used for Mg_3Cd was applied to $MgCd_3$. The frozen-in disorder corresponded to 0.02 e.u., which leads to a corrected value for the residual entropy of 0.16 ± 0.04 e.u. for $MgCd_3$. The probable origin of this entropy will be considered in a later section of this paper.

Standard Heats, Free Energies and Entropies of Formation at 25°.—Values for all of these quantities have been reported earlier[4,11] for 270°. Using the present heat capacity data it is possible to calculate values for these quantities for 25°. Results of such calculations are shown in Table II. For Mg_3Cd the results pertain to the hypothetical state in which there is the equilibrium value of the order parameter s. In other words for this material the heat capacities used below 310° were not the data obtained experimentally but those taken from the dashed extension in Fig. 1. Although this is the way the calculations were made, the actual data might have been employed without incurring errors exceeding the listed uncertainties. Those uncertainties are rough estimates based upon the uncertainties in the various measured quantities employed in making the calculations. The principal contribution to the uncertainty in ΔH_f and ΔF_f is the uncertainty in the value of these quantities as measured at 270°. The uncertainties in the heat capacity data make a negligible contribution to uncertainty of those quantities but account for about half of the uncertainty in the ΔS_f values.

TABLE II

STANDARD HEATS, FREE ENERGIES AND ENTROPIES OF FORMATION OF $MgCd_3$ AND Mg_3Cd AT 25°

	$MgCd_3$		Mg_3Cd	
ΔH_f (cal./g. atom)	−1130	± 60	−1330	± 50
ΔF_f (cal./g. atom)	−1177	± 55	−1286	± 45
ΔS_f (e.u./g. atom)	+ 0.16	± 0.02	+ 0.15	± 0.03

Buck, Wallace and Rulon measured ΔH_f for these substances at 25° using a differential solution calorimetric technique.[17] They obtained −1595 and −775 cal./g. atom of compound for $MgCd_3$ and Mg_3Cd, respectively. These data are in poor agreement with the quantities given in Table II. The present data are undoubtedly more reliable. There are two reasons for believing that this is the case. First, as was pointed out earlier,[17] the directly determined ΔH_f's are extremely sensitive to experimental error. An error of 0.001 in mole fraction leads to an error of 180 cal./g. atom in ΔH_f and a weighing error of only 0.1 mg. affected ΔH_f to the extent of 450 cal. Second, there is a better appreciation now of the care which must be taken to establish equilibrium in the samples at 25°. It is possible that in the earlier study there was a considerable amount of frozen-in disorder in the samples of Mg_3Cd accounting for the large discrepancy in that case. The present results should be free of this difficulty since the electrochemical cell work was carried out at temperatures ranging from 270 to 300° where configurational equilibrium is quickly and easily established. Furthermore, sufficient attention was given to maintaining equilibrium during the heat capacity work that it is felt that no significant errors are introduced from this source into the data in Table II.

Discussion of Results

Heat Capacities.—The heat capacities reported in this paper join smoothly with the results obtained earlier[3] for the low temperature region. In addition to the work of Welber, *et al.*, referred to earlier, Nagasaki, Hirabayashi and Nagusa[18] and more recently Rosenbaum and Welber[19] have studied alloys with compositions fairly near to Mg_3Cd. The continuous heating technique was used in these studies. Their results resemble qualitatively the behavior exhibited in Fig. 1 except that the low temperature peak does not appear. However, because of the composition difference a detailed quantitative comparison seems unwarranted. Khomyakov, Kholler and Troshkina[20] have measured the heat capacity of a magnesium–cadmium alloy with composition which is stated to be 75.15 atomic % cadmium, also using continuous heating. Their results agree within about 3% with the present results up to 75°. Their specific heats reached a maximum at 77.7° whereas the present results continue to rise and reach a peak 25% higher at 83.9°. At 160°, the highest temperature reached by Khomyakov, *et al.*, the results again agree within a few per cent. The discrepancy between the temperatures at which C_p peaks in these two cases is in the wrong direction to be ascribed to kinetic factors. It must arise because the composition of the sample studied by Khomyakov deviated from 75.0 atomic % cadmium by

more than the published composition would indicate, since Stepanov and Kornilov[21] have shown that the transformation point is maximal for the composition $MgCd_3$ and falls away for alloys whose cadmium contents are either greater or less.

The present study serves to emphasize the great care which must be exercised to obtain equilibrium heat capacities in systems which are undergoing atomic rearrangements. It is clear that the conventional continuous heating technique may in these cases lead to results which are seriously in error. Only if diffusion is exceptionally rapid, such as in beta brass, will the results be meaningful. For reasons which have been set forth earlier spurious heat capacity maxima can appear. (This to a lesser degree may also happen with the intermittent heating procedure.) Furthermore the heat capacity distribution under the λ-point for the continuously heated sample may be seriously distorted from its equilibrium shape. Thus, some aspects of the intense theoretical work of the 1930's dealing with order–disorder phenomena seems like effort misplaced. Much theoretical work was done in attempts to account for the exact temperature dependence of experimental configurational heat capacities, when due to the experimental method employed, the results obtained are now open to question.

Residual Entropy of $MgCd_3$.—As was shown earlier, even after allowing for frozen-in disorder associated with interchanged Mg and Cd atoms, $MgCd_3$ has a residual entropy of 0.16 e.u./g. atom of alloy. It is suggested that this entropy originates with vacant lattice sites (Schottky defects) which persist in this system down to the lowest temperatures studied. The density of $MgCd_3$ has been found[22] to be 1.7% less than that computed[23] from the unit cell dimensions. This density discrepancy has been attributed to the fact that an average of 1.7% of the lattice sites are unoccupied in $MgCd_3$. The special factors which lead to such an abundance of Schottky defects in this substance and which account for the fact that they are not removed on cooling are discussed elsewhere.[24,25] If it is assumed that the observed number of defects is randomly distributed over the lattice sites, the computed entropy is 0.17 ± 0.01 e.u./g. atom of alloy. This is, of course, in excellent agreement with the observed value.

It is appropriate to inquire about the results of a corresponding treatment for Mg_3Cd. Its measured density agrees with that computed from the unit cell dimensions within experimental error (0.2%). Therefore, one expects no residual entropy in this compound.

The low temperature at which the configuration freezes in and the small correction for frozen-in disorder for $MgCd_3$ are both suggestive of extensive vacancies in this substance at low temperatures. Atomic interchanges most likely occur through a mechanism involving a series of interchanges with a vacancy. The persistence of mobility to such low temperatures and low amounts of disorder is consistent with the notion that extensive vacancies exist in this system at low temperatures.

Acknowledgment.—The assistance of W. G. Saba in making a number of the calculations included in the work is gratefully acknowledged.

The Heat Capacities of Magnesium and Cadmium between 20 and 270°[1]

BY W. G. SABA, K. F. STERRETT, R. S. CRAIG AND W. E. WALLACE

RECEIVED MARCH 23, 1957

Heat capacities of magnesium and cadmium are reported for the temperature interval 20 to 270°. Measurements were made using an adiabatic calorimeter. Results are compared with previous determinations in the same temperature range. Deviations from the values accepted in the compilations by Kelley and Stull and Sinke are substantial for magnesium. For cadmium they are smaller but still appreciable. Results are in good agreement with the data obtained at lower temperatures by Craig, *et al.*

In making the thermodynamic calculations reported in the preceding paper[2] it was necessary to know the heat capacities of magnesium and cadmium in the temperature interval 25 to 270°. Values obtainable from the literature were not sufficiently precise, particularly for the residual entropy calculations, and so it became necessary to redetermine these quantities. The results of those redeterminations are reported in this paper.

Experimental Details

The apparatus employed and method of measurement have been described elsewhere.[3-5] The procedure employed in the present work differed from that used in the study of the magnesium–cadmium compounds only in that for some of the measurements on magnesium the individual determinations covered somewhat larger temperature intervals

(10°). This was possible because the heat capacities were almost linear with temperature. In contrast with the behavior observed when the compounds were being studied the calorimeter came to thermal equilibrium in the normal length of time (about 30 min.) throughout the temperature range covered.

The samples employed were portions of samples used in the study of the low temperature specific heats of these metals published earlier.[6] The masses of the samples used were: magnesium, 127.613 g. or 5.2472 g. atoms; cadmium, 639.451 g. or 5.6886 g. atoms.

Results

For magnesium thirty-seven determinations were made covering the range 20 to 275°. The data for cadmium consisted of 39 measurements extending from 27 to 280°. The smoothed heat capacities obtained are given in Table I. The average deviation from a smooth curve drawn through all the points was 0.12 for magnesium and 0.08 for cadmium, indicating a precision of about 0.1%. Of the 76 results only 9 deviated from the smooth curve by more than 0.2%. The maximum deviations were 0.4% and 0.35% for magnesium and cadmium, respectively.

TABLE I

HEAT CAPACITIES OF MAGNESIUM AND CADMIUM

T, °K.	C_p, cal./deg. g. atom Magnesium	Cadmium	T, °K.	C_p, cal./deg. g. atom Magnesium	Cadmium
298.16	5.941	6.212	430	6.314	6.556
300	5.948	6.218	440	6.339	6.586
310	5.982	6.239	450	6.363	6.616
320	6.013	6.259	460	6.386	6.652
330	6.042	6.283	470	6.414	6.692
340	6.072	6.307	480	6.440	6.728
350	6.104	6.334			
360	6.134	6.361	490	6.467	6.769
370	6.163	6.390	500	6.493	6.814
380	6.189	6.416	510	6.517	6.869
390	6.216	6.443	520	6.541	6.927
400	6.241	6.470	530	6.561	6.988
410	6.266	6.499	540	6.583	7.054
420	6.289	6.527	543.16	6.591	7.076

It is of interest to compare the present data with results obtained in earlier studies. Kelley[7] and Stull and Sinke[8] have reviewed existing heat capacity data for these two elements and have accepted certain values as the best representation of their heat capacities for the above room temperature range. Their accepted values coincide for cadmium but differ appreciably for magnesium. Both accepted values for magnesium deviate on the average from the present results by about a per cent.; Kelley's equation leads to a result which is very much too low at the low temperature limit (4% at 300°K.). Agreement with the present data is somewhat better for cadmium. Between 300 and 500°K. the deviations average 0.22%, but above 500°K. the differences rapidly increase until at 540°K. the accepted results computed from Kelley's equation are low by 2.4%. Examination of the original literature, and limiting consideration to the last 25 years, reveals that cadmium has been studied by Bronson and Wilson[9] (−80 to 120°) and magnesium has been studied by Jaeger and Poppema[10] (0 to 550°) and Seekamp[11] (18 to 500°). As was the case in the earlier study of cadmium at lower temperatures the results of Bronson and Wilson are in good agreement with those obtained in this Laboratory. Over the 90° interval of temperature common to both series of determinations the maximum deviation is 0.22% and the average deviation is 0.15%, Bronson and Wilson's results being consistently higher by this amount. Seekamp's data for magnesium scatter about the present results; the deviations average about 0.8% and rise to a maximum of 1.1%. Jaeger and Poppema's results are consistently lower than those reported in this paper by about 0.7% but the difference in no case exceeds 0.9%.

Low temperature heat capacities of magnesium and cadmium were determined[6] in this Laboratory several years ago covering the range 12 to 320°K. In the 20 degrees of overlap it is found that the present results are consistently about 0.2% lower than the previous results. Since the two sets of data were obtained using entirely different instruments, this difference is perhaps indicative of the combined systematic error present in the measurements. Considering the deviations normally observed between independently determined heat capacities, this close agreement between the two sets of data is gratifying.

The rather rapid rise of the heat capacities of cadmium above the equation of Kelley for temperatures in excess of 500°K. has been mentioned above. This appears to be the beginning of a heat capacity anomaly associated with premelting, or heterophase fluctuations,[12] such as have been observed for the alkali metals.[13] Khomyakov, *et al.*,[14] have studied pure cadmium in the immediate vicinity of the melting point. They find a sharp rise in the heat capacity curve and claim that more than one third of the normally reported latent heat of fusion is associated with this premelting heat capacity anomaly. The rapidly increasing slope in the curve obtained in this study for cadmium above 500°K. represents perhaps the faint beginnings of the more pronounced effects observed by Khomyakov, *et al.*, above 570°K. In contrast, the curve for magnesium near the upper limit of the present study appears to be leveling off, which is not surprising since this substance is still so far removed from its melting point that any influence of heterophase fluctuations on its heat capacity is expected to be slight.

Acknowledgment.—The authors wish to acknowledge the assistance of Dr. L. J. Hyvönen in making some of the measurements reported in this paper.

Heats of Formation of Crystalline Silicates of Strontium and Barium

BY R. BARANY, E. G. KING AND S. S. TODD

RECEIVED MARCH 5, 1957

Heats of formation from the component oxides at 298.15°K. were obtained for strontium metasilicate, strontium orthosilicate, barium metasilicate, barium orthosilicate, dibarium trisilicate and barium disilicate by measuring heats of reaction of the silicates and oxides with hydrofluoric acid.

This paper presents heats of formation of two crystalline strontium silicates ($SrSiO_3$ and Sr_2SiO_4) and four crystalline barium silicates ($BaSiO_3$, Ba_2SiO_4, $Ba_2Si_3O_8$ and $BaSi_2O_5$). Previous papers from this Laboratory by Torgeson and Sahama[1] and King[2] contained corresponding data for some magnesium and calcium silicates.

Materials and Method

The silicates were prepared by repeated, prolonged sintering of stoichiometric mixtures of reagent-grade strontium or barium carbonate and pure quartz. In each instance several heats were required, with intervening grinding, mixing, analysis and adjustment of composition, to obtain a satisfactory product.

In preparing strontium metasilicate the total heating time was 246 hr. between 1000 and 1350°, of which 32 hr. were above 1200°. The product gave an X-ray diffraction pattern agreeing virtually perfectly with that reported by Carlson and Wells.[3] Chemical analysis gave 63.26% strontium oxide, 36.66% silica and 0.12% iron and aluminum oxides (theoretical analysis, 63.30% strontium oxide and 36.70% silica).

Strontium orthosilicate required four heats totaling 35 hr. at 1200–1300°, which were conducted in a platinum vessel. X-Ray diffraction of the product gave no evidence of uncombined oxides, but the pattern disagreed with that of O'Daniel and Tscheischwili,[4] who may have had a different crystalline variety. Analysis gave 77.51% strontium oxide, 22.47% silica and 0.03% sodium oxide (theoretical analysis, 77.52% strontium oxide and 22.48% silica).

The stoichiometric mixture for the preparation of barium metasilicate was pelletized and heated nine times for a total of 247 hours between 1000 and 1410°, of which 48 hours were above 1200°. Silverman and co-workers[5] list two crystalline varieties of barium metasilicate. Austin[6] obtained the X-ray diffraction pattern of one variety, but that of the other has not been reported in the literature. The pattern for the present material showed no evidence of uncombined oxides but disagreed with that of Austin, indicating that it probably is the variety labeled "$BaO{\cdot}SiO_2$(II)" by Silverman and co-workers. Analysis gave 71.95% barium oxide and 28.17% silica, as compared with the theoretical 71.85 and 28.15%.

Barium orthosilicate was prepared in a nickel crucible; the stoichiometric mixture was heated five times for a total of 10 days at 1000–1150° and 16 hours at 1150–1300°. There was some attack of the crucible, making it necessary to discard the surface layer after each heat. The cleaned product gave no visible precipitate of nickel glyoxime from a 1-g. sample. The X-ray diffraction pattern agreed with that reported by Austin.[6] Analysis showed 83.78% barium oxide and 16.39% silica, as compared with the theoretical 83.62 and 16.38%.

The preparation of dibarium trisilicate required many days at 1050°, 78 hr. at 1200°, 24 hr. at 1250°, and 6 hr. at 1300°. The product gave an X-ray diffraction in excellent agreement with that of Austin.[6] Chemical analysis showed 63.00% barium oxide, 37.05% silica, and 0.01% iron and aluminum oxides (theoretical analysis, 62.98% barium oxide and 37.02% silica).

The stoichiometric mixture for preparing barium disilicate was pelletized and heated for a total of 100 hr. at 1100° and 30 hr. at 1300°. The X-ray diffraction pattern obtained immediately after the last heat checked that in the ASTM Catalog. However, the pattern changed slowly with time on standing at room temperature, indicating the compound to be unstable. In using this substance in the subsequently reported measurements, it was reheated to 1300° and quenched to room temperature immediately before each run. Chemical analysis gave 56.05% barium oxide and 43.92% silica, as compared with the theoretical 56.06 and 43.94%.

Strontium oxide was prepared from reagent-grade strontium carbonate by first repeatedly boiling in water and filtering and then heating to 1400° until decomposition was essentially complete. Analysis gave 99.75% strontium oxide and less than 0.1% carbon dioxide. The substance was kept in sealed glass bulbs before use in the measurements.

Barium oxide was prepared from reagent-grade barium hydroxide. The latter was dissolved in water and treated with hydrogen peroxide to precipitate hydrated barium peroxide. The precipitate was dried, heated *in vacuo* to 1300° to decompose it to the normal oxide, and sealed in glass bulbs for preservation. Analysis of the product showed 0.15% water, 0.02% silica and 0.05% barium carbonate as impurities.

The heats of formation were determined by measuring the heats of reaction of the silicates and their constituent oxides with 20.1% hydrofluoric acid at 73.7°. In all instances 940.1 g. of the acid was employed. The masses of the silicates, strontium oxide and barium oxide conformed stoichiometrically in each instance with 0.7420 g. of quartz, which was adopted as a basis. The samples were contained in gelatin capsules for dropping from room temperature (measured and correction made to 25°) into the calorimeter. Correction for the capsules was made from separate measurements of the heat of solution of gelatin under the same calorimetric conditions.

The various compounds that were run picked up small amounts of water in handling. In each instance the amount of this water was determined by weight loss on ignition and correction was applied for it.

It was found expedient to mix about 0.1 g. of barium carbonate per capsule with the barium compounds to prevent clumping and therefore to obtain complete reaction with the acid. The heat of reaction of barium carbonate with the acid was determined as −31.5 cal./g. in separate experiments, and proper correction was applied. The heat of reaction of the barium carbonate was between 0.5 and 2% of the total heat evolved, depending upon the substance under study.

The calorimetric apparatus was that described by Torgeson and Sahama[1] with the modifications reported by King.[2]

Measurements and Results

All values are in terms of the defined calorie (1 cal. = 4.1840 abs. joules). All weighings were reduced to vacuum, and all molecular weights accord with the 1954–55 Report on Atomic Weights.[7]

TABLE I

HEATS OF REACTION (CAL./MOLE)

	Reaction	No. of detns.	ΔH	Uncertainty
(1)	SiO_2(c, 25°) + 6HF(sol, 73.7°) → H_2SiF_6(sol, 73.7°) + $2H_2O$(sol, 73.7°)	7	−33,290	80
(2)	SrO(c, 25°) + 2HF(sol, 73.7°) → SrF_2(p, 73.7°) + H_2O(sol, 73.7°)	5	−65,290	80
(3)	2SrO(c, 25°) + 4HF(sol, 73.7°) → $2SrF_2$(p, 73.7°) + $2H_2O$(sol, 73.7°)	5	−131,070	100
(4)	BaO(c, 25°) + 2HF(sol, 73.7°) → BaF_2(p, 73.7°) + H_2O(sol, 73.7°)	11	−73,040	120
(5)	2BaO(c, 25°) + 4HF(sol, 73.7°) → $2BaF_2$(p, 73.7°) + $2H_2O$(sol, 73.7°)	11	−146,080	240
(6)	$SrSiO_3$(c, 25°) + 8HF(sol, 73.7°) → SrF_2(p, 73.7°) + H_2SiF_6(sol, 73.7°) + $3H_2O$(sol, 73.7°)	6	−67,340	110
(7)	Sr_2SiO_4(c, 25°) + 10HF(sol, 73.7°) → $2SrF_2$(p, 73.7°) + H_2SiF_6(sol, 73.7°) + $4H_2O$(sol, 73.7°)	6	−114,320	200
(8)	$BaSiO_3$(c, 25°) + 8HF(sol, 73.7°) → BaF_2(p, 73.7°) + H_2SiF_6(sol, 73.7°) + $3H_2O$(sol, 73.7°)	6	−68,300	90
(9)	Ba_2SiO_4(c, 25°) + 10HF(sol, 73.7°) → $2BaF_2$(p, 73.7°) + H_2SiF_6(sol, 73.7°) + $4H_2O$(sol, 73.7°)	6	−114,890	110
(10)	$Ba_2Si_3O_8$(c, 25°) + 22HF(sol, 73.7°) → $2BaF_2$(p, 73.7°) + $3H_2SiF_6$(sol, 73.7°) + $8H_2O$(sol, 73.7°)	6	−165,530	80
(11)	$BaSi_2O_5$(c, 25°) + 14HF(sol, 73.7°) → BaF_2(p, 73.7°) + $2H_2SiF_6$(sol, 73.7°) + $5H_2O$(sol, 73.7°)	3	−98,340	150

Each heat of formation is the resultant of measurements of a series of reactions for which skeleton equations are given in Table I. The precision uncertainties were calculated according to the methods of Rossini and Deming.[8]

The experimental data are given in Table I which shows the reactions, numbers of determinations, average heat values, and precision uncertainties. In this table, "c" denotes a crystalline substance, "sol" denotes a substance in solution, and "p" denotes a precipitate.

The heat of reaction 1 is from the paper of King,[2] who employed the same equipment and calorimetric conditions as in the present work.

Each of reactions 2 to 5 were conducted in solutions identical in composition with the final solution from reaction 1. Each of reactions 6 to 11 were conducted in fresh acid, without previous additions. This procedure is necessary to produce the exact material balance in the summation of the reaction heats to obtain the desired heats of formation of the silicates from their constituent oxides.

The heat of reaction 3 is nearly 500 cal. more than twice that of reaction 2, showing that there is a considerable concentration effect. On the other hand, the concentration effect for reactions 4 and 5 was negligible. Eleven determinations were made of the heat of reaction of barium oxide with acid containing the proper amount of dissolved silica. The samples of barium oxide were varied in size to cover the composition range necessary to conform stoichiometrically with compounds ranging from $BaSi_2O_5$ to Ba_2SiO_4. No significant dependence of the heat of reaction on sample size was noted, and so the same molal value is used in obtaining the heats of formation of all the barium silicates.

Measurement of the heat of reaction 11 was difficult because of the previously mentioned instability of barium disilicate. Even though the samples were heated to 1300° and quenched to room temperature, the results were uncertain. The three best values obtained are −98,220, −98,470 and −98,330 with a mean of −98,340 ± 150 cal.

Table II illustrates the use of the data in Table I for obtaining heats of formation of the silicates from their constituent oxides.

(8) F. D. Rossini and W. E. Deming, *J. Wash. Acad. Sci.*, **29**, 416 (1939).

TABLE II

HEAT OF FORMATION OF $SrSiO_3$ (CAL./MOLE)

	Reaction	ΔH	Uncertainty
(1)	SiO_2(c, 25°) + 6HF(sol. 73.7°) → H_2SiF_6(sol. 73.7°) + $2H_2O$(sol. 73.7°)	−33,290	80
(2)	SrO(c, 25°) + 2HF(sol. 73.7°) → SrF_2(p, 73.7°) + H_2O(sol. 73.7°)	−65,290	80
(6)	$SrSiO_3$(c, 25°) + 8HF(sol. 73.7°) → SrF_2(p. 73.7°) + H_2SiF_6(sol. 73.7°) + $3H_2O$(sol. 73.7°)	−67,340	110
(12)	SrO(c, 25°) + SiO_2(c, 25°) → $SrSiO_3$(c, 25°) $\Delta H_{12} = \Delta H_1 + \Delta H_2 - \Delta H_6$	−31,240	160

As the final solution after conducting reactions 1 and 2 consecutively in the same acid solution is identical in composition with the solution after conducting reaction 6 in fresh acid, it follows that the reactions and heats may be added as indicated to obtain the heat of formation of strontium metasilicate at 25° from its constituent oxides.

The heats of formation of the crystalline strontium and barium silicates, obtained in this manner, appear in Table III. Because of the before mentioned difficulty of measurement, it is recommended that the value for barium disilicate be interpreted as setting an upper limit (algebraic) to the heat of formation, rather than as clearly defining its value.

TABLE III

HEATS OF FORMATION FROM THE OXIDES (KCAL./MOLE)

Substance	$\Delta H_{298.16}$	Substance	$\Delta H_{298.16}$
$SrSiO_3$	−31.24 ± 0.16	Ba_2SiO_4	−64.48 ± 0.28
Sr_2SiO_4	−50.04 ± .24	$Ba_2Si_3O_8$	−82.42 ± .35
$BaSiO_3$	−38.03 ± .17	$BaSi_2O_5$	−41.28 ± .25

Related Thermal Data.—The heats of formation of the meta- and orthosilicates of magnesium, calcium, strontium and barium are assembled for comparison in Table IV. The values for the magnesium and calcium compounds are from the work of Torgeson and Sahama[1] and King,[2] except for $Ca_2SiO_4(\gamma)$, which was derived from unpublished data of Coughlin and O'Brien of this Laboratory.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Rossini and co-workers[9] list values leading to the following heats of formation from the oxides (kcal./mole): −24.7 for strontium metasilicate, −33.0 for strontium orthosilicate, −20.7 for barium metasilicate, and −24.6 for barium orthosilicate, based upon older thermochemical work. The present values are considered much superior. It is of interest to note that the new values become increasingly negative in going from magnesium to barium in both the meta- and ortho-series whereas the solder work indicated a reversal in this trend.

TABLE IV

HEATS OF FORMATION FROM THE OXIDES AT 298.15°K. (KCAL./MOLE)

Substance	ΔH	Substance	ΔH
$MgSiO_3$[a]	− 8.69 ± 0.15	Mg_2SiO_4[c]	−15.12 ± 0.21
$CaSiO_3$[b]	−21.25 ± .13	$Ca_2SiO_4(\beta)$	−30.19 ± .23
$SrSiO_3$	−31.24 ± .16	$Ca_2SiO_4(\gamma)$	−32.7
$BaSiO_3$	−38.03 ± .17	Sr_2SiO_4	−50.04 ± .24
		Ba_2SiO_4	−64.48 ± .28

[a] Clinoenstatite. [b] Wollastonite. [c] Forsterite.

The heats of formation of the silicates from the oxides may be converted to heats of formation from the elements by means of available data for the oxides. In this connection, the heat of formation of quartz (−210.26 kcal./mole) obtained by Humphrey and King[10] and the recent value of Huber and Holley[11] for calcium oxide (−151.79 kcal./mole) are adopted. Shomate and Huffman[12] and Holley and Huber[13] have obtained values of the heat of formation of magnesium oxide that differ by only 140 cal./mole; the mean, −143.77 kcal./mole, is adopted. Values for strontium oxide (−141.1 kcal./mole) and barium oxide (−133.4 kcal./mole) are from NBS Circular 500.[9] These values lead to the heats of formation from the elements listed in Table V, which also brings up-to-date the values given by Torgeson and Sahama[1] and King.[2]

TABLE V

HEATS OF FORMATION FROM THE ELEMENTS AT 298.15°K. (KCAL./MOLE)

Substance	ΔH	Substance	ΔH
$MgSiO_3$	−362.7	$SrSiO_3$	−382.6

Low Temperature Heat Capacities of Magnesium Diboride (MgB_2) and Magnesium Tetraboride (MgB_4)

BY ROBINSON M. SWIFT AND DAVID WHITE[1]

RECEIVED FEBRUARY 14, 1957

The heat capacities of magnesium diboride (MgB_2) and magnesium tetraboride (MgB_4) were measured in the temperature range 18 to 305°K. The values of heat capacity, entropy, enthalpy and free energy function have been tabulated at integral values of temperature. The entropy at 298.16°K. of MgB_2 is 8.60 ± 0.04 cal. deg.$^{-1}$ mole^{-1}, that of MgB_4 is 12.41 ± 0.06 cal. deg.$^{-1}$ mole^{-1}. The heat capacity of these compounds at the lowest temperatures measured do not exhibit at T^2 relationship characteristic of some substances having a layer structure.

Introduction

The existence of magnesium borides with formulas MgB_2[2,3] and $MgBr_4$[2] has been shown by X-ray diffraction studies and chemical analysis. The diboride has a layered structure in which hexagonal nets of boron atoms are separated by layers of magnesium atoms. The structure of the tetraboride is not known. Recent studies have shown that in crystalline substances with layer structures, such as graphite[4] and gallium,[5] the heat capacity at low temperatures follows a T^2 law, rather than the Debye T^3 law. However, for CdI_4, a compound having a layered structure, it has been found that neither the T^2 nor T^3 relationship was followed at low temperatures.[6] The pronounced anisotropy characteristic of the graphite and gallium structures does not prevail in CdI_4 which may account for the lack of a T^2 relationship in the latter case.

The layer structure of MgB_2 is more closely related to that of CdI_4 than that of graphite from the standpoint of anisotropy. However, in the case of MgB_4, if the hexagonal boron network is retained, the interactions between the layers may be sufficiently diminished so as to lead to a T^2 dependence in the heat capacity at relatively low temperatures.

Apparatus and Procedure

Calorimeter.—The Nernst type vacuum calorimeter which was used for the measurements was similar to that described by Johnston and Kerr[7] with only minor changes being made in the calorimeter assembly and vacuum system.

The calorimeter itself had a capacity of about 60 ml. Its cylindrical surface was wound with AWG 40, formex-insulated gold–0.15% silver wire. This served as both resistance thermometer and heater and its resistance at room temperature was about 300 ohms. The winding was covered with gold foil cemented with General Electric Adhesive No. 7031. The calorimeter assembly was inserted directly into a Collins helium cryostat.

Electrical Circuits.—A White double potentiometer with a 100,000 microvolt range was used for the resistance thermometer and energy measurements together with suitable standard resistors calibrated by the National Bureau of Standards. A Wenner potentiometer with a 10,000 microvolt range was used to measure the thermocouple electromotive forces. A 30,000:100 ohm voltage divider was used in the energy circuit.

Timing.—The timing of the energy input was done by a clutch-operated Standard Electric Timing Company timing clock which read directly to 0.01 sec. This clock was driven by the amplified output of a General Radio Company precision fork and was actuated by a single master switch which also controlled the energy input.

Temperature Scale.—The thermodynamic temperature scale for this Laboratory was established by comparison of a copper–constantan thermocouple against a standard thermocouple obtained from the Ohio State University Cryogenic Laboratory, and calibrated there against a primary standard, No. 80.[8] Absolute temperatures are probably accurate to within ±0.05°. The uncertainties in the measured temperature differences of the heat capacity runs are no greater than ±0.005°.

Data Computation.—The calculations were made as outlined by Giauque[9] and Johnston.[7] Corrections were made to the measured heat capacities for the energy lost in the potential divider and leads, heat leaks, calorimeter surface superheating during energy input, drifts in block temperatures, radiation to the calorimeter from the blocks, potentiometer battery drifts, and heat generated in the leads connecting the calorimeter winding with the block terminals. The same corrections were applied to the empty calorimeter calculations. Helium gas was introduced into the calorimeter after filling with solid and before sealing to reduce superheating. Corrections were made for this and for the other impurities as listed in Table I, assuming that the heat capacities of the individual substances were completely independent and additive.

Preparation of the Magnesium Borides.—Magnesium diboride was prepared by heating together in a helium atmosphere at 900 ± 25° for three hours stoichiometric quantities of the elements. The magnesium was a commercial grade analyzing 99.9%. The boron was obtained by vacuum sublimation at 1500° of Fisher Scientific Company "purified amorphous boron." After our further purification the residue analyzed 99.70 ± 0.25% boron by sodium hydroxide–mannitol titration of the oxidized product. The MgB_2 product included gross impurities as given in Table I and spectroscopic impurities totalling less than 0.1% and consisting principally of iron, aluminum, manganese, silicon and calcium.

The magnesium tetraboride was made by treating the magnesium diboride with somewhat more than two equivalents of purified boron at 1050 ± 25° for four hours in an argon atmosphere. Higher temperatures favored production of a colored magnesium boride thought to be MgB_6; lower temperatures and shorter times gave lower yields of MgB_4 and larger amounts of unreacted MgB_2. The latter, together with other soluble impurities, was removed by treatment with warm dilute hydrochloric acid and subsequent washing with water. Considerable free boron remained with the MgB_4.

X-Ray diffraction studies identified the substances present and chemical analysis established the amounts in each of the two boride preparations. The analysis for each is given in Table I.

Results and Discussion

The calculated molal heat capacity of magnesium diboride is shown in Table II and that of magnesium tetraboride in Table III. These results have been corrected for the impurities listed in Table I.[10] They are listed in the order done. Temperature increments may be inferred from the mean temperatures. They never exceeded 10% of the temperature scale or 10°, whichever was smaller. Computed thermodynamic functions for these compounds are given in Tables IV and V. The ice point was taken as 273.16°K. and the results are expressed in calories equal to 4.1840 absolute joules.

The heat capacities of MgB_2 and MgB_4 do not follow the Debye T^3 law at low temperatures; hence, a graphical extrapolation was made to absolute zero to determine the entropy and other

thermodynamic functions. The entropy of the MgB_2 at 298.16°K. is 8.60 ± 0.04 cal. deg.$^{-1}$ mole^{-1}, with 0.013 (0.15%) being obtained by the extrapolation. For MgB_4, the entropy at 298.16°K. is 12.41 ± 0.06 cal. deg.$^{-1}$ mole^{-1}, with 0.062 (0.50%) being obtained by the extrapolation.

Since the X-ray diffraction studies[1,2] had shown layered structures for at least one of these compounds, MgB_2 plots of log C_p *versus* log T were made to determine whether a region of T^2 dependency existed. A linear relationship was found for MgB_2 from 20 to 80°K. with slope of 3.5 and for MgB_4 from 30 to 70°K. with slope of 2.6.

Heat Capacity and Magnetic Susceptibility of Copper(II) Tetrammine Sulfate Monohydrate from 1.3 to 24°K.

BY J. J. FRITZ AND H. L. PINCH

RECEIVED JANUARY 24, 1957

The heat capacity and magnetic susceptibility of copper tetrammine sulfate have been investigated between 1.3 and 29°K. The results indicate strong interactions between copper ions, leading to a transition, of order higher than the second, with a maximum in the heat capacity of 0.75 cal. mole^{-1} deg.$^{-1}$ at 3.0°K. The magnetic susceptibility is nearly constant between 1 and 4°K., and thereafter falls gradually; the maximum value of the molar susceptibility is 0.04. It is believed that the interaction is directly related to the coördination with ammonia.

Introduction

The magnetic behavior of crystalline salts of cupric ion varies considerably from salt to salt. The Tutton salt, $CuSO_4 \cdot K_2SO_4 \cdot 6H_2O$, is one of the most ideal of all paramagnetic salts, and has been used in the attainment of temperatures far below 1°K.[1] The ordinary hydrated sulfate, $CuSO_4 \cdot 5H_2O$, has a magnetic transition[2] in the vicinity of 1°K., the exact nature of which is not clear. The hydrated chloride, $CuCl_2 \cdot 2H_2O$, has a lambda-type transition at about 4.2°K. below which the salt becomes anti-ferromagnetic.[3] The acetate, $Cu(C_2H_3O_2)_2 \cdot H_2O$, becomes diamagnetic at about 50°K.[4]

With the exception of the acetate, the properties of all the salts described above may be explained in terms of the effect of crystalline environment on a substantially free copper ion. The ground state of free cupric ion is $^2D_{5/2}$. At temperatures above the magnetic transitions, the typical copper salts behave almost as ^2S states; their magnetic susceptibilities are but slightly higher than the "spin-only" values.

Copper tetrammine sulfate differs formally from $CuSO_4 \cdot 5H_2O$ only in the replacement of four of the water molecules by ammonia molecules. In the crystal the basic unit is $Cu(NH_3)_4^{++}$, rather than $Cu(H_2O)_4^{++}$; due to differences in crystal structure, the less near neighbors of the copper ion are different in the two salts. At the outset of this research, it was expected that the ammine salt would behave in the same general fashion as the hydrate, so that comparison of the two would show the effect of the ammonia and in addition shed further light on the behavior of the ordinary hydrate.

Experimental

The experimental procedures were substantially the same as those employed by Fritz and Pinch in the investigation of vanadium ammonium alum,[5] and will not be described in detail. The ellipsoidal sample container had an internal volume of 31.13 cm.^{3}, and contained 32.64 g. of the salt. The weight of the container was 19.56 g. The carbon thermometer had a resistance at room temperature of about 6000 ohms. At low temperatures its sensitivity was decidedly higher than that of the thermometer previously described,[5] but it was also considerably less stable.

The specimen used in the investigation was prepared by addition of C.P. ammonium hydroxide to a solution of C.P. copper sulfate according to the method of Walton.[6] The crystalline salt was obtained by cooling of the resulting hot solution. The crystals used were ground to a powder; the portion selected for use passed through a 20-mesh screen, but failed to pass through a 100-mesh screen. The irregular particles were stored for a time under a saturated solution of the salt and then dried manually.

A sample for analysis was withdrawn during the filling of the sample tube. Its copper content was determined electrolytically to be 25.92% (theoretical 25.87%); the ammonia–copper ratio was determined by titration to be 3.92 to 1.

Measurements of heat capacity and magnetic susceptibility were made in the manner previously described.[5] For the low temperature susceptibility measurements, the coil constants were obtained with the specimen near 70°K., after the coils had been cooled by liquid helium or hydrogen. The effect of the sample at 70°K., upon the coils was determined in a separate experiment in which the specimen was cooled from room temperature to 70°K. The susceptibilities were thus based upon the room temperature susceptibility of the salt. The molar susceptibility at 290°K. is 1.40 $\times 10^{-3}$, according to Bhatnage, Lessheim and Khanna.[7] An independent check on our specimen by the Gouy method gave a result of 1.35×10^{-3}. (For the purpose of the correction this susceptibility is required only to about 20%.)

Results

The heat capacity of the salt was measured between 1.3 and 24°K. The observed measurements were corrected for the heat capacity of 19.56 g. of Pyrex as previously described.[5] At the highest temperatures, this represented 1/4 of the observed heat capacity. In view of the unusual behavior of the heat capacity between 12 and 20°K., this region was investigated in three separate sets of experiments; the results of the several sets were consistent. The heat capacity measurements are given

The magnetic susceptibility was measured between 1.2 and 20.2°K. The results are shown in Fig. 1, where the molar susceptibility is plotted against the temperature. Because of the small magnitude of the susceptibility, the error is estimated as 5%, although (as will be seen from Fig. 1) the internal consistency of the measurements was better than this. The results indicate a slight maximum near 4°K., but the diminution below 4° is within the accuracy claimed; accordingly the curve is drawn with the maximum at the lowest temperature. The results between 11 and 20°K. are represented by the formula

$$\chi_M = 0.53/(T + 5.3)$$

Upon adiabatic magnetization of the salt at 1.4°K., the temperature remained constant within 0.002°K.

Discussion

The nature of the heat capacity of the salt was unexpected and remarkable. There is a maximum at 3.0°K. which evidently is due to a magnetic transition. The height of the maximum is very nearly half that required for a transition from a single lower state to a doubly degenerate upper state. (In this connection, it is interesting to note that for $CuSO_4 \cdot 5H_2O$ Giauque and Geballe[2] obtained a maximum which was half that required for a transition between two singly degenerate states.) Moreover, the heat capacity between 1 and 6°K., after correction for the small lattice heat capacity, may be represented within several per cent. by a function

$$C/R = 0.975(\delta/kT)^2 e^{-\delta/kT}(1 - 2e^{-\delta/kT})^{-2}$$

with $\delta/k = 7.9$°K. (The lattice heat capacity may be estimated as about 0.006 cal. mole^{-1} deg.$^{-1}$ at 2.5°K. and about 0.08 cal. mole^{-1} deg.$^{-1}$ at 6°K.)

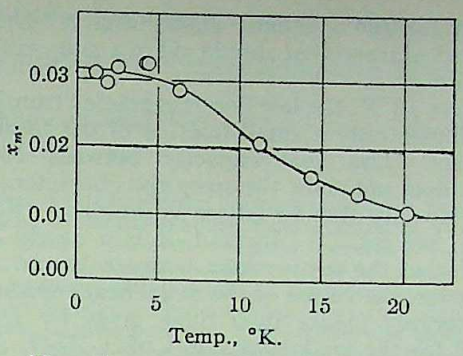

Fig. 1.—Magnetic susceptibility of copper tetrammine sulfate monohydrate.

In view of the fit of the Schottky function given above, it is tempting to view the basic unit in the salt (at low temperatures) as a pair of ions with their spins coupled. In this view, the state observed is the "triplet" state of the pairs, with total spin of unity. Such a state would have three magnetic energy levels, just as in vanadium alum,[5] and would give rise to the observed heat capacity below 6°K. There are two serious arguments against such specific "pairing" of ions. First, if the ions are paired, there should be both the "triplet" state and a "singlet" state, the latter with total spin of zero. This state of affairs has been observed with copper acetate[8]; both states are observed, with the singlet having the lower energy. In the present case, there is no evidence for a low-lying singlet level; on the other hand, it would be surprising to find it at an energy well above the ground state. Second, the crystal structure of copper tetrammine sulfate at room temperature[9] gives no evidence of pairing of copper ions. On the other hand, in copper acetate the crystal structure[10] indicates clearly the grouping of copper ions by pairs. A change in structure so as to bring copper ions together by pairs would require a substantial change in crystal structure below room temperature.

Actually it is not necessary to assume a coupling mechanism as specific as pair-formation to explain the observed results. The crystal structure of the tetrammine salt indicates that the copper ions are arranged in zig-zag chains parallel to the 100 planes of the crystal, with the units linked together by coordination with water molecules. Strong exchange interactions (with energy of the order of that given above as δ) along the chains will give rise to the same general behavior as the pairing considered above.[11] In chemical terms this mechanism corresponds to a weak bonding along the chains $Cu(NH_3)_4$–H_2O–$Cu(NH_3)_4$–H_2O——. The microwave results at room temperature[12] show the single transition typical of single electron spins, but the line is abnormally narrow; this narrowing previously has been attributed to strong exchange coupling between copper ions.

Either of the coupling (exchange) mechanisms suggested will give rise to the sort of behavior ob-

served for the magnetic susceptibility. Detailed theoretical treatment should aid in a more exact description.

Above 10°K. the low lying magnetic "transition" contributes only a small fraction of the total heat capacity. The heat capacity between 10 and 20°K. does not show the steep rise characteristic of heat capacity due to lattice vibrations. (For example, see ref. 5.) Instead, it is a nearly linear function of the temperature between 12 and 24°K. Moreover, the values of the molal heat capacity are considerably higher than those given by Duyckaerts[13] for the analogous salt, $CuSO_4 \cdot 5H_2O$. Comparison of the data for the two salts shows that the difference between the heat capacities reaches a maximum near 20°K. and diminishes at higher temperatures. Any other reasonable assignment for the lattice heat capacity gives a similar broad maximum in the heat capacity due to other causes. It is possible that the excess heat capacity is due to a second magnetic "transition." There is no evidence of a sharp rise in the heat capacity such as might be associated with a coöperative transition. Complete examination of this "transition" will require additional measurements above 20°K.

Magnetic Behavior of Copper Tetrammine Sulfate.—The unquestionably large coupling between copper ions in the tetrammine sulfate was surprising, particularly in view of the observed crystal structure. It is possible that this coupling is an accident of the structure, but we think this quite unlikely in view of the rather large distance between copper ions. In the tetrammine, the smallest distance between copper ions is 5.3 Å. compared with 5.7 Å. in $CuSO_4 \cdot 5H_2O$, 3.5 Å. in $CuCl_2 \cdot 2H_2O$, and 2.6 Å. in $Cu(C_2H_3O_2)_2 \cdot H_2O$. The chloride displays large exchange interactions, leading to the previously cited transition to antiferromagnetism at 4.2°K. However, the minimum Cu–Cu distance is much smaller than in the tetrammine, and there are in fact two other pairs of copper ions within only 5.5 Å. of each ion. The exchange interactions in the tetrammine are much larger than would be expected by comparison.

We believe that the (comparatively) large exchange interactions are no accident, but are probably enhanced greatly by the presence of the ammonia molecules. Ammonia is well known to coordinate with copper (and some other iron group ions) much more strongly than does water or the sulfate ion. (Copper acetate is a special case, in that in crystalline copper acetate adjacent copper ions in a pair are at a distance almost equal to the Cu–Cu separation in metallic copper.[10] Thus it is almost certain that the very strong exchange interactions in the acetate occur because of directly coupling between adjacent copper ions.[8]) To our knowledge, the present case is the first where extensive low temperature investigation has been made of a cupric salt in which the copper was coordinated with species other than water, halide ions or oxygenated anions. The latter species are notoriously poor coördinating agents for copper ion, and it is not surprising that the introduction of stronger coördinating agents might enhance interactions between the cupric ions.

(13) G. Duyckaerts, *Soc. Roy. Sci. Liege*, **14**, 284 (1941).

Conclusions

The heat capacity and magnetic susceptibility of copper tetrammine sulfate below 20°K. indicate that there is strong interaction between cupric ions. This coupling may be simply of the exchange variety, or may occur as a result of a low temperature crystal transition. It will be highly desirable to carry out both X-ray and microwave investigations on this salt below 90°K. There is evidence of a transition (not first order) in the salt starting about 10°K. We propose to investigate this transition further by other means, and plan for the future a complete Third Law study of the salt. In addition we strongly recommend investigations of copper salts containing strong coördinating and chelating agents. One such investigation is already in progress.

Acknowledgments.—We wish to thank Dr. S. Seki and Mr. R. G. Taylor for assistance with the experimental measurements, and Mr. L. F. Shultz for aid in production of refrigerants. We thank E I. du Pont de Nemours and Company and the Office of Naval Research for financial aid in the early stages of the experiments, and the National Science Foundation for aid during their completion. We gratefully acknowledge the provision of funds for the iron-free solenoid magnet by the Research Corporation and the Westinghouse Electric Company.

The Mechanism of Formation of Sodium Triphosphate from Orthophosphate Mixtures[1]

BY JAMES W. EDWARDS AND ARNO H. HERZOG

RECEIVED FEBRUARY 13, 1957

The condensation reactions which take place when mixtures of sodium orthophosphates, having a mole ratio Na_2O/P_2O_5 of 5/3, are heated to higher temperatures have been investigated by means of thermal analysis, X-ray diffraction, chromatographic analysis and wet-chemical analysis coupled with dehydration studies. Intimate equimolar mixtures of $NaH_2PO_4 \cdot Na_2HPO_4$ and $Na_2HPO_4 \cdot 2H_2O$, obtained as polycrystalline granules by drying of aqueous solutions, lose 3/2 moles of constitutional water when heated to 210° and change to a mixture of crystalline $Na_4P_2O_7$, and an amorphous phase. The amorphous phase is shown by combined X-ray and chromatographic analysis to be a mixture of ortho-, pyro-, tri-, ring meta-, and longer chain polyphosphates. Further heating at somewhat higher temperatures results in evolution of more water and consumption of equivalent amounts of $Na_4P_2O_7$ and the amorphous phase to give $Na_5P_3O_{10}$ (I), the high temperature form, which then changes to the low temperature form II. A mechanism is proposed which involves diffusion of only small cations and water through the amorphous phase to support the reaction. Mobile equilibrium between water and condensed phosphate ions maintains a level of orthophosphate to support the reaction $HPO_4^{2-} + HP_2O_7^{3-} \rightarrow P_3O_{10}^{5-} + H_2O$, which occurs at the growing crystal face of $Na_5P_3O_{10}$.

Introduction

Sodium triphosphate, $Na_5P_3O_{10}$, can be prepared[2] by thermal dehydration and/or fusion of various mixtures of any variety of phosphates having an over-all mole ratio, Na_2O/P_2O_5, of 5/3; however, the most efficacious method employs intimate mixtures of orthophosphates prepared *in situ* by drying appropriate solutions. Thermal dehydration of such an *in situ* mixture at temperatures between *ca.* 300 and *ca.* 600° then gives good yields of $Na_5P_3O_{10}$ without fusion of the entire mass.

$Na_5P_3O_{10}$ is bimorphic; it has low and high temperature modifications, II and I, respectively, that have, according to thermal analysis, high temperature microscopy and quench studies, a transition temperature of *ca.* 500°. This is an erratic transformation and the existence of $Na_5P_3O_{10}$-I in preparations which were never heated higher than *ca.* 400° were interpreted to mean that the transition point was considerably below 500°.

Heating of ortho mixtures to constant weight at successively higher temperatures[3] points to a mechanism involving initial condensation of pyrophosphate salts with subsequent condensation and/or reorganization to give form II. This is shown by the following equations which describe preliminary studies[3] on the thermal decomposition of some crystalline phosphates

$$2Na_2HPO_4 \cdot 2H_2O \xrightarrow{200°} Na_4P_2O_7 + 5H_2O \quad (1)$$

$$2(NaH_2PO_4 \cdot Na_2HPO_4) \xrightarrow{200°} Na_2H_2P_2O_7 + Na_4P_2O_7 + 2H_2O \quad (2)$$

$$2Na_4P_2O_7 + Na_2H_2P_2O_7 \xrightarrow{250°} 2Na_5P_3O_{10} + H_2O \quad (3)$$

In eq. 3, it should be noted that three dimeric molecules, in crystalline state as derived from reactions 1 and 2, react to give two trimeric molecules. Obviously many complex intermediate steps must be involved. It has been observed[3] that the pyrophosphates obtained *via* the reaction given in eq. 2 give much poorer yields at, say 350°, than the direct, uninterrupted heating of the ortho mixture at the same temperature.

$$NaH_2PO_4 \cdot Na_2HPO_4 + Na_2HPO_4 \cdot 2H_2O \longrightarrow Na_5P_3O_{10} + 4H_2O \quad (4)$$

It appeared then that the two-step conversion might have a different mechanism from that of the direct conversion, hence a new approach was made in which techniques of thermal-, X-ray diffraction, chromatographic- and chemical-analyses of quenched, partly reacted mixtures were combined with dehydration studies.

Experimental

Starting Materials.—In most of the experiments below the ortho mixture used was prepared by drum-drying an aqueous sodium orthophosphate solution which had a mole ratio Na_2O/P_2O_5 = 1.686 as determined by *p*H titration analysis, total P_2O_5 content of 51.98% and an ignition loss of 14%. X-Ray diffraction analysis of this mixture showed it to consist of $NaH_2PO_4 \cdot Na_2HPO_4$, $Na_2HPO_4 \cdot 2H_2O$ and anhydrous Na_2HPO_4.[4] The drum-dried mixture had the form of coarse polycrystalline aggregates ranging from less than 1 mm. to about 8 mm. Some particles were thin and flake-like while others were dense and roughly spherical.

Thermogravimetric Analysis.—A thermogravimetric apparatus was constructed in which both sample weight and temperature could be observed simultaneously and continuously during the reaction. Three or four gram samples of the orthophosphate mixture, contained in a small porcelain crucible, were suspended by a three mil tungsten wire from one arm of a chainomatic analytical balance. The suspension wire passed through the floor of the balance and through the top of a high table. A pot furnace, 3 in. in diameter by 5 in. deep, was mounted beneath the table so that it could be raised into position around the sample. The furnace could then be closed with a split cover containing a small hole through which the suspension and thermocouple wires could pass without contact. This thermocouple, made of 3 mil Pt and Pt + 10% Rh wire, was placed with its hot junction in the middle of the sample and the extension leads brought out along the suspension wire and over to a fixed support at right angles to the suspension wire. The sensitivity of the balance was about 0.3 mg. with these wires in place. The temperature was recorded continuously on a 2.5 millivolt recording potentiometer. The sample weight was obtained manually by one observer at intervals of about 5 mg. weight change, with the corresponding time in seconds being recorded by another observer. The zero of time was taken when the pre-heated furnace was raised into position around the

pletion of the reactions of eq. 1 and 2, but with no crystalline $Na_2H_2P_2O_7$ except in mixtures heated for long periods near 200°.

Thermal analysis curves made in an attempt to determine the beginning of the reaction of eq. 3 on the assumption that 1 and 2 were completed before formation of the triphosphate failed to shed light on this particular part of the problem because no breaks due to triphosphate formation were detectable, as can be seen by examination of the upper curve in Fig. 1.

In a further effort to find the reaction temperature, the thermal analysis experiments were expanded to thermogravimetric analysis, thus obtaining a simultaneous record of the temperature and weight of the sample with respect to heating time. Several runs were made with typical data as shown in Fig. 1. Breaks in the thermal curve show incongruent melting of $Na_2HPO_4 \cdot 2H_2O$ at 82° and boiling of the saturated solution at 109°. The strong break at 210° indicates the first loss of constitutional water. No other breaks could be discerned at higher temperatures. The weight *vs.* time curve reflects the corresponding losses of water without any particular effect being evident in the neighborhood of point B, a point calculated to represent the weight loss corresponding to completion of reactions in eq. 1 and 2.

[a] According to the chromatographic analysis sample B contained 0.15% P as trimeta, an amount barely above the detection limit. [b] "Long chain" is principally tetrapoly-, containing some pentapolyphosphate. [c] F heated to constant weight at 400°.

sample. This furnace contained a large heavy-walled stainless steel crucible which surrounded the sample and thus reduced thermal gradients. The furnace was temperature controlled and kept at a fixed temperature throughout each experiment.

Prior to the construction of the thermogravimetric apparatus, thermal analysis curves on the orthophosphate mixtures were made using the same furnace but without suspending the sample from a balance.

X-Ray Diffraction Analysis.—All of the X-ray diffraction work was done using a Geiger-counter recording X-ray diffractometer (G. E. XRD-3). The X-ray analyses were made using the diffraction maxima recommended by Mabis and Quimby[5]; however, their detailed procedure was not used and therefore the results are considered semi-quantitative in nature. The accuracy is estimated to be within ±10% of the absolute value. Cu Kα radiation was used.

Chromatographic Analyses.—The products from some of the dehydration experiments were also analyzed by paper chromatography[6] using both the one- and two-dimensional techniques. The comparison of these analyses with the X-ray diffraction results helps to characterize the noncrystalline components in the samples. These chromatographic analyses are believed to be accurate to 0.5%, with a sensitivity of detection of 0.1%.

Results and Discussion

The steps involved in the thermal conversion of an orthophosphate mixture ($Na_2O/P_2O_5 = 1.686$) to sodium tripolyphosphate were first determined by analysis of quenched two-gram portions that had been heated for various periods of time at several different temperatures. Typical X-ray diffraction data, showing the variation of composition with time in the temperature range 225 to 300°, are illustrated by the results at 250° given in Table I. These data clearly indicate that $Na_4P_2O_7$ and $Na_5P_3O_{10}$ (I), both crystalline, rise in concentration successively and then diminish as they are consumed by subsequent reactions. In other similar experiments both of these compounds have been observed in even higher amounts, the highest for $Na_4P_2O_7$ approaching the theoretical for com-

In order to identify the actual chemical species in the mixture at points A, B, C, D, E and F in Fig. 1, identical thermogravimetric runs were made which were then stopped short at these points of weight and the samples quickly removed and cooled by immediately grinding them in a large mortar. The results of these experiments are recorded in Table II. The X-ray diffraction analysis gives the crystalline components only, with Na_2HPO_4 and $NaH_2PO_4 \cdot Na_2HPO_4$ accounting for the ortho-, $Na_4P_2O_7$ being the only pyro- compound, while both forms I and II triphosphate were observed. Note that the crystalline orthophosphates fell rapidly below the detection limit (*ca.* 1%) even though appreciable amounts of ortho- remained in the mixture for samples B, C, and D as shown in the chromatographic analyses. This leaves most of the ortho- in the amorphous phase. Similar comparison shows the amorphous phase to contain a large amount of pyrophosphate. It is believed that the triphosphate in B is in the amorphous phase since strong diffraction maxima of form I, which subsequently appears first, would be detectable if present in excess of about 1%. The data

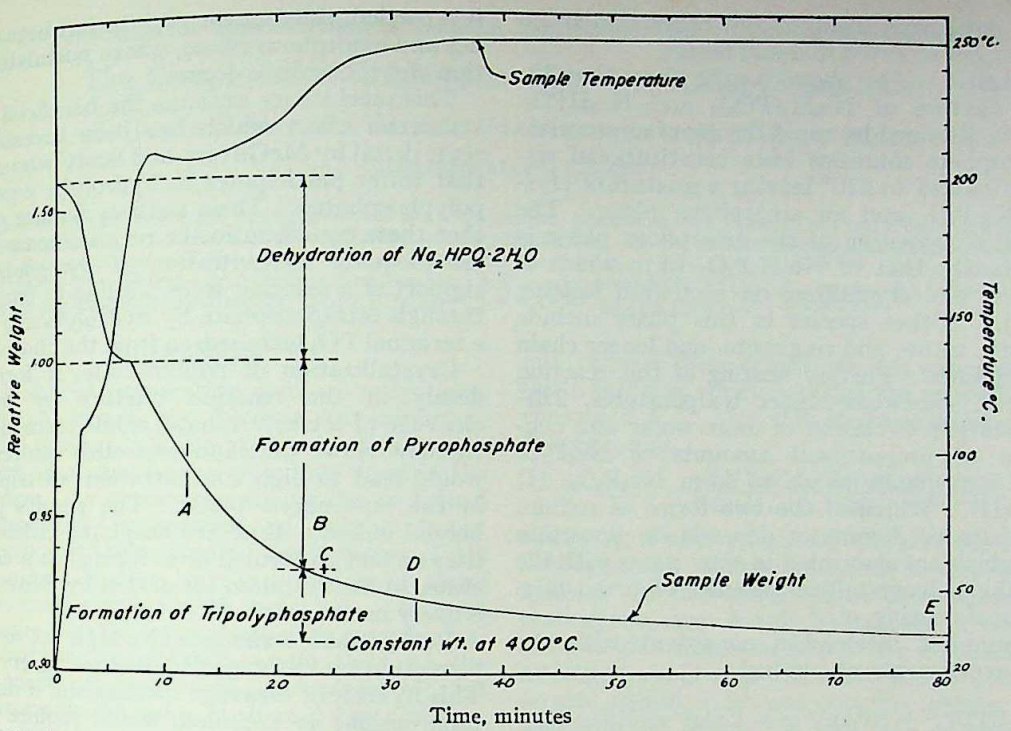

Fig. 1.—Thermogravimetric curves for dehydration of an orthophosphate mixture to sodium triphosphate.

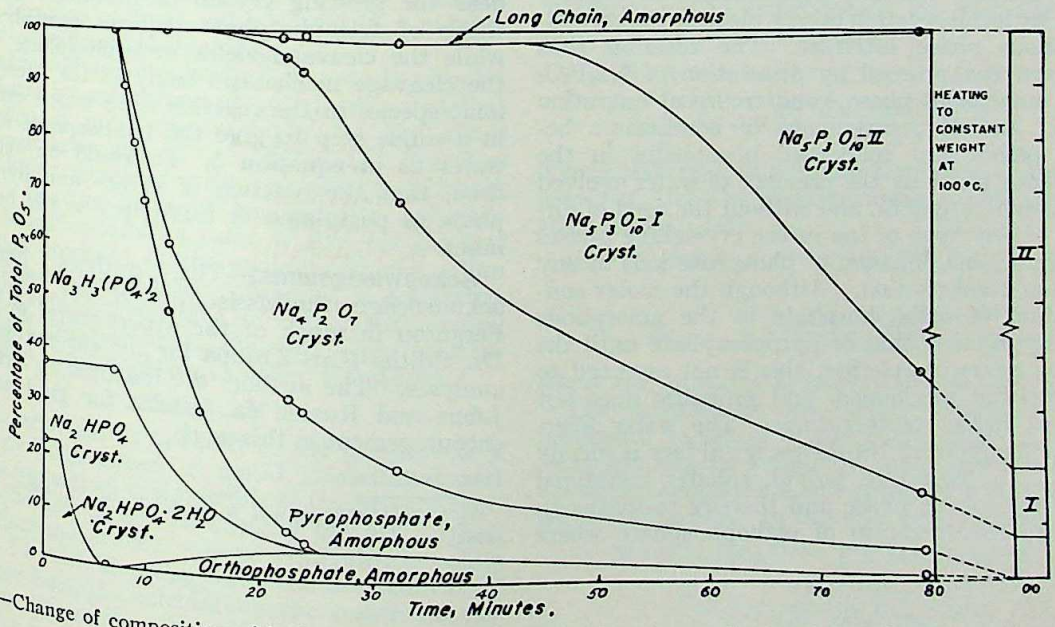

Fig. 2.—Change of composition with time during thermal dehydration of an orthophosphate mixture to sodium triphosphate.

do not permit firm conclusions about amorphous triphosphate in subsequent samples although the preponderance of high X-ray results suggest that the amorphous phase contains at most only a low concentration of triphosphate. Analytical results for long chains are erratic for unknown reasons; however, the trend in the data suggests that long chains build up to a maximum concentration and then decline. The long chain polyphosphates were mostly tetrapolyphosphate.

The results given in Fig. 1 and Table II have been combined to construct Fig. 2, a cumulative plot of the change of composition with time for the reaction mixture heated at 250°. The boundaries have been drawn in on the basis of the various analyses while the weight loss data were used for interpolation of several curves. For example, the boundary between $Na_4P_2O_7$ and $Na_5P_3O_{10}$ is established by analytical data at the points shown by circles while the curve from 32 to 79 min. was interpolated on the assumption that for this region triphosphate formation is directly proportional to the amount of water evolved. The curve between the two forms of $Na_5P_3O_{10}$ was sketched in on the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

basis of data from Table I and other similar experiments not reported in detail herein.

Mechanism.—The above results show that the *in situ* mixture of $Na_3H_3(PO_4)_2$ and Na_2HPO_4-(0–2)H_2O, obtained by rapid drying of appropriate orthophosphate solutions loses constitutional water when heated to 210° leaving a mixture of crystalline $Na_4P_2O_7$ and an amorphous phase. The elemental composition of the amorphous phase is approximately that of $Na_2H_2P_2O_7$ (into which it transforms and crystallizes on prolonged heating at 200°).[3] Other species in this phase include ortho-, tri-, tetra-, and ring meta- and longer chain polyphosphates. Further heating of this reaction mixture at somewhat higher temperatures, 225–400°, results in evolution of more water and consumption of proportional amounts of $Na_4P_2O_7$ and the amorphous phase to form $Na_5P_3O_{10}$ (I) and/or (II). Which of the two forms of sodium triphosphate predominates depends on uncertain factors which are associated in some cases with the size of the polycrystalline granules of ortho mixture, rate of heating, etc.[3]

The simplest mechanism consistent with the various experiments above has

$$HPO_4^{2-} + HP_2O_7^{3-} \longrightarrow P_3O_{10}^{5-} + H_2O \quad (5)$$

as the primary reaction for formation of triphosphate, with this reaction taking place at the crystal-amorphous phase interface. The reaction thus conceived can proceed by dissolution of $Na_4P_2O_7$ in the amorphous phase, countercurrent migration of Na^+ and H^+, sustenance of equilibrium between ortho- and condensed phosphates in the amorphous phase by the presence of water evolved in the reaction (eq. 5), and without the need of diffusion of any type of ion in the crystalline phases nor appreciable diffusion of phosphate ions of any degree of condensation. Although the molar concentration of orthophosphate in the amorphous phase approaches that of pyrophosphate until the reaction nears completion, this is not essential to the proposed mechanism and probably does not occur at higher temperatures. The water liberated at the growing $Na_5P_3O_{10}$ crystal face is ideally situated to hydrolyze polyphosphates contained in the amorphous phase and thereby maintain an adequate concentration of orthophosphate where it is needed, that is, near the interface between product and amorphous phase, where postulated formation of triphosphate occurs.

This mechanism explains the beneficial effect of water, an effect which has been investigated in some detail by McGilvery and Scott[7] who suggested that water participates in hydrolytic equilibria of polyphosphates. These authors further suggested that these equilibria in the reaction mass maintain an adequate concentration of *pyrophosphate* for support of a reaction series leading to triphosphate through tetraphosphate by hydrolytically cleaving a terminal PO_4 tetrahedron from the chain.

Crystallization of triphosphate, if formed randomly in the reaction mixture by hydrolytic cleavage of tetraphosphate, would seem to be an extremely slow, diffusion-controlled process which would lead to high concentrations of triphosphate in the amorphous phase. The results presented herein indicate that triphosphate either crystallizes as fast as formed or is formed in a crystalline state, so that random formation by cleavage is not a likely mechanism.

Rather than a random cleavage, let us consider formation by cleavage at the growing crystal face. This hydrolytic cleavage mechanism, if diffusion of large anions is excluded, would require synthesis and subsequent cleavage of tetraphosphate ions near the growing crystal of product. The synthesis of tetraphosphate requires pyrophosphate while the cleavage yields orthophosphate. Thus the cleavage mechanism leads to the presence of ionic species in the reaction zone which can react in a single step to give the triphosphate ion and water as in equation 5. It would be expected, then, that the reaction of ortho- and pyrophosphate as postulated in this paper would be dominant.

Acknowledgments.—The authors gratefully acknowledge the assistance of Mr. Ralph R. Ferguson in much of the experimental work and Dr. Editha Karl-Kroupa for the chromatographic analyses. The authors are indebted to Drs. I. B. Johns and Russell L. Jenkins for guidance and encouragement in this work.

The Complexes of Triphosphate Ion with Alkali Metal Ions[1]

BY JAMES I. WATTERS, SHELDON M. LAMBERT AND E. DAN LOUGHRAN

RECEIVED MARCH 6, 1957

The stabilities of the complexes of triphosphate ion with sodium, potassium and lithium ions have been calculated from the pH lowering during titrations of triphosphate ion with hydrogen ion. In one M tetramethylammonium chloride at 25°, formulas of the complexes and the values of their formation constant are: $KP_3O_{10}^{4-}$, $10^{1.39 \pm 0.06}$; $NaP_3O_{10}^{4-}$, $10^{1.64 \pm 0.06}$; $LiP_3O_{10}^{4-}$, $10^{2.87 \pm 0.06}$. Sodium and lithium ions also form acidic complexes with $HPO_3O_{10}^{4-}$, having the following formulas and values for their formation constants: $Na(HPO_3O_{10})^{3-}$, $10^{0.77 \pm 0.06}$; and $Li(HP_3O_{10})^{3-}$, $10^{0.88 \pm 0.06}$.

Introduction

Since Huber's[2] preparation and investigations, sodium triphosphate has become an important commercial product. Triphosphate ion forms complexes with most metal ions including those of the alkali group. As a consequence of the biological and commercial importance of triphosphates, several authors[3-5] have studied the lowering of pH of triphosphate buffers by the addition of alkali and particularly alkaline earth metal ions. In most of the studies the effect was ascribed to complex formation, but no quantitative evaluations of the stability constants were made. Recently, Martell and Schwarzenbach[6] have evaluated the stability constants of magnesium and calcium complexes with triphosphate by treating the data obtained in the titration of triphosphoric acid in a manner similar to that used in this study.

Schendewolf and Bonhoeffer[7] in a study of polyphosphates by membrane potentials observed that the order of increasing stability for the alkali metal complexes was $K^+ < Na^+ < Li^+$ and that the stability increased with polyphosphate chain length. On the basis of conductivity measurements Monk[8] obtained a value of $10^{2.5}$ for the first formation constant of the sodium complex. Van Wazer and Campanella[9] obtained a somewhat smaller complexity constant for sodium with several condensed polyphosphate glasses. They also investigated the complexes of other metal ions.

Theoretical

If an acid can be titrated in the presence of a relatively large excess of metal ion without precipitate formation, it is possible to investigate complex formation by the lowering of the pH. When the inflections at the various equivalence points persist for the stepwise addition or removal of hydrogen ions, the calculations are greatly simplified. In this case, it is evident that each ligand adds one hydrogen ion in a stepwise manner even though the ligand may also be bound to a metal ion. Under these conditions it is expedient to define a function which is called the apparent acidity constant,[6] $K_5'_{-n}$, for this stepwise addition of hydrogen ion as

$$K'_{5-n} = \frac{[H^+]\Sigma q(M_m(H_nP_3O_{10})_q^{(5q-nq-m)-})}{\Sigma q(M_m(H_{n+1}P_3O_{10})_q^{(4q-nq-m)-})} \quad (1)$$

where m, n and q indicate the number of metal, hydrogen and triphosphate ions in any particular species. In this paper parentheses indicate concentrations and brackets indicate activities. n has a single value from zero to five if the addition of hydrogen ion is stepwise while m and q may have several values if several complex species and the uncomplexed ligand, as well, are in equilibrium. The general equation for the stepwise addition of hydrogen ion to triphosphate ion and the corresponding acidity constant are

$$H^+ + H_nP_3O_{10}^{(5-n)-} \rightleftharpoons H_{n+1}P_3O_{10}^{(4-n)-} \quad (2)$$

$$K_{5-n} = \frac{[H^+](H_nP_3O_{10}^{(5-n)-})}{(H_{n+1}P_3O_{10}^{(4-n)-})}$$

The general equation for the formation of any complex ion and the corresponding complexity constant, $\beta_{M_mH_nL_q}$, are

$$mM^+ + qH_nP_3O_{10}^{q(5-n)-} \rightleftharpoons M_m(H_nP_3O_{10})_q^{(5q-nq-m)-} \quad (3)$$

$$\beta_{M_mH_nL_q} = \frac{(M_m(H_nP_3O_{10})_q^{(5q-nq-m)-})}{(M^+)^m(H_nP_3O_{10}^{(5-n)-})^q}$$

where the subscript L indicates the ligand $P_3O_{10}^{5-}$.

The calculations are further simplified if the maximum values of m and q are unity. This assumption can be tested by calculations based on varied concentrations and ratios of metal ion and triphosphate ion. In this case eq. 3 reduces to

$$M^+ + H_nP_3O_{10}^{(5-n)-} \rightleftharpoons MH_nP_3O_{10}^{(4-n)-} \quad (4)$$

$$K_{MH_nL} = \frac{(MH_nP_3O_{10}^{(4-n)-})}{(M^+)(H_nP_3O_{10}^{(5-n)-})}$$

A high concentration of an essentially non-complexing electrolyte such as tetramethylammonium chloride and relatively low concentrations of metal ion and triphosphate ion are used in order to minimize the effect of the varied concentrations of the reacting species on the various activity coefficients. Under these conditions a lowering of the pH in the titration curve indicates complex formation since the presence of metal ion in an acid enhances its acidity. In regions where no pH lowering occurs, one may conclude that complex formation does not occur to an appreciable extent. Since no pH lowering occurred in the triphosphate curves for n values larger than 2, when the concentrations of the reactants were relatively small

the following equations were derived by substituting equations having the forms of (2) and (3) into (1) with m and q equal to unity in the metal complex.

$$K'_4 = \frac{[H^+][(HP_3O_{10}^{4-}) + (MHP_3O_{10}^{3-})]}{(H_2P_3O_{10}^{3-})} = K_4 + K_{MHL}K_4(M^+) \quad (5)$$

$$K'_5 = \frac{[H^+][(P_3O_{10}^{5-}) + (MP_3O_{10}^{4-})]}{(HP_3O_{10}^{4-}) + (MHP_3O_{10}^{3-})} = \frac{K_5 + K_{ML}K_5(M^+)}{1 + K_{MHL}(M^+)} \quad (6)$$

K_4 and K_5 are the acidity constants of triphosphoric acid, while K_{ML} and K_{MHL} are the formation constants of the form in eq. 4 for the complexes $M(P_3O_{10})^{4-}$ and $M(HP_3O_{10})^{3-}$.

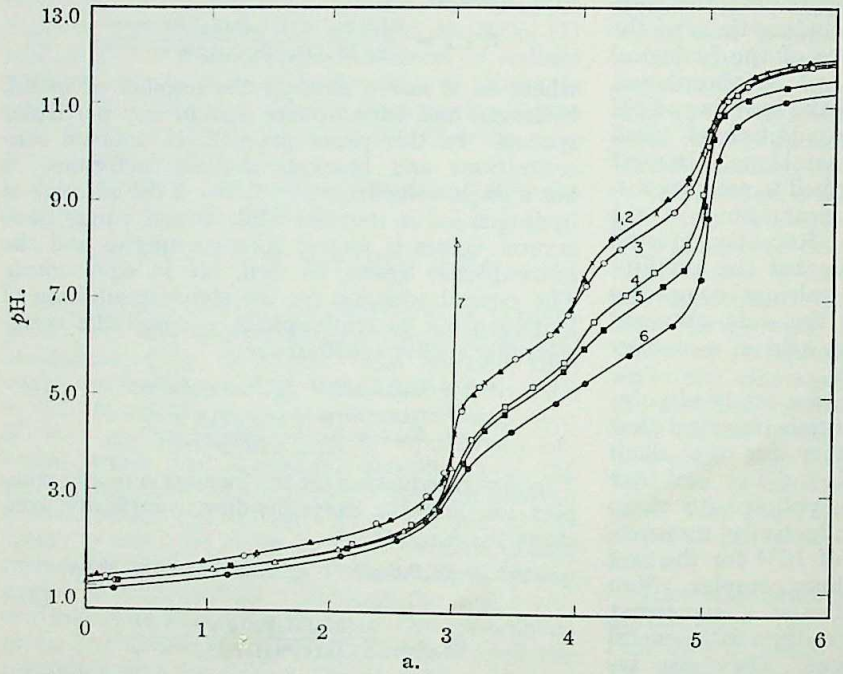

Fig. 1.—A comparison of the effects of potassium, sodium and lithium ions on titration curves of triphosphoric acid with tetramethylammonium hydroxide: curve 1, 0.0393 M $H_5P_3O_{10}$ titrated with 0.1326 N $(CH_3)_4NOH$; curve 2, 0.0396 M $H_5P_3O_{10}$ with 0.0868 N $(CH_3)_4NOH$, μ = 1.0 M with $(CH_3)_4NCl$; curve 3, 0.0399 M $H_5P_3O_{10}$ with 0.1108 N KOH; curve 4, 0.0396 M $H_5P_3O_{10}$ with 0.0961 N KOH, μ = 1.0 M with KNO_3; curve 5, 0.0379 M $H_5P_3O_{10}$ with 0.1194 N NaOH, μ = 1.0 M with $NaNO_3$; curve 6, 0.0415 M $H_5P_3O_{10}$ with 0.0960 N KOH, μ = 1.0 M with $LiNO_3$; curve 7, 0.1162 M HCl with 0.1004 N $(CH_3)_4NOH$, μ = 1.0 M with $(CH_3)_4NCl$.

From these equations it follows that the apparent acidity constants are constants if the concentration of unbound metal ion is constant, provided precautions are taken to avoid changes in activity coefficients. The apparent constants can be calculated by the following form of eq. 1 for the titration of the triphosphate ion with hydrogen ion

$$K'_{5-n} = \frac{[H^+][(n + 1 - a)C_p - K_w/[H^+]f + [H^+]/f]}{(a - n)C_p + K_w/[H^+]f - [H^+]/f} \quad (7)$$

where "a" is the number of moles of hydrogen added per mole of triphosphate ion present in any form. The symbol f indicates the activity coefficient of a univalent ion. If the acid is not too dilute pK'_{5-n} has the same value as the pH at $a = n + 1/2$.

Experimental

The sodium triphosphate, tetramethylammonium chloride and tetramethylammonium hydroxide were prepared according to a procedure described in a previous paper.[10] Carbonate-free potassium and sodium hydroxide solutions were prepared from Baker Analyzed pellets and stored in paraffin-lined bottles. All water used in preparing solutions and washing the columns was demineralized, doubly distilled, and purged with nitrogen to remove the dissolved carbon dioxide. Mallinckrodt reagent grade salts were used.

The potassium and lithium triphosphate solutions were prepared by passing a 0.03 M solution of the recrystallized sodium salt[10] through a 90 cm. by 2 cm. column filled to a height of 50 cm. with Dowex 50-x12 cation-exchange resin, 100–200 mesh, low porosity, supported on a Pyrex glass wool plug. The resin was in the potassium or lithium form, depending upon the triphosphate salt desired. The column was fitted with a Pyrex water jacket, 4 cm. in diameter, through which ice-water was circulated constantly. The column resembled a Liebig condenser, differing in that it had a stopcock on the lower end and a rubber stopper fitted with an ascarite bulb and a tube to facilitate the entry of nitrogen at the top. The eluted solution was warmed to 25 ± 0.1°, diluted to the desired concentration and immediately titrated with standardized hydrochloric acid containing the same concentration of triphosphate as the solution titrated. The inclusion of the triphosphate in both solutions eliminated the dilution of the triphosphate during the titration.

In order to prevent any hydrogen ion leakage, the resin which was originally in the acidic form was charged with potassium or lithium ions by passing through it a 10% solution of KCl or LiCl containing enough KOH or LiOH to make the solution slightly basic. Then a 15% solution of KCl or LiCl was passed through the column which was finally rinsed with water. The titrations were performed in a stoppered Berzelius beaker, placed in a water thermostat at 25 ± 0.1°, with a stream of nitrogen flowing over the solution. pH measurements were made with the Beckman model G pH meter with the Beckman All Purpose Glass electrode and the Beckman reference electrode inserted directly in the solution.

Results and Discussion

Figure 1 illustrates the pH lowering effect due to the presence of large concentrations of sodium, potassium and lithium nitrate in the titration of approximately 0.04 M $H_5P_3O_{10}$ with approximately 0.1 N $(CH_3)_4NOH$. Curve 1 was obtained in the absence of extraneous electrolytes while curves 2 and 3 were obtained with sufficient $(CH_3)_4NCl$ to produce an ionic strength of 1.0. Curve 3 was obtained for the titration of 10 ml. of 0.0339 M triphosphoric acid with 0.1108 N potassium hydroxide. At "a" values below 4 this curve coincides with curve 1 for the titration using tetramethyl-

ammonium hydroxide in the absence of metal ions. Above this "a" value the pH is lower, indicating the presence of a complex ion since any activity coefficient effect should have appeared at lower "a" values also. Curves 4, 5 and 6 illustrate the effect of one M potassium, sodium and lithium nitrate on the titration curve for triphosphoric acid. At "a" values below 3 there is a small pH decrease due to the different effects of the various alkali salts on the activity coefficients. At "a" values above 3 the pH drop is much larger due to complex formation. The increasing complex stability in the order $K^+ < Na^+ < Li^+$ is quite evident from curves 4, 5 and 6 of Fig. 1. The necessity of using a constant large concentration of a non-complexing electrolyte and relatively low concentrations of complexing species is evident from these curves for there is a pH lowering when the mean number of bound hydrogen ions exceeds 2 where no complex formation occurs. This conclusion was based on results such as those in Fig. 2. The effect did not occur for $n > 2$ with lower total concentrations but the same ratios of triphosphate and metal ion with sufficient tetramethylammonium chloride present to adjust the ionic strength to unity.

Curve 1, Fig. 2, was obtained for the titration of 0.00919 M $((CH_3)_4N)_5P_3O_{10}$ with a solution containing 0.0543 M HCl and exactly the same concentration of $H_5P_3O_{10}$ as the solution titrated. Curves 2, 3, 4 and 5 were obtained in titrations of solutions containing approximately 0.01 M $Na_5P_3O_{10}$ and different concentrations of NaCl. The acid solution contained approximately 0.05 M HCl and the same concentrations of NaCl and triphosphate as the solution titrated. Since no complex formation was observed between any of the metal ions and triphosphate ions containing two or more hydrogen ions, eq. 5, 6 and 7 were sufficient to calculate the formation constants. The data and results are given in Table I.

TABLE I

DATA AND RESULTS FOR THE TITRATION OF TRIPHOSPHATE ION WITH HYDROGEN ION IN THE PRESENCE OF VARIOUS ALKALI METAL IONS

The heading "a" is the number of moles of hydrogen ion added per mole of triphosphate ion, $C_L \times 10^3$ is the total triphosphate concentration and $C_M \times 10^3$ is the total concentration of metal ion. The ionic strength was adjusted to unity with $(CH_3)_4NCl$, 25°.

Metal ion	"a"	pH	$C_L \times 10^3$	$C_M \times 10^3$	log K
Potassium					log K_{KL}
	0.50	8.69	2.274	13.87	1.43
	.50	8.61	2.274	28.87	1.36
	.50	8.52	2.274	33.87	1.38

	.50	7.87	2.623	42.12	2.89
				Av.	2.87 ± 0.06
					log K_{LiHL}
	1.50	5.29	3.208	31.04	1.90
	1.50	5.19	3.208	46.04	1.87
	1.50	5.13	3.208	61.04	1.86
				Av.	1.88 ± 0.06

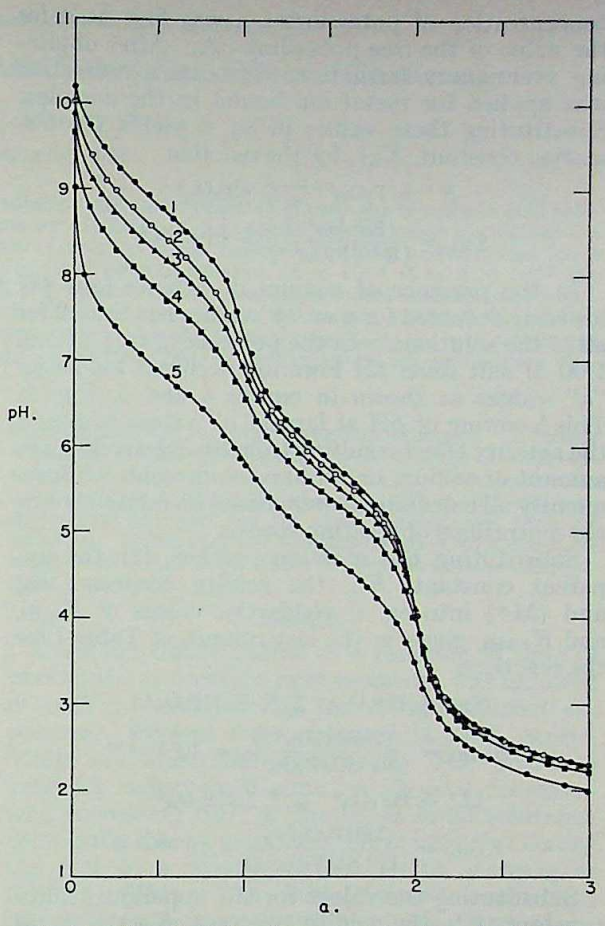

Fig. 2.—The effect of various concentrations of sodium ion on titration curves for the titration of triphosphate ion with hydrochloric acid: curve 1, 0.00919 M $((CH_3)_4N)_5P_3O_{10}$ titrated with a solution 0.0543 M in HCl and 0.00919 M in $H_5P_3O_{10}$. All solutions adjusted to $\mu = 1$ with $(CH_3)_4NCl$. Curve 2, similar to curve 1 but 0.05 M in Na^+; curve 3, 0.10 M in Na^+; curve 4, 0.25 M in Na^+; curve 5, 1.00 M in Na^+.

In the presence of potassium ion a lowering of the pH occurred only for "a" values less than unity proving the absence of detectable concentrations of potassium hydrogen triphosphate complexes, so eq. 6 reduced to the form

$$K'_5 = K_5 + K_{KL}K_5(K^+) \qquad (8)$$

The apparent constant, K'_5, is equal to the pH at the corresponding "a" value of $1/2$. The values for the acidity constants of triphosphoric acid in 1 M $(CH_3)_4NCl$ at 25° taken from the previous paper were $10^{-5.53}$ for K_4 and $10^{-8.81}$ for K_5. The total

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

concentration of potassium ion was first used for the value of the free potassium ion. After obtaining preliminary formation constants a correction was applied for metal ion bound in the complex. Substituting these values in eq. 6 yields the formation constant, K_{KL}, for the reaction

$$K^+ + P_3O_{10}^{5-} \rightleftharpoons KP_3O_{10}^{4-}$$

$$K_{KL} = \frac{(KP_3O_{10}^{4-})}{(K^+)(P_3O_{10}^{5-})} = 10^{1.39 \pm 0.06}$$

In the presence of sodium or lithium ions pH lowering occurred for n or "a" values less than 2 for all of the solutions. In the presence of 0.25 M and 1.00 M salt some pH lowering occurred for larger "a" values as shown in curves 4 and 5, Fig. 2. This lowering of pH at larger "a" values is due to the activity effect resulting from the relatively large amount of sodium or lithium ion present. Consequently all calculations were based on relatively low concentrations of reacting species.

Substituting the individual values for the apparent constant, K'_4, the acidity constant, K_4, and (M^+) into eq. 5 yields the values of K_{LiHL} and K_{NaHL} given in the last column of Table I for the reactions

$$Na^+ + HP_3O_{10}^{4-} \rightleftharpoons NaHP_3O_{10}^{3-}$$

$$K_{NaHL} = \frac{(NaHP_3O_{10}^{3-})}{(Na^+)(HP_3O_{10}^{4-})} = 10^{0.77 \pm 0.06}$$

$$Li^+ + HP_3O_{10}^{4-} \rightleftharpoons LiHP_3O_{10}^{3-}$$

$$K_{LiHL} = \frac{(LiHP_3O_{10}^{3-})}{(Li^+)(HP_3O_{10}^{4-})} = 10^{1.88 \pm 0.06}$$

Substituting the values for the apparent acidity constant, K'_5, the acidity constant, K_5, the metal concentration, (M^+), and the above metal–hydrogen formation constants into eq. 6 yields the values of the metal formation constant given in the last column of Table I for the reactions

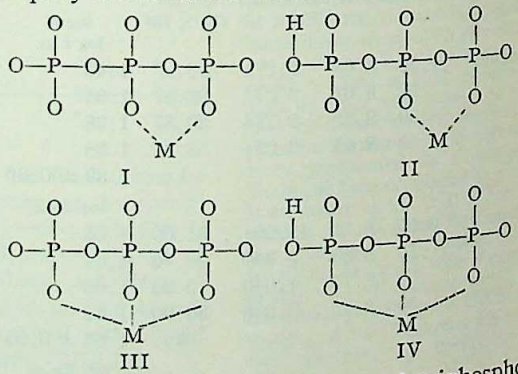
$$Na^+ + P_3O_{10}^{5-} \rightleftharpoons NaP_3O_{10}^{4-}$$

$$K_{NaL} = \frac{(NaP_3O_{10}^{4-})}{(Na^+)(P_3O_{10}^{5-})} = 10^{1.64 \pm 0.06}$$

$$Li^+ + P_3O_{10}^{5-} \rightleftharpoons LiP_3O_{10}^{4-}$$

$$K_{LiL} = \frac{(LiP_3O_{10}^{4-})}{(Li^+)(P_3O_{10}^{5-})} = 10^{2.87 \pm 0.06}$$

These results establish moderately stable complex formation between triphosphate ion and these alkali metals which should be considered in calculating the stabilities of other complexes of triphosphate ions. It is probable that the metal ions are members of at least one chelate ring containing two phosphorus and three oxygen atoms, structure I, as suggested by Kolthoff and Watters[11] for the manganese(III) complex with pyrophosphate and by Van Wazer[9] and his co-workers for complexes of higher phosphates since no complexes were observed in similar experiments with orthophosphate. In these structures the three resonating double bonds and the ionic charges are omitted. It is possible that, in the acidic complexes, the hydrogen ion is bound in the same way. However, the strong bonding of the last hydrogen ion in phosphoric acid relative to its bonding in higher phosphates indicates that the hydrogen ion may be bonded to a single phosphate tetrahedron as shown in structure II. In the next paper of this series it will be shown that the acid triphosphate complexes of lithium are slightly less acidic than the acidic pyrophosphate complexes. This evidence supports a structure for the acidic complex in which the metal ion is not bonded to the same phosphate tetrahedron as the hydrogen ion. Accordingly, structure II seems feasible for the acidic complex. Hydrogen bonding in the same or adjacent tetrahedron probably occurs. Martell and Schwarzenbach[6] have proposed that the triphosphate ion may be tridentate, structures III and IV, in the corresponding complexes with calcium and magnesium. Their structure III for triphosphate is supported by similar experiments with pyrophosphate. These studies indicate that the pyrophosphate complexes with the alkali metals are somewhat less stable than the triphosphate complexes. Hirshfelder–Taylor models indicate that bonding of the metal ion to the two terminal phosphate tetrahedra and to the center tetrahedron as well can occur without strain. However, the bonding with alkali metals is probably essentially electrostatic rather than covalent in nature so the exact position of the metal ion as part of any particular chelate ring may be more a function of field strength than of bonding direction. On this basis it is probable that neither structure I or III uniquely describes the actual situation.



The last four acidity constants of triphosphoric acid and the four acidity constants of ethylenediaminetetraacetic acid are somewhat similar. It is of interest that this similarity persists in the sodium and lithium complexes of these ligands.

Photoreduction of Ceric Ion in Sulfuric Acid Solutions. Effect of Thallous Ion[2a]

BY THOMAS J. SWORSKI[2b]

RECEIVED MARCH 14, 1957

Evidence has been obtained for the OH radical as an intermediate in the photoreduction of ceric ion in sulfuric acid solutions. The observed chemical reaction in the photolysis of ceric ion–thallous ion mixtures is the oxidation of thallous ion by ceric ion. The initial quantum yield (ΦCe^{+++}) for reduction of ceric ion in the absence of initially added cerous ion is markedly enhanced by thallous ion but is independent of the thallous ion concentration (2×10^{-4} M to 2×10^{-2} M). At any particular initial cerous ion concentration, the initial ΦCe^{+++} decreases with decreasing initial thallous ion concentration. These data obtained in 0.4 M sulfuric acid are quantitatively interpreted by a mechanism in which thallous ion competes with cerous ion for reaction with OH radical. The measured value of 42 for $k_{Tl^+, OH}/k_{Ce^{+++}, OH}$ is in agreement with the value of 38 previously determined in 0.4 M sulfuric acid for the radiolysis of ceric ion–cerous ion–thallous ion mixtures with cobalt-60 γ-radiation.

Introduction

When ceric ions in perchloric acid solution absorb ultraviolet radiation, oxygen is evolved with concomitant reduction of ceric ions to cerous ions.[3,4] Weiss and Porret[4] postulated the formation of an OH radical in the photochemical primary process. This assumption has been a subject of controversy.[5,6]

Photoreduction of ceric ions also occurs[7] in sulfuric acid solutions in disagreement with the observations of Weiss and Porret.[4] Although no definitive evidence was presented, the OH radical was also postulated[7] as an intermediate in sulfuric acid solutions. This paper reports the results of a kinetic study of the photolysis of ceric ion–cerous ion–thallous ion mixtures in 0.4 M sulfuric acid. These results, when compared with those reported[8] for the radiolysis of ceric ion–cerous ion–thallous ion mixtures with cobalt-60 γ-radiation also in 0.4 M sulfuric acid, yield supporting evidence for the intermediate formation of OH radical in the photoreduction of ceric ion in sulfuric acid solutions.

Experimental

The source of ultraviolet radiation was a G. E. 4-watt germicidal lamp operating from a Sola Electric constant voltage transformer. The light was used without collimation, the solutions being reproducibly placed several centimeters from the light source. The light flux incident upon the solutions was measured with an equal volume of actinometer solution.[9] The light absorbed from this source by the uranyl actinometer is reported[10] to be almost entirely 253.7 mμ. The quantum efficiency for oxalate oxidation was observed to be constant up to 65% of completion.

Solutions of 50-ml. volume were contained in a silica vessel of 3 cm. diameter. The ceric ion solutions in 0.4 M sulfuric acid were prepared in the same manner as previously reported[8] for the radiolysis of ceric ion–cerous ion–thallous ion mixtures with cobalt-60 γ-radiation. Ceric ion concentrations were determined spectrophotometrically with a Cary model 11 recording spectrophotometer. A molar extinction coefficient for ceric ion at 320 mμ of 5580 was used for 0.4 M sulfuric acid solutions.[11] Molar extinction coefficients of 2440 at 370 mμ and 1020 at 395 mμ were determined and used for the more concentrated ceric ion solutions. Cerous ion and thallous ion have no measurable effect on these molar extinction coefficients at the concentrations employed.

Results

Ceric ion concentration as a function of time of photolysis, at constant light intensity, was followed in each solution through use of intermittent exposures. Typical data obtained in such experiments are illustrated by Fig. 1. The quantum yield for reduction of ceric ion ($\Phi_{Ce^{+++}}$) decreased with increasing time of photolysis in all solutions, principally due to an internal filter action of cerous ion and to a smaller extent to an increase in $(Ce^{+++})/(Tl^+)$. The initial $\Phi_{Ce^{+++}}$ could not, therefore, be measured with any high degree of accuracy or reproducibility. The initial $\Phi_{Ce^{+++}}$ obtained under a variety of experimental conditions in air-saturated 0.4 M sulfuric acid are listed in Table I.

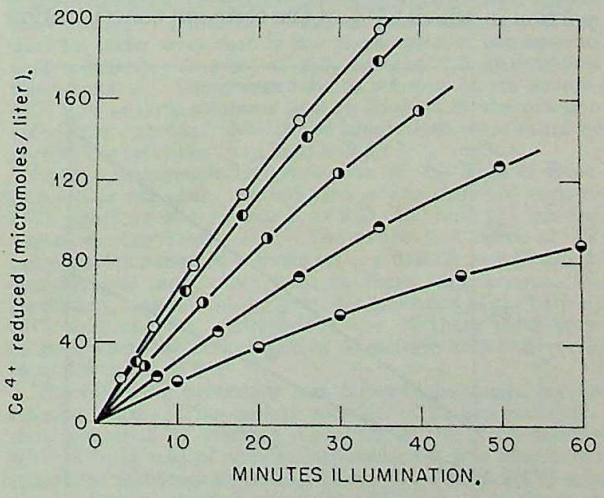

Fig. 1.—Effect of variation in initial thallous ion concentration on the rate of photoreduction of ceric ion at constant initial ceric and cerous ion concentrations. Initial cerous ion concentration in all solutions was 10^{-2} M. Initial ceric ion concentration in all solutions was 3.64×10^{-4} M. Initial thallous ion concentrations were: ○, 10^{-2} M; ◐, 10^{-3} M; ◑, 4×10^{-4} M; ◒, 2×10^{-4} M; ◓, 10^{-4} M.

[a] Quantum yields are based on total light absorbed by the solutions.

The chemical change which occurs during photolysis is oxidation of thallous ion by ceric ion. This was experimentally established by two different methods. (I) In a solution containing initially 10^{-3} M ceric ion and 2.67×10^{-4} M thallous ion, the rate of photoreduction markedly decreased when 5.40×10^{-4} mole/l. of ceric ion had been reduced. (II) For a solution containing initially 10^{-3} M ceric ion and 2.67×10^{-3} M thallous ion, equal volumes of either the original solution or a portion in which 85% of the ceric ion concentration had been photochemically reduced oxidized equal amounts of ferrous ion.

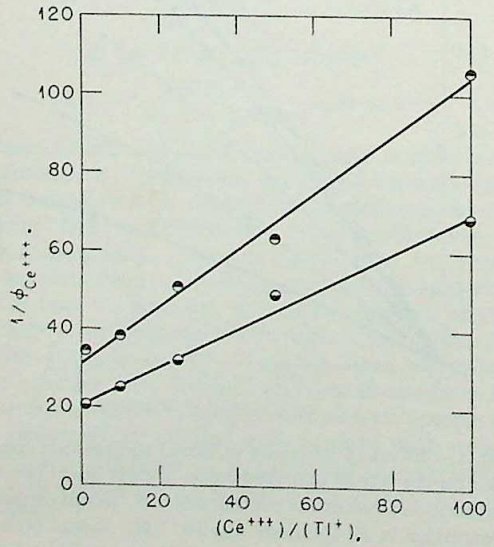

Fig. 2.—Effect of $(Ce^{+++})/(Tl^{+})$ ratio on the initial rate of photoreduction of ceric ion in air-saturated 0.4 M sulfuric acid solutions. Initial cerous ion concentrations were: ◓, 2×10^{-2} M and ◒, 10^{-2} M. Initial ceric ion concentrations were: ◓, 3.25×10^{-4} M; ◒, 3.64×10^{-4} M.

In ceric ion–thallous ion mixtures, the initial $\Phi_{Ce^{+++}}$ is independent of the ceric ion concentration (2.4×10^{-4} M to 1.9×10^{-3} M). This indicates that essentially all the incident light is absorbed by these solutions. These results in sulfuric acid solutions differ markedly with those obtained in perchloric acid solutions by Heidt and Smith[5] where $\Phi_{Ce^{+++}}$ increases with increasing ceric ion concentration.

The initial $\Phi_{Ce^{+++}}$ is also independent of thallous ion concentration (2×10^{-4} M to 2×10^{-2} M) but only in the absence of initially added cerous ion. At any particular initial cerous ion concentration, the initial $\Phi_{Ce^{+++}}$ decreases with decreasing thallous ion concentration. Since cerous ion acts as an internal filter, dependence of initial $\Phi_{Ce^{+++}}$ on $(Ce^{+++})/(Tl^{+})$ was investigated at constant concentration of ceric and cerous ions.

Discussion

The reactions of ceric and cerous ions with radicals in aqueous solution have been elucidated by recent studies in radiation chemistry. $G(Ce^{+++})$[12] in the radiolysis of sulfuric acid solutions containing ceric ions was postulated[13] to be equal to $2G_{H_2O_2} + G_H - G_{OH}$. The following radical reactions were assumed

$$Ce^{4+} + H \longrightarrow Ce^{+++} + H^{+} \quad (1)$$

$$Ce^{+++} + OH \longrightarrow Ce^{4+} + OH^{-} \quad (2)$$

This mechanism was confirmed[14] by a demonstration of ceric ion reduction with concomitant oxidation of radioactive cerous ion.

Thallous ion increases[15] $G(Ce^{+++})$ to $2G_{H_2O_2} + G_H + G_{OH}$ according to the reaction mechanism

$$Tl^{+} + OH \longrightarrow Tl^{++} + OH^{-} \quad (3)$$

$$Ce^{4+} + Tl^{++} \longrightarrow Ce^{+++} + Tl^{+++} \quad (4)$$

A value of 38 was measured[8] for the ratio k_3/k_2 in 0.4 M sulfuric acid.

If the postulate is correct that an OH radical is formed in the primary photochemical process in sulfuric acid solutions

$$Ce^{4+} + H_2O \xrightarrow{h\nu} Ce^{+++} + H^{+} + OH \quad (5)$$

then the experimental data should be fully described by a reaction mechanism containing only reactions 5, 2, 3 and 4. From this reaction mechanism, the following kinetic relationship can be derived

$$\frac{1}{\Phi_{Ce^{+++}}} = \frac{1}{2\Phi_{OH}} + \frac{k_2(Ce^{+++})}{2\Phi_{OH}k_3(Tl^{+})}$$

Φ_{OH} is the quantum yield for the OH radicals formed in the primary photochemical process.

A linear relationship does exist between $1/\Phi_{Ce^{+++}}$ and $(Ce^{+++})/(Tl^{+})$ as shown in Fig. 2. Treatment of the data by the method of least

(12) In the decomposition of water by ionizing radiation, 100 e.v. yields of the intermediates H, OH, H_2 and H_2O_2 are denoted by G_H, G_{OH}, G_{H_2} and $G_{H_2O_2}$. The 100 e.v. yield of any measurable product in radiolysis of aqueous solutions is denoted by G(product).

squares yields the equations

$$1/\Phi_{Ce^{+++}} = 31.2 + 0.730(Ce^{+++})/(Tl^{+}) \quad (I)$$

$$1/\Phi_{Ce^{+++}} = 20.5 + 0.495(Ce^{+++})/(Tl^{+}) \quad (II)$$

Equation I is obtained from the data with 2×10^{-2} M cerous ion solutions while eq. II is obtained from the data with 10^{-2} M cerous ion solutions.

From eq. I and II, k_3/k_2 is evaluated by division of the intercept by the slope. From eq. I, k_3/k_2 is equal to 31.2/0.73 or 42.7. From eq. II, k_3/k_2 is equal to 20.5/0.495 or 41.4. The average value of 42 is in excellent agreement with the value of 38 measured[8] for the radiation chemistry of the same chemical system using cobalt-60 γ-radiation.

This comparison of the photochemistry with the radiation chemistry of ceric ion–cerous ion–thallous ion mixtures thus yields convincing evidence for the postulated formation of OH radical in the photoreduction of ceric ion in sulfuric acid solutions.

Let us assume that OH is an intermediate in perchloric acid and that OH radical can reduce[6] ceric ion in perchloric acid. Then, the following kinetic relationship can be derived

$$\frac{1}{\Phi_{Ce^{+++}}} = \frac{1}{x\Phi_{OH}} + \frac{k_2(Ce^{+++})}{x\Phi_{OH}k_y(Ce^{4+})}$$

The value of x would be either 2 or 4 and k_y would be either k_6 or k_7 depending whether ceric ion oxidized OH radical according to reaction 6 or reaction 7

$$Ce^{4+}\cdot H_2O + OH \longrightarrow Ce^{+++} + H^{+} + H_2O_2 \quad (6)^{6}$$

$$Ce^{4+} + OH \longrightarrow Ce^{+++} + H^{+} + {}^1/_2O_2 \quad (7)$$

Heidt and Smith[5] report that for 1.1×10^{-2} M ceric ion solutions in perchloric acid $1/\Phi_{Ce^{+++}} = 5 + 670(Ce^{+++})$. Thus, k_y/k_2 would have a value of 0.68. Whether reaction 6 or reaction 7 occurs could be determined if Φ_{OH} were known. This would have required a study of the effect of added solutes, such as reported here, which was not investigated by Heidt and Smith.[5]

A Study of the Kinetics of the Reaction between Oxalate Ion and Cerium(IV) in Aqueous Sulfuric Acid Solution

BY VANCE H. DODSON AND ARTHUR H. BLACK

RECEIVED FEBRUARY 7, 1957

The kinetics of the reaction between cerium(IV) and oxalate ion, bioxalate ion and oxalic acid in aqueous sulfuric acid has been studied over the temperature range of 19 to 35°. The reaction appears to be second order, and the rate of the reaction is dependent upon the concentration of sulfuric acid. The experimental energy of activation is 16.5 ± 0.4 kcal./mole in 0.5, 1.0 and 2.0 M sulfuric acid solutions.

Kinetic studies of the reactions between cerium(IV) and tin(II),[1] arsenic(III)[2] and oxalic acid[3] have been reported in the literature. In a recent examination of the reaction between cerium(IV) and oxalate ion[4] in aqueous sulfuric acid, it was noted that the rate of the reaction decreased as the concentration of the sulfuric acid was increased. Since the previously published work[3] merely established the order of the reaction, it was of interest to re-examine the kinetics of the reaction and attempt to establish a mechanism for it.

Experimental Part

Equipment and Reagents.—Reaction rates were determined by using a Bausch and Lomb Spectronic 20 colorimeter. The solutions were kept in a constant temperature bath, then mixed and immediately transferred to the cell and placed in the instrument. In all of the experiments conducted, the cell and its contents were never in the instrument longer than one minute. Over the temperature range of 19 to 35° this short exposure to the heat of the exciter lamp produced no deviations greater than ±0.1° in the reaction mixtures.

The reagents were prepared by dissolving anhydrous cerium(IV) acid sulfate (G. Frederick Smith Chemical Co.) and C.P. Special Grade anhydrous sodium oxalate (Baker Chemical Co.) in aqueous sulfuric acid of known molarity. The cerium(IV) solutions were standardized with iron(II). Ferrous o-phenanthroline was used as the indicator. The concentrations of the oxalate solutions were checked against the cerium(IV) solutions. Reagent grade sulfuric acid and distilled water were used in the preparation of the aqueous acid solutions. A series of 2.0, 1.0 and 0.5 M solutions was prepared. These were used as solvents in the cerium(IV) and oxalate solutions and as diluents in the reaction rate measurements. No special precautions were taken to protect the solutions from light and air.[5]

Spectrophotometric Determination of the Rate of Reaction.—The per cent. transmission of the standard cerium(IV) solutions was measured at 425, 450 and 475 mμ and found to obey Beer's law. The calibration curve at 450 mμ over the range of concentrations 0.0055 to 0.00025 M was the one most often used in these experiments. No significant variation in per cent. transmission of the cerium(IV) solutions was observed at any of these three wave lengths when the concentration of sulfuric acid was varied from 0.5 to 2.0 M.[6]

The following procedure was followed in measuring the reaction rates. The oxalate solution of known concentration, prepared by diluting a portion of the stock solution with sulfuric acid of appropriate molarity, was placed in a stoppered wide-mouth conical flask. The cerium(IV) solution of known concentration (in sulfuric acid of the same molarity as that in the oxalate solution) was placed in a stoppered soft glass test-tube whose bottom had been blown to form a thin-walled bulb. Both the bulb and flask were then placed in the constant temperature bath. At time zero the bulb of cerium(IV) solution was broken in the conical flask and the solutions were mixed by rapid swirling. A portion of the reaction mixture was immediately transferred to the colorimeter cell and per cent. transmission readings were taken at various time intervals.

The time required by the experimenters to mix the solutions and place them in the instrument varied from eight to ten seconds. The number of readings taken per experiment ranged from three to seven in number. The concentration of unreacted cerium(IV) at the various time intervals was then determined from a plot of the logarithm of per cent. transmission *versus* concentration that had been predetermined from the standard solutions.

Results

The initial concentration of the oxalate ion, bioxalate ion or oxalic acid was varied from 0.007 to 0.005 *M* in the experiments, while that of the cerium(IV) was approximately 0.01 *M*. The reaction was observed to be second order, first order each in cerium(IV) and oxalate, bioxalate or oxalic acid. A graphical treatment of the results of several typical experiments is shown in Fig. 1.

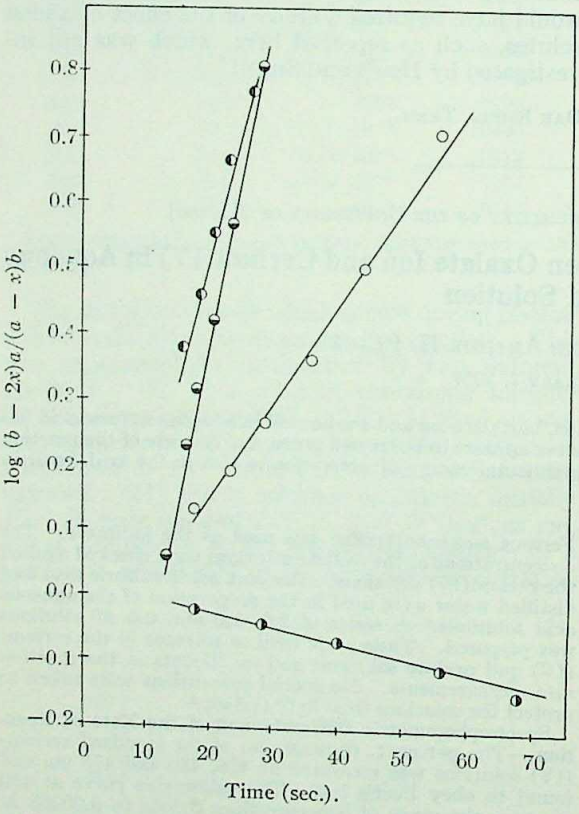

Fig. 1.—Typical second-order rate plots: ◐, $a = 0.01045$ *M* Ce(IV), $b = 0.00613$ *M* oxalate, in 1.0 *M* H_2SO_4 at 27°; ◒, $a = 0.01045$ *M* Ce(IV), $b = 0.00750$ *M* oxalate, in 1.0 *M* H_2SO_4 at 19°; ○, $a = 0.01050$ *M* Ce(IV), $b = 0.00693$ *M* oxalate, in 2.0 *M* H_2SO_4 at 25°; ◑, $a = 0.01050$ *M* Ce(IV), $b = 0.00495$ *M* oxalate, in 2.0 *M* H_2SO_4 at 25°.

The second-order rate constants that are reported in Table I were calculated from the slopes of plots similar to those of Fig. 1 and represent the average of several experiments. The deviations reported in Table I are average deviations.

The plots of log *k versus* $1/T$, shown in Fig. 2, for the reactions carried out in the three different concentrations of sulfuric acid have approximately the same slope. The activation energies calculated from the slopes of these plots are 16.9 kcal./mole (in 0.5 *M* acid), 16.7 kcal./mole (in 1.0 *M* acid)

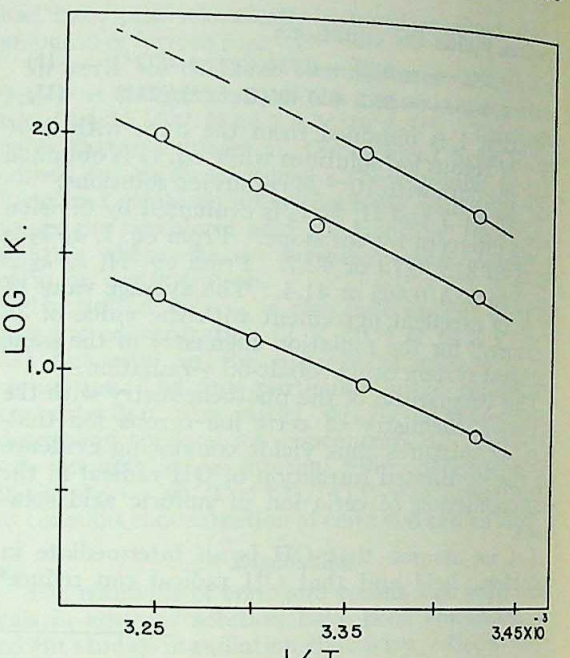

Fig. 2.—Arrhenius plot: upper curve, reactions in 0.5 *M* H_2SO_4; middle curve, reactions in 1.0 *M* H_2SO_4; lower curve, reactions in 2.0 *M* H_2SO_4.

TABLE I

RATE CONSTANTS FOR THE OXIDATION OF OXALATE BY CERIUM(IV) AT VARIOUS TEMPERATURES IN AQUEOUS SULFURIC ACID

No. of exp.	Concn. of H_2SO_4, *M*	Temp., °C. ±0.1°	$k_{av.}$, l. × mole^{-1} × sec.$^{-1}$
7	0.5	19.0	49.7 ± 8.7
8		25.0	87.6 ± 7.2
9	1.0	19.0	22.6 ± 0.9
10		27.0	42.8 ± 4.0
10		30.0	62.9 ± 4.3
4		35.0	97.0 ± 10.5
8	2.0	19.0	5.45 ± 0.26
9		25.0	9.02 ± 0.27
6		30.0	13.7 ± 0.7
6		35.0	20.9 ± 1.6

and 15.8 kcal./mole (in 2.0 *M* acid) and average 16.5 ± 0.4 kcal./mole.

Discussion and Conclusions

The total ionic strength of each of the reaction mixtures examined in this work is extremely large in comparison with that of the reactants; and, as might be expected, the deviations in the reaction rates with changes in concentration of the reactants are not significant. Had there been a noticeable variation, an interpretation would not be entirely justified in view of the high ionic strength of the solutions.[7]

A plot of log k − log k_0 *versus* $\sqrt{\mu}$ is shown in Fig. 3. In this graph, log k_0 is the rate constant at infinite dilution with respect to sulfuric acid, k is the average measured rate constant (Table I), and μ is the total ionic strength of the hydrogen, bisulfate and sulfate ions in solution. The concentrations

(7) S. Glasstone, "Textbook of Physical Chemistry," 2nd Ed., D. Van Nostrand Co., New York, N. Y., 1946, Chap. 13.

Digitized by Arya Samaj Foundation Chennai and eGangotri

of these ions were roughly estimated from the dissociation constants of oxalic acid and bisulfate ion.[8] Molar concentrations were converted to molalities and ionic strengths were derived from these latter values. The graph in Fig. 3 shows that the differences between log k and log k_0 over the temperature range 19 to 35° are approximately the same for solutions of similar ionic strength (with respect to sulfuric acid). This same conclusion can be reached by comparing the slopes of the curves in Fig. 2. The data plotted in Figs. 2 and 3 indicate that the same species of reactants are involved in the rate-determining step, regardless of the acidity of the reaction medium.

There is considerable evidence that the cerium(IV) ion exists primarily as the trisulfato complex ion in sulfuric acid solutions. This is especially true in acid concentrations such as those employed in this work.[6,9] It is also reasonable to assume that in these strongly acid solutions the oxalate is present mainly as oxalic acid with smaller amounts of bioxalate ion and only traces of oxalate ion. The rate-determining step must then be either (I) or (II)

$$2Ce(SO_4)_3^{-2} + HC_2O_4^{-1} \longrightarrow 2Ce^{+3} + 2CO_2 + 5SO_4^{-2} + HSO_4^{-1} \quad (I)$$

$$2Ce(SO_4)_3^{-2} + H_2C_2O_4 \longrightarrow 2Ce^{+3} + 2CO_2 + 4SO_4^{-2} + 2HSO_4^{-1} \quad (II)$$

Since both reactions I and II produce bisulfate ions, they might be expected to respond to a change in acid concentration. The presence of excess sulfate ions in the reaction medium would also tend to reduce the rate of the reaction. From the standpoint of the concentration of the reactants, an increase in acid concentration would tend to slow down reaction I and speed up reaction II. However, as the concentration of the sulfuric acid solutions is increased from 0.5 to 2.0 M, the concentration of bioxalate ion and oxalic acid remains fairly constant. Therefore, the noted effect of the acid on the reaction rates must be due to the excess sulfate, bisulfate and hydrogen ions in solution.

The Chemical Properties of Nitrosyl Perchlorate: The Neutralization Equivalent

BY MEYER M. MARKOWITZ, JOHN E. RICCI, RICHARD J. GOLDMAN AND PAUL F. WINTERNITZ

RECEIVED MARCH 5, 1957

The quantitative preparation of nitrosyl perchlorate from dinitrogen trioxide and perchloric acid is limited by the subsequent hydrolysis of the product below a minimum acid concentration. The neutralization equivalent weight of nitrosyl perchlorate under defined conditions is $NOClO_4/2$. Some aspects of the thermal behavior of the salt are treated briefly.

Introduction

Interest in the nitric oxide molecule stems from the diversity of bond types into which the group may enter.[1-3] Previous studies concerning nitrosyl perchlorate ($NOClO_4$), as representative of a compound containing a nitric oxide cation (NO^+), have dealt with the electrolytic behavior in anhydrous nitromethane,[4] the Raman spectrum in perchloric acid,[5] the crystallographic structure,[6] the heat of formation,[7] and the thermal decomposition.[8] The material to follow presents lab-

oratory investigations directed at the further elucidation of the chemical properties of nitrosyl perchlorate.

Experimental

Preparation.—Nitrosyl perchlorate was prepared by passage of dinitrogen trioxide into aqueous perchloric acid, following the method of Hofmann and Zedtwitz.[9] The gas from 89 g. of sodium nitrite (1.3 moles), on to which 57 ml. of 70% nitric acid (0.89 mole) was added dropwise, was passed slowly into 40 ml. of 70–72% perchloric acid (0.47–0.49 mole) immersed in an ice-bath. The gas generator was contained in an ice-bath to moderate the gas flow. Drying tubes, filled with sodium nitrite and glass beads, and Drierite, respectively, were interposed between the gas generator and reaction tube in order to prevent the passage of nitric acid and water into the perchloric acid.

The precipitated nitrosyl perchlorate was suction-filtered on a fritted glass funnel, and washed with six 20-ml. portions of nitromethane which previously had been dried over anhydrous magnesium perchlorate and then vacuum distilled. The washed material was pumped down for five hours in a vacuum desiccator sealed with a fluorocarbon grease. The nitrosyl perchlorate subsequently was allowed to stand *in vacuo* over phosphorus pentoxide for five days.

It should be noted that nitrosyl perchlorate is a strong oxidant and that suitable care must be taken in its handling; yield 18.3 g. (30% of theory on the basis of 0.48 mole of $HClO_4$). Preparation of nitrosyl perchlorate by the direct reaction of sodium or potassium nitrite with aqueous perchloric acid was not possible.

Analytical Methods.—Analyses for chlorine were performed by admixture of the product with anhydrous sodium carbonate in a platinum crucible, addition of water dropwise to allow for conversion to sodium perchlorate, oven-drying at 90°, and ignition over a blast lamp for decomposition of the perchlorate to chloride.[10] Chlorine was then determined gravimetrically as silver chloride.

Direct determination of the nitrosyl group was afforded by suspension of the salt (0.5 g.) in concentrated sulfuric acid (100 ml.), and slow addition, accompanied by constant stirring, of excess potassium permanganate (0.2 *N*).[11,12] The permanganate solution must be added below the surface of the acid to avoid any loss of sample by hydrolysis. The excess permanganate was titrated with acidified ferrous sulfate solution (0.2 *N*).

Anal. Calcd. for $NOClO_4$:Cl, 27.39; nitrosyl group, 23.17. Found: Cl, 27.28; nitrosyl group, 23.16.

Hydrolysis of Nitrosyl Perchlorate.—The low yield obtained may, in part, be traced back to the ready hydrolysis of ionic nitrosyl compounds.[1,13] Solution of dinitrogen trioxide in strong, concentrated acids yields the nitrosyl ion.[14,15] Thus, with perchloric acid, the following reaction must occur

$$N_2O_3 + 3HClO_4 \longrightarrow 2NO^+ + 3ClO_4^- + H_3O^+$$

As the addition of dinitrogen trioxide is continued, nitrosyl perchlorate will precipitate and the concentration of the water will rise. However, precipitation can only proceed to the point at which hydrolysis of the product ensues because of the augmenting water concentration. Hydrolysis will yield nitrous acid as per

$$NOClO_4 + H_2O \longrightarrow HNO_2 + HClO_4$$

which may, in turn, decompose according to the disproportionation reaction

$$3HNO_2 \longrightarrow HNO_3 + 2NO + H_2O$$

Titration with sodium hydroxide of the filtrate obtained from the above-described preparation of nitrosyl perchlorate showed that the alkali titer, expressed as equivalents of base per 1000 g. of solution, had changed from the value of 7.10 for the original perchloric acid (71.4%) to a final value of 6.18 after precipitation.

Nitrosyl perchlorate placed in 51.7% perchloric acid at 25.0° (5.14 equivalents per 1000 g. of dilute acid) decomposed until the alkali titer of the acid plus nitrosyl perchlorate decomposition products reached 5.44. These data indicate that nitrosyl perchlorate will hydrolyze in perchloric acid solutions of less than about 55% concentration.

The Neutralization Equivalent of Nitrosyl Perchlorate.—Previous studies of the alkali titers of nitrosyl compounds suggest neutralization equivalent weights dependent upon the reaction conditions which would determine the extent of the nitrous acid disproportionation reaction.[7,16] Cruse, *et al.*,[7] reported the reaction of nitrosyl perchlorate with 0.5 *N* sodium hydroxide to be given by

$$9NOClO_4 + 16NaOH \longrightarrow 9NaClO_4 + 6NaNO_2 + NaNO_3 + 2NO + 8H_2O$$

In order to determine the neutralization equivalent under conditions such that the disproportionation reaction would be minimized, a series of titrations with sodium hydroxide was carried out at 0°. 0.25–0.30 g. of nitrosyl perchlorate contained in a small vial was dropped into a flask containing 25 ml. of water and 45–50 ml. of 0.1 *N* sodium hydroxide. The flask was stoppered quickly, shaken vigorously, and allowed to stand for three minutes whereupon the contents were titrated with 0.1 *N* sulfuric acid to a phenolphthalein end-point. Of ten such determinations, an average titer corresponding to 98.82% nitrosyl perchlorate (average deviation, 2.3 parts/1000) on the basis of a neutralization equivalent weight of $NOClO_4/2$ was obtained. This substantiates the neutralization reaction to be

$$NOClO_4 + 2OH^- \longrightarrow NO_2^- + ClO_4^- + H_2O$$

No appreciable variations in the alkali titer were found in performing the titrations at higher temperatures, *i.e.*, 25 and 30°, indicating that the neutralization reaction under the described conditions is sufficiently rapid to avoid a significant amount of interference from nitrous acid disproportionation. At 25°, the average value of six titrations was 98.54% (average deviation, 2.1 parts/1000), and at 35°, for three determinations, 98.40% (average deviation, 2.8 parts/1000). This titration method thus affords a convenient means for the analysis of nitrosyl perchlorate-containing materials.

Nitrosyl perchlorate was found to deteriorate on exposure to and handling in the open air because of the extreme hygroscopicity of the substance. This was seen in a lower alkali titer from a subsequent series of experiments at 0°. The average value for seven experiments on such a treated sample corresponded to 98.14% nitrosyl perchlorate (average deviation, 1.0 part/1000).

Thermal Behavior of Nitrosyl Perchlorate.—Nitrosyl perchlorate is thermally unstable,[8] yielding volatile decomposition products as per the equations

$$2NOClO_4 \longrightarrow 2ClO_2 + {}^1/_2O_2 + N_2O_5 \text{ and}$$

$$2NOClO_4 \longrightarrow N_2O_4 + 3O_2 + Cl_2$$

It was determined in the present work that at 92°, under vacuum (3–5 mm.), weight losses of 27, 61, 94 and 100% occurred with a 0.5-g. sample after 3, 6, 9 and 12 hr., respectively. Losses at 100°, under similar conditions, were 65, 80 and 99%, after 3, 6 and 9 hr., respectively.

Unlike ammonium perchlorate and the alkali metal perchlorates,[17] nitrosyl perchlorate undergoes no crystallographic transition before the onset of rapid decomposition. This was determined by thermal analyses[18] of the compound (5-g. samples), performed over the range from 0 to 100° at heating rates of 5 and 10° per minute. Because nitrosyl perchlorate is isomorphous with ammonium perchlorate,[6] it may be supposed that the normal rhombic structure of the latter is retained by nitrosyl perchlorate at least up to 100°.

Miscellaneous Reactions.—Because the nitrosyl group contains an unshared pair of electrons about the nitrogen atom,

attempts were made to obtain coördinate bond formation between nitrosyl perchlorate and oxygen (to yield nitronium perchlorate), boron trifluoride and dinitrogen tetroxide, respectively. Nitrosyl perchlorate was thus brought in contact with a rapid stream of gaseous oxygen at room temperature, heated with nitrosyl fluoborate, and treated with liquid dinitrogen tetroxide at 0°, all without any indications of compound formation.

The Nitronium Ion Catalyzed Decomposition of Caro's Acid

BY LESTER P. KUHN

RECEIVED DECEMBER 26, 1956

Caro's acid in strong sulfuric acid is catalytically decomposed by small amounts of nitronium ion to yield sulfuric acid and oxygen. The kinetics of the reaction have been studied and a mechanism is presented which is compatible with the data. An unusual feature of the reaction is that both the rate and the order depend upon the strength of the sulfuric acid. Below 91% sulfuric acid the reaction is −1 order in peroxide and above 95% acid, the order in peroxide is +1. Throughout the entire range studied, from 85 to 98% acid the reaction is second order in nitric acid.

Aqueous solutions of Caro's acid, H_2SO_5, are relatively unstable; the kinetics and mechanism of their decomposition recently has been reported.[1] Solutions of Caro's acid in concentrated sulfuric acid, on the other hand, are quite stable and may be stored for days at room temperature without change of peroxide titer. It has been found that the addition of a very small amount of nitric acid to such solutions produces a reaction in which oxygen is evolved and the Caro's acid is converted completely to sulfuric acid. The nitric acid is recovered unchanged. A study of the kinetics of this reaction

$$H_2SO_5 \xrightarrow[H_2SO_4]{HNO_3} H_2SO_4 + {}^1/_2O_2$$

and a mechanism which is compatible with the data are presented in the succeeding paragraphs.

Experimental

The reaction was followed by measuring the rate of gas evolution. The gas was collected in inverted graduated cylinders over water which had previously been saturated with oxygen. The reactions were run in a 125-ml. erlenmeyer flask containing a sidearm which was connected through a gas bubbler containing concentrated sulfuric acid to the inverted cylinders. The mouth of the flask was closed with a rubber stopper which held a buret that was calibrated in 0.05 ml. The flask was held in a constant temperature bath that was constant to ±0.05°. The reaction mixture was stirred with a magnetic stirrer, the motor of which was below the constant temperature bath. Two sets of stock solutions were made up, one for reactions in the more concentrated acid, and the other for the less concentrated acid region. The latter was J. T. Baker C.P. concentrated sulfuric acid, and the former was made by mixing 75 parts by volume of concentrated acid with 25 parts of 20% fuming sulfuric acid. Nitric acid stock solutions approximately 0.05 *M* were made by dissolving 98% nitric acid or potassium nitrate in each of the sulfuric acid stock solutions. The stock solutions were saturated with oxygen. In a typical run a volume of the sulfuric acid stock solution, such that after the addition of the peroxide and nitric acid stock solution flask and the stirrer started. The appropriate amount, usually 0.5 to 1 ml. of 90% hydrogen peroxide was then added and the flask was stoppered and allowed to stand in the constant temperature bath for 40 minutes to allow for temperature equilibration. The reaction was started by the addition of the nitric acid stock solution, 1 to 10 ml., from the buret. Readings of gas volumes were taken at 30-second or longer intervals, depending upon the rate. Immediately after each run two 10-ml. samples were pipetted from the reaction mixture and, after dilution with distilled water in 500-ml. volumetric flasks, titrated with standard base to give the normality of the reaction mixture. Before each run the glassware which was to come in contact with the sulfuric acid was washed with distilled water, rinsed with alcohol and dried at 130° for several hours. Every effort was made to minimize the exposure of the sulfuric acid solutions to atmospheric moisture. In those experiments in which water was required to obtain the desired acid strength, the appropriate amount of water was added prior to the peroxide.

Results and Discussion

One of the most interesting features of this reaction is the profound effect that water has on both the rate and the order of the reaction. In the region below 91% sulfuric acid the reaction is −1 order in peroxide, above 95.5% acid, the order in peroxide is +1, and in a very narrow region at about 93% acid the reaction is zero order in peroxide. In the regions of about 91–92.5% and 93.5–95.5% acid one observes no integral order. Over the entire range studied, from 85 to 98% acid the reaction is second order in nitric acid. The rate constants in the region below 91% acid will be called k_{-1} and those for the region above 95.5% acid will be designated as k_1. These constants were obtained graphically from the relationships

$$k_1 = \frac{2.303\Delta \log (1 - V_t/V_f)}{\Delta t\ (HNO_3)^2}$$

$$k_{-1} = \frac{\Delta(1 - V_t/V_f)^2 C_0^2}{2\Delta t (HNO_3)^2}$$

Concentration is in moles per liter, time is in seconds, C_0 is the initial concentration of peroxide, V_t is the volume of gas given off at time t and V_f is the total volume of gas given off. Typical curves from which the k's were calculated are shown in Fig. 1. Straight lines were generally obtained for at least 60% of the reaction. Values of k's from runs using different initial concentrations of peroxide and nitric acid are shown in Table I. As will be shown shortly, the values of the k's are extremely

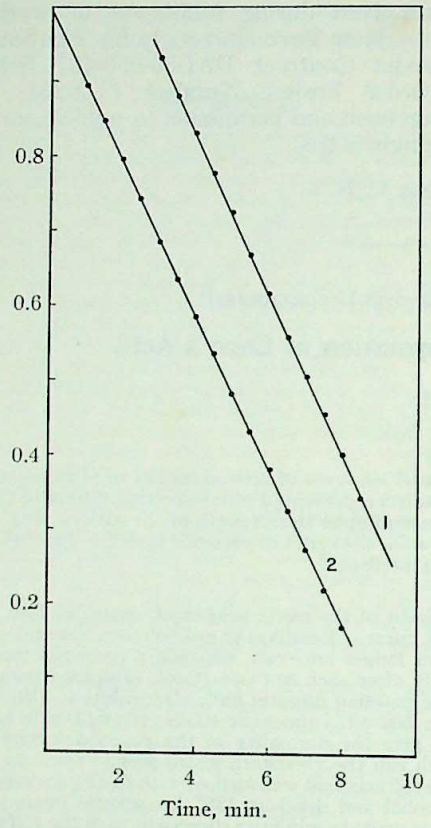

Fig. 1.—Curve 1, first-order reaction, log $(1 - V_t/V_f)$ *vs.* time, run no. 23; curve 2, -1 order reaction, $(1 - V_t/V_f)^2$ *vs.* time, run no. 11. Experimental conditions given in Table I. Curve 1 displaced along time axis.

sensitive to the amount of water present. For this reason, in order to obtain constant values for the k's, it is necessary to compare runs in which the acid strength is as constant as possible. Since duplicate runs are not always of the same acidity because of the hygroscopic nature of sulfuric acid, and since varying the initial concentration of peroxide at the same time varies the acidity, it was necessary to make a great number of runs in order to get enough comparable curves to yield the data shown in Table I.

The rate of the reaction is very sensitive to the strength of the sulfuric acid, it being at a maximum at 93 to 94% acid. In Fig. 2 are plotted k_1 and k_{-1} as a function of the acid strength. The addition of water increases k_1 and decreases k_{-1}. The effect of the addition of potassium or ammonium bisulfate is qualitatively the same as that of water.

Some miscellaneous experiments were performed which have a bearing on the reaction mechanism. Substitution of potassium nitrite for potassium nitrate as the catalyst, or substitution of potassium persulfate for hydrogen peroxide as the source of Caro's acid produces no change in the course of the reaction or its kinetics. To determine whether free radicals are intermediates in the reaction, a run was made in the presence of *m*-dinitrobenzene (nitrobenzene was nitrated under our reaction conditions, and thus could not be used). No change in the yield of oxygen or the kinetics was observed.

Table I

Rate Constants, k_1 and k_{-1}, for the Decomposition of Caro's Acid at Various Acid Strengths; T = 303.0°K.

No.	Acid, N	(N)[a]	(P)[b]	k_1
4	36.50	0.01	0.21	30.8
12	36.47	.01	.42	32.4
14	36.48	.005	.42	31.5
10	36.40	.01	.42	36.0
13	36.36	.01	.21	38.1
23	35.93	.005	.42	156.8
24	35.91	.005	.21	165.6

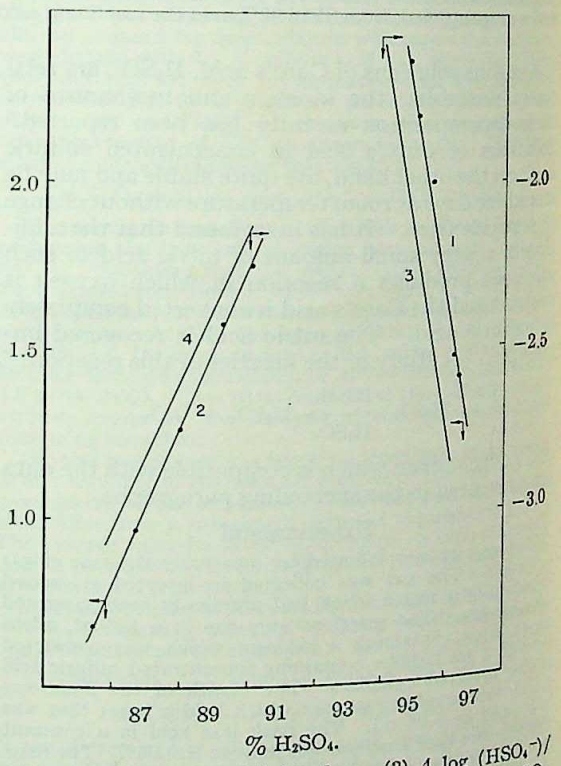

Fig. 2.—(1) log k_1; (2) log k_{-1}; (3) 4 log $(HSO_4^-)/(H_2SO_4)$; (4) $2 + 2\log (H_2SO_4)/(HSO_4^-)$; each *vs.* % H_2SO_4.

In another run the reaction mixture was irradiated with ultraviolet light from a mercury vapor lamp. Again no effect was observed, indicating that free radicals are probably not involved. To determine whether the reaction of hydrogen peroxide or potassium persulfate with the solvent to yield Caro's acid is kinetically important, several runs were made in which solutions of either of these were allowed to stand 18 hours before the addition of the nitric acid. The results were identical with those in which the nitric acid was added after 30 minutes.

The following reasonable mechanism is compatible with the experimental data. The following reversible equilibria are rapidly established

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

$$H_2O_2 + 2H_2SO_4 \overset{K_1}{\rightleftharpoons} H_3O^+ + HSO_4^- + H_2SO_5$$

$$H_2SO_5 + HSO_4^- \overset{K_2}{\rightleftharpoons} HSO_5^- + H_2SO_4$$

$$HSO_5^- + NO_2^+ \overset{K_3}{\rightleftharpoons} HSO_5NO_2$$

$$HSO_5NO_5 + HSO_4^- \overset{K_4}{\rightleftharpoons} SO_5NO_2^- + H_2SO_4$$

$$H_2SO_4 + H_2SO_5 \overset{K_5}{\rightleftharpoons} H_2O + H_2S_2O_8$$

$$HNO_3 + 2H_2SO_4 \overset{K_6}{\rightleftharpoons} NO_2^+ + H_3O^+ + 2HSO_4^-$$

$$H_2O + H_2SO_4 \overset{K_7}{\rightleftharpoons} H_3O^+ + HSO_4^-$$

The first equilibrium represents the formation of Caro's acid from the reaction between hydrogen peroxide and sulfuric acid.[2] The fact that identical kinetics are observed when either hydrogen peroxide or potassium persulfate are used gives further support to this equilibrium. The product of the third equilibrium is the mixed anhydride of nitric and Caro's acids. Although this anhydride has never been reported its existence is not unreasonable. Peracids have a strong tendency to form mixed anhydrides with ordinary acids, *e.g.*, acetyl peroxide, benzoyl peroxide and peroxydisulfuric acid, $H_2S_2O_8$. The other equilibria require no comment.

The total amount of nitric acid present in all forms will be designated by N and the total amount of peroxide will be designated by P.

$$(N) = (HNO_3) + (NO_2^+) + (NO_2HSO_5) + (NO_2SO_5^-) \quad (1)$$

$$(P) = (H_2SO_5) + (HSO_5^-) + (NO_2HSO_5) + (NO_2SO_5^-) + (H_2S_2O_8) \quad (2)$$

Since the measurements were made under conditions such that $(P)/(N)$ is in the range of 25 to 500

$$(NO_2HSO_5) + (NO_2SO_5^-) << (H_2SO_5) + (HSO_5^-) + (H_2S_2O_8)$$

and eq. 2 can be replaced by

$$(P) = (H_2SO_5) + (HSO_5^-) + (H_2S_2O_8) \quad (3)$$

From the above equilibria and eq. 1 and 3 the following relationships can be derived

$$(NO_2^+) = \frac{K_6K_7Z(N)}{K_4K_7Z + K_7(H_3O^+)X^2Z + K_2K_3K_6X^2(H_3O^+)(P)(1 + K_4X)} \quad (4)$$

$$(NO_2SO_5^-) = \frac{K_2K_3K_4K_6X^3(H_3O^+)(N)(P)}{K_4K_7Z + K_7(H_3O^+)X^2Z + K_2K_3K_6X^2(H_3O^+)(P)(1 + K_4X)} \quad (5)$$

Where $X = (HSO_4^-)/(H_2SO_4)$ and $Z = K_2X(H_2O) + (H_3O) + K_5(H_2SO_4)$.

The reaction proceeds in two steps

$$NO_2 + NO_2SO_5^- \xrightarrow{\text{slow}} NO^+ + NO_2^+ + SO_4^{--} + O_2$$

$$NO^+ + HSO_5^- \xrightarrow{\text{fast}} NO_2^+ + HSO_4^-$$

The rate of the reaction is given by the equation

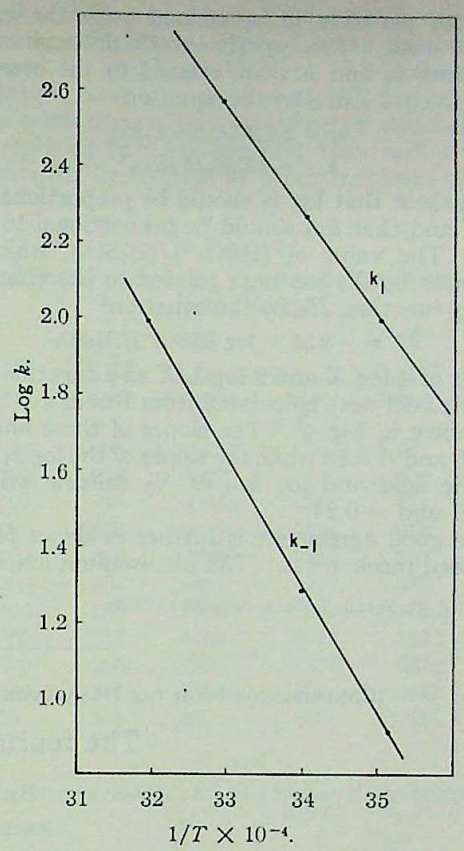

Fig. 3.—Temperature dependence of k_1 and k_{-1}. The acid concentrations were 95.8% acid for k_1 and 88.9% for k_{-1}.

$$r = k(NO_2^+)(NO_2SO_5^-) = \frac{kK_2K_3K_4K_6^2X^3Z(H_3O^+)PN^2}{[K_6K_7Z + K_7ZX^2(H_3O^+) + K_2K_3K_6(P)X^2(H_3O^+)(1+K_4X)]^2} \quad (6)$$

Since peroxy acids are weaker than the corresponding non-peroxidic acids, K_2 and K_4 must be smaller than one. We shall assume then that $K_4X << 1$ and that $K_5(H_2SO_4) >> (H_2O) + K_2X(H_2O)$. The first assumption means that $(NO_2SO_5^-) << (NO_2SO_5H)$ and the second assumption means that the peroxide is predominantly in the form of $H_2S_2O_8$ in the acid range we have used. Therefore $Z = K_5(H_2SO_4)$.

Since addition of water increases X and decreases Z at acid strength greater than 95% the first term in the denominator of eq. 6 is much larger than the second and third terms and the equation reduces to

$$r = kK_2K_3K_4X^3(H_3O^+)PN^2/K_5K_7^2(H_2SO_4)$$

Since (H_3O^+) is approximately equal to (HSO_4^-) this may be written as

$$r = kK_2K_3K_4PN^2X^4/K_5K_7^2 \quad (7)$$

At acid strength below 91% acid the last term in the denominator of eq. 6 becomes large compared to the first two terms and the equation reduces to

$$r = kK_4N^2Z/K_2K_3(P)X(H_3O^+) = kK_4K_5N^2/K_2K_3PX^2 \quad (8)$$

According to eq. 7 the reaction in strong acid is second order in nitric acid and first order in peroxide whereas in more dilute acid eq. 8 requires that the reaction be second order in nitric acid and −1

(2) N. V. Sidgwick, "The Chemical Elements and their Compounds," Oxford Press, New York, N. Y., 1950, p. 939.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

order in peroxide in agreement with the experimental data. The experimentally determined rate constants k_1 and k_{-1} are related to the constants given in eq. 7 and 8 by the equations

$$k_1 = kK_2K_3K_4X^4/K_6K_7^2 \quad (9)$$

$$k_{-1} = kK_4K_5/K_2K_3X^2 \quad (10)$$

which show that log k_1 should be proportional to 4 log X and that k_{-1} should be proportional to 2 log $1/X$. The value of $(HSO_4^-)/(H_2SO_4)$, which we designate by X, has been related to the Hammett acidity function, H_0, by the equation[3]

$$H_0 = -8.36 + \log (HSO_4^-)/(H_2SO_4)$$

Values of 4 log X and 2 log $1/X$ as a function of % sulfuric acid were calculated from Brand's data and are shown in Fig. 2. The slopes of these lines are -0.58 and $+0.23$ while the slopes of the log k_1 *vs.* % sulfuric acid and log k_{-1} *vs.* % sulfuric acid are -0.59 and $+0.24$.

The good agreement is further evidence for the proposed mechanism. The nitrosonium ion, NO^+, which is formed in the rate-determining step, is rapidly oxidized to NO_2^+ by a persulfate ion. Since potassium nitrite yields the nitrosonium ion in sulfuric acid, it is just as effective a catalyst as potassium nitrate or nitric acid.

The temperature dependence of k_1 and k_{-1} is shown in Fig. 3, the former being determined in 95.8% sulfuric acid and the latter in 88.9% acid. From the slopes of these lines the activation energy of k_1 is 13.3 kcal. per mole, and of k_{-1}, 15.3. Since K_3 and X have negative temperature coefficients and since these appear in the numerator in the equation for k_1 and in the denominator for k_{-1}, the temperature dependence and hence the activation energy of k_1 would be expected to be lower than that of k_{-1}.

The rate-determining step shown above is probably a sequence of steps which may be formulated as

$$NO_2^+ + SO_5NO_2^- \longrightarrow O_2N\text{–}O\text{–}O\text{–}SO_2\text{–}ONO_2$$

$$O_2N\text{–}O\text{–}O\text{–}SO_2\text{–}ONO_2 \longrightarrow NO_3^+ + SO_4^{--} + NO_2^+$$

$$NO_3^+ \longrightarrow NO^+ + O_2$$

ABERDEEN PROVING GROUND, MD.

The Ionization of Sulfuric Acid[1]

BY MILTON KERKER

RECEIVED OCTOBER 8, 1956

The method of Sherrill and Noyes, based on conductance and transference number, has been used to calculate the ionization of sulfuric acid at 18 and 50° from data in the literature and to extend the results at 25° to higher concentrations. The results have been compared with those obtained by other methods. The effect of the nature of the counterion on the equivalent conductance of sulfate and hydrogen ion has been examined. The equivalent conductance of bisulfate ion has been calculated at 18, 25 and 50°.

The ionization of sulfuric acid has been studied by electromotive force,[2] colorimetry,[3,4] kinetics,[5] Raman spectra[6–8] and a combination of conductance and transference number.[9] Sherrill and Noyes employed transference number as well as conductance data because of the unavailability of the equivalent conductance of the bisulfate ion. Assuming the first hydrogen is completely ionized, they developed the equations

$$\alpha = (\Lambda + \Lambda T - \Lambda_H)/(\Lambda_H + \Lambda_{SO_4}) \quad (1)$$

$$\Lambda_{HSO_4} = (\Lambda - \Lambda T - \alpha\Lambda_{SO_4})/(1 - \alpha) \quad (2)$$

where

α	fraction of HSO_4^- dissociated
Λ	equivalent conductance of H_2SO_4
Λ_H	equivalent conductance of H^+ in the H_2SO_4
Λ_{SO_4}	equivalent conductance of SO_4^- in the H_2SO_4
Λ_{HSO_4}	equivalent conductance of HSO_4^- in the H_2SO_4
T	stoichiometric transference number

In solving the above equation, Sherrill and Noyes used values of Λ_H and Λ_{SO_4} obtained from the conductance and transference number of hydrochloric acid and potassium sulfate at the ionic strength prevailing in the sulfuric acid solution under consideration. However, they did recognize that this "ionic strength principle" could not be justified theoretically. Since the ionic strength in the sulfuric acid is given by $m(1 + 2\alpha)$, eq. 1 had to be solved by a series of successive approximations.

The results of Sherrill and Noyes are confined to 25° because of the limited data for T available at that time.[10] In this paper we extend their calculations to 18 and 50° using data which have since appeared in the literature. We have also carried the 25° calculations to higher concentrations.

The stoichiometric transference number, T, which appears in the above equations is related to the individual ionic transference number,[11] t, by

$$T = t_H - t_{HSO_4} \quad (3)$$

where

$$t_H = c_H\Lambda_H/c\Lambda \quad (4)$$

$$t_{HSO_4} = c_{HSO_4}\Lambda_{HSO_4}/c\Lambda \quad (5)$$

and c_H, c_{HSO_4} and c are the normalities of H^+, HSO_4^- and H_2SO_4, respectively. In the Hittorf

method T is equal to the number of equivalents of sulfuric acid transferred from anode to cathode region per faraday of electricity passed when electrodes reversible to sulfate ion (*e.g.*, Ag, Ag_2SO_4; Hg, Hg_2SO_4) are used. With the galvanic cell method T is obtained from

$$T = dE_T/dE \qquad (6)$$

E is the electromotive force of the sulfuric acid concentration cell without transference in which the anode is reversible to hydrogen ion and the cathode to sulfate ion. E_T is the electromotive force of the sulfuric acid concentration cell with transference in which both electrodes are reversible to sulfate ion.

Hamer[12] has determined T for sulfuric acid over a wide range of concentration and temperature by the galvanic cell method. He found that T remained constant in the range from 0.05 to 0.2 m and then dropped rapidly with increasing concentration, falling to about 0.5 in concentrated sulfuric acid. Using the Onsager equation, he calculated the variation of t_H with concentration in the infinitely dilute range where the sulfuric acid is completely ionized. Since in this range T would be expected to increase with concentration he suggested that the constancy of T in his dilute solutions was actually a manifestation of a flat maximum and that at concentrations lower than 0.05 m, T would decrease. Hamer's work is discussed by Harned and Owen.[13] Kanning and Waltz[14] extended the work of Hamer to solutions of sulfuric acid in anhydrous methanol at 25°. Ferguson and France[15] had made an earlier study of the same cell as Hamer at 25° for one pair of concentrations.

We have used Hamer's extensive values of T to calculate the dissociation of sulfuric acid at 18 and 50° by the method of Sherrill and Noyes and to extend their results at 25° to higher concentrations. The equivalent conductance of HSO_4^- also has been calculated.

Values of Λ_H were obtained from the equivalent conductance[16,17] and transference number[18,19] of HCl. For Λ_{SO_4} we used the equivalent conductance[20,21] and transference number[22,23] of K_2SO_4. For the equivalent conductance of H_2SO_4 we used the data of Noyes,[20] Kohlrausch,[21] Campbell,[24] and Roughton.[25]

Our results are presented in Tables I, II and III. The equilibrium quotient K_2' for the second ionization of sulfuric acid extrapolates to the ionization constant K_2, at infinite dilution. The values of the ionization constant at 18 and 50°, as calculated from conductance and transference number data, are reported here for the first time and are compared with the results of other methods in Table IV.

TABLE I

IONIZATION OF H_2SO_4 AND EQUIVALENT CONDUCTANCE OF HSO_4^- AT 18°

TABLE IV

DISSOCIATION CONSTANT OF HSO_4^- × 10^2

Temp., °C.	From conductance and transference no.	From electromotive force Hamer Hamer[25]	Hamer recalcd. by Davies[25]	Davies[25]	From spectrophotometry, Klotz[3] and Singleterry[4]
18	1.24	1.30	1.14	1.26	1.26
25	1.02	1.20	1.02	1.03	1.02
50	0.53	0.79	0.69	0.50	0.48

Hamer's electromotive force results, citing instead those of Klotz[3] and Singleterry[4] obtained by a colorimetric method. The temperature dependence of their ionization constants leads to heats of ionization which are in accord with the accepted values, while those of Hamer are in gross disagreement. Klotz and Singleterry report that the error in their results is probably less than 2%. Davies, Jones and Monk[2] have recalculated Hamer's data, introducing correct values of activity coefficients and bringing them into slightly better agreement with the colorimetric work. They have, furthermore, carried out electromotive force measurements in a cell which minimizes the ion association, obtaining results in good agreement with Klotz and Singleterry. The ionization constants calculated from the data of Sherrill and Noyes at 25° and by us at 18 and 50° are also in agreement with the colorimetric work.

Although Sherrill and Noyes recognized that ionic conductivities are not determined by ionic strength, they formally used an ionic strength principle in estimating the equivalent conductance of the sulfate and hydrogen ions in sulfuric acid, and we have followed their heuristic procedure.

We have used the data for potassium sulfate in estimating the equivalent conductance of sulfate ion because they are available over a wide range of conditions. In Tables V and VI there is compiled the equivalent conductance of sulfate ion at several ionic strengths at 18 and 25° as obtained from a number of other salts. For the bi-bivalent salts, where ion association is appreciable, the equivalent conductance of the sulfate ion is calculated from the product of the anion transference number and the equivalent conductance of the salt, divided by the degree of dissociation. The correction for ion association is not so easily made for the uni-bivalent salts but even a rough approximation indicates it is small enough to be neglected. The equivalent conductance of sulfate at 0.1 ionic strength obtained from sodium and potassium sulfate differs from that obtained from thallium sulfate in the direction that would be expected from the greater ion association in the latter.

TABLE V

EQUIVALENT CONDUCTANCE OF SULFATE AT 18° FROM CONDUCTANCE AND TRANSFERENCE NUMBER OF VARIOUS SALTS[27-30]

Ionic strength	Na_2SO_4	K_2SO_4	$CdSO_4$	$CuSO_4$	$MgSO_4$
0.002	63.0	63.4	64.7	66.0	63.5
.010	59.0	59.6	60.0	60.5	58.2
.050	53.8	54.2	54.1	..	..
.100	50.4	51.3	51.8	..	..

TABLE VI

EQUIVALENT CONDUCTANCE OF SULFATE AT 25° FROM CONDUCTANCE AND TRANSFERENCE NUMBER OF VARIOUS SALTS[20-23,27-30]

Ionic strength	Na_2SO_4	K_2SO_4	Tl_2SO_4	$ZnSO_4$	$CdSO_4$
0.002	76.1	76.0	76.0	76.1	76.0
.010	71.2	71.3	70.0	71.1	70.4
.050	63.4	63.4	59.7	..	63.8
.100	58.9	59.0	53.4	..	61.2

Although the equivalent conductance of the sulfate ion does depend to some extent upon the nature of the cation, the agreement among the results is quite good, especially in view of the uncertainties involved in the ion association of the solutions. Even at 0.1 ionic strength, the fraction ionized would differ by only 1.5% if the equivalent conductance of 53.4 derived from the thallium sulfate data had been used instead of 59.0 derived from the potassium sulfate data.

The fraction ionized α is not very sensitive to the equivalent conductance of sulfate ion since in eq. 1 it is added to the much larger equivalent conductance of the hydrogen ion. This simply transfers the onus of the method to the determination of the equivalent conductance of the hydrogen ion. In Table VII we have compared the values of Λ_H obtained from several monobasic acids at comparable ionic strengths. It is apparent that the anion effect is small. We should like to call attention to the agreement between the hydrochloric and iodic acid results where the available conductance and transference number data are quite accurate. What is especially striking about the agreement is that iodic acid is only partially dissociated so that the equilibrium data have also entered into the calculation much as in the case for the bi-bivalent salts treated above.

TABLE VII

EQUIVALENT CONDUCTANCE OF HYDROGEN ION AT 25° FROM CONDUCTANCE AND TRANSFERENCE NUMBER OF VARIOUS ACIDS

Ionic strength	HCl[16-19]	HNO_3[21,27]	HI[27]	HIO_3[27,31]
0.01	339.9	340	..	339.3
.05	330.9	330	331	330.0
.10	325.5	325	326	...
.20	320.4	..	316	...

The quotient of activity coefficients γ_R is defined by

$$\gamma_R = (\gamma_H)(\gamma_{SO_4^-})/\gamma_{HSO_4^-} \quad (7)$$

and

$$K_2 = K_2'\gamma_R \quad (8)$$

where K_2 and K_2' are the ionization constant and equilibrium quotient, respectively, and γ_{H^+}, $\gamma_{SO_4^-}$ and $\gamma_{HSO_4^-}$ are ionic activity coefficients. Young and Blatz[32] have compared the values of γ_R at 25° obtained in dilute solutions by the conductance and transference number method of Sherrill and Noyes

and the kinetic method of Bray and Liebhafsky with those obtained in more concentrated solutions by Rao[6] using Raman spectra. Later, Smith[7] and Maranville[8] obtained more accurate Raman spectral data. Since we have extended the values of γ_R at 25° to the concentration range used in the kinetic and Raman spectral studies, it is of interest to compare results again, especially in the overlapping region. Figure 1 is a curve of γ_R at 25° *versus* the square root of the ionic strength. The agreement among the three methods is excellent up to an ionic strength somewhat greater than 1. This agreement is remarkable, especially at the higher ionic strengths. Our only justification for extending the 25° calculations to these high concentrations has been this unexpected agreement among the three methods.

A comment on the work of Bray and Liebhafsky is in order. There was considerable scatter in their results. In plotting a function of γ_R against the square root of the ionic strength, they drew a smooth curve which they presumed was an extrapolation of Sherrill and Noyes conductance and transference number results but which obviously was not the best representation of their own data. Previous workers[7,8,32] have used these smoothed data but we find, despite the scatter, that the actual data of Bray and Liebhafsky give better agreement with both our calculations and the Raman spectral results. In Fig. 1, points representing both their actual and smoothed results are shown.

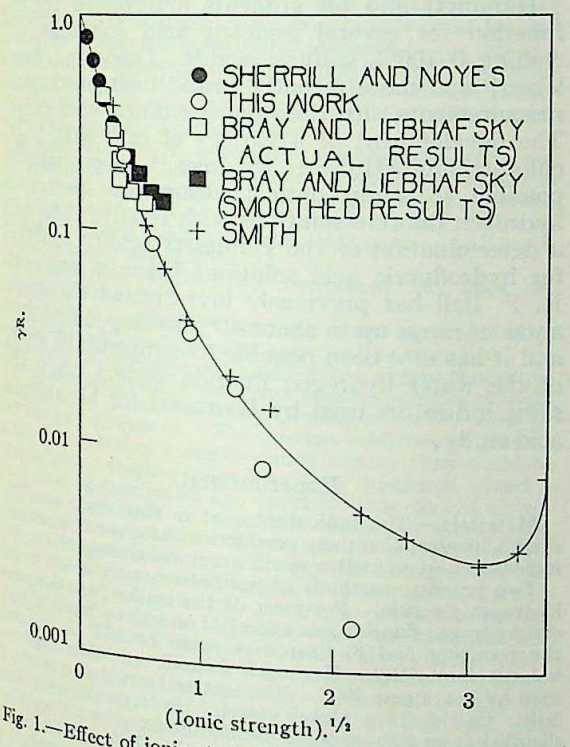

Fig. 1.—Effect of ionic strength on the quotient of activity coefficients, γ_R, of HSO_4^- at 25°.

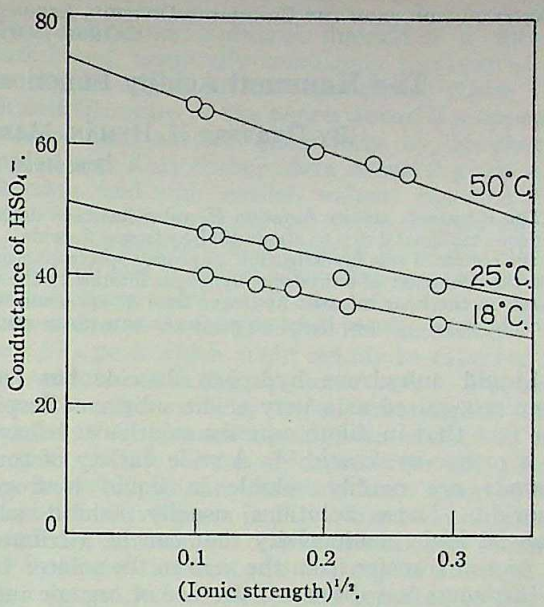

Fig. 2.—Equivalent conductance of HSO_4^-. Circles are computed from conductance and transference number data. Lines are drawn with slope from limiting Onsager law.

The conductance data at 50° do not extend to sufficiently high concentrations to compare γ_R with those from Raman spectra at that temperature.

In Tables I, II and III is also found the equivalent conductance of the bisulfate ion as calculated by eq. 2. In Fig. 2, the equivalent conductance of bisulfate ion is extrapolated to infinite dilution using the limiting Onsager slope for a uni-univalent electrolyte. Since the slope itself is dependent on the intercept, it had to be determined by a series of successive approximations.

The Hammett Acidity Function H_0 for Hydrofluoric Acid Solutions[1]

BY HERBERT H. HYMAN, MARTIN KILPATRICK AND JOSEPH J. KATZ

RECEIVED FEBRUARY 28, 1957

The Hammett acidity function H_0 value has been determined for hydrogen fluoride in the concentration range from anhydrous material down to about 40% hydrogen fluoride. The dryest hydrogen fluoride prepared had an H_0 value of −10.2. In the course of this investigation, improved spectrophotometric cells were developed for handling hydrofluoric acid solutions and the spectrum of anhydrous hydrogen fluoride in the near infrared was determined. The effect of sodium fluoride and water on the near infrared hydrogen fluoride spectrum was investigated and an analytical method for water in hydrogen fluoride was developed based on measurements of the water absorption at 1.95 μ.

Liquid anhydrous hydrogen fluoride has long been recognized as a very acidic substance despite the fact that in dilute aqueous solution it behaves as a rather weak acid.[2,3] A wide variety of compounds are readily soluble in liquid hydrogen fluoride. These solutions usually exhibit substantial ionic conductivity that can be attributed to proton transfer from the acid to the solute.

Hammett has discussed the use of organic indicators for the determination of relative acidity and suggested an acidity scale based on the relative concentration of protonated and non-protonated species in the medium under investigation.[4]

Paul and Long[5] recently have reviewed the determination and use of the H_0 function. In particular, the acidity of any solution on the H_0 scale is determined by the fraction of the neutral indicator which is converted from an uncharged molecule to a protonated species. Hammett also discussed the H_- and H_+ scales in which the original indicator was an anion or cation rather than a neutral molecule.

For practical use of the H_0 acidity functions, it is defined by the equation

$$H_0 = pK_a^I + \log (C_I/C_{IH^+})$$

$$pK_a^I = -\log \frac{C_{H^+} C_I}{C_{IH^+}} - \log \frac{f_{H^+} f_I}{f_{IH^+}}$$

for the indicator, I, is determined by a series of intercomparisons with indicators of decreasing pK_a^I. The activity coefficient term for a constant charge type is supposed to be independent of the medium or indicator, and H_0 approaches pH in dilute aqueous solution.

Paul and Long have reviewed previous intercomparisons and extrapolations and suggest a best value for each indicator which has been studied. As they point out, these values are not entirely self-consistent within the expected limit of error. Different indicators will give different values for the same solution. Other workers[6] have questioned the general applicability of the H_0 concept, or sought more satisfying acidity functions.[7] In spite of this, the H_0 function is very useful in correlating and predicting for different media properties such as solubility or catalytic effects which depend on acidity. In the highly acid, high dielectric solvents, such as those considered here, it is probably fair to assume that a medium which shows a more negative H_0 value for a specific indicator is the more acidic medium.

Hammett and his students determined the H_0 function for several aqueous acid solutions, including 0–100% sulfuric acid.[8,9] Lewis and Bigeleisen[10] and more recently Brand[11] extended these measurements into the fuming sulfuric acid range. The development of a variety of cells with polychlorotrifluoroethylene windows,[12] now make it possible to study optical absorption spectra in hydrogen fluoride solutions with relative ease, and a determination of the Hammett acidity function for hydrofluoric acid solutions becomes practical. R. P. Bell has previously investigated the dilute aqueous range up to about 40% hydrogen fluoride[13] and it has now been possible to complete the study of the water–hydrogen fluoride system using the same indicators used by Hammett for his sulfuric acid study.

Experimental

Materials.—The indicators used in this work were Aldrich Chemical Company products sold for use as Hammett indicators and no further purification was attempted.

Two separate methods of purification were used for the hydrogen fluoride. For most of the earlier runs commercial hydrogen fluoride was absorbed on sodium fluoride, and the resulting $NaHF_2$ heated *in vacuo* at 150° to remove volatile impurities. Hydrogen fluoride was then regenerated by heating at 300°. The material was stored over cobaltic fluoride in a nickel vessel. Hydrogen fluoride was distilled from this vessel as needed directly into a conductivity cell or an optical absorption cell. Hydrogen fluoride purified in this way showed conductivities in the range 4 to 6×10^{-4} ohm^{-1} cm.$^{-1}$ at 0° indicating a water content of 0.01% or less. More recently a better quality acid has been obtained. As suggested by Runner, Balog and Kilpatrick, the hydrogen fluoride was purified by fractional distillation in an efficient column.[14] The product was collected and handled entirely in polychlorotrifluoroethylene and gold lined fittings thus avoiding contact with base metal (nickel). Under these conditions, batches of acid have been obtained with conductivities below 10^{-5} ohm^{-1} cm.$^{-1}$. Measurably higher acidities (more negative H_0 values) were found for

hydrogen fluoride purified by distillation than for the earlier material.

Sodium fluoride was reagent grade material and was dried before use.

Optical Equipment.—The optical cells employed polychlorotrifluoroethylene bodies and windows. The cells were made vacuum and pressure tight with external metal fittings but no metal was in contact with the solution. At the beginning of the work the cells were fitted with small metal valves of the bellows type; however, a polythene tubing and pinch clamp arrangement was found more convenient and made it possible completely to eliminate base metal from contact with the solution.

The absorption cells are connected to a vacuum line through the polythene tubing. After evacuating and filling the cell, the tubing is pinched shut, and the cell removed from the line.

For highly absorbing solutions, variable spacer cells of the type described by Quarterman, Hyman and Katz[15] were employed. These could be closed down to useful thicknesses of 50 μ with sapphire windows and 10 μ with selected polychlorotrifluoroethylene windows. These cells have nickel bodies, some of which have been gold plated, and because of the difference of expansion between the window and body cannot be subjected to severe temperature changes without leaking. This problem introduces minor changes in filling procedure. For example, hydrogen fluoride must be condensed in a separate vessel and transferred to the cell as a liquid, rather than condensed directly in the cell. However, if severe temperature changes are avoided these cells may be evacuated, filled and emptied, and the optical path changed repeatedly without incident.

A Beckman DK-1 automatic spectrophotometer was equipped with a secondary container to prevent damage in case of leaky cells. With the exception of this precaution, the instrument was used in a conventional way. The instrument was in a constant temperature room and all measurements were made at 25 ± 2°.

The electrical conductivity equipment has been described elsewhere.[15]

Solution Preparation.—Solutions were prepared in a variety of ways, usually using vacuum line technique. In most cases the indicator was made up to a known concentration in benzene and a measured volume pipetted directly into the cell. The solution was frozen, cooled to below 0° and the cell evacuated. The benzene sublimed off leaving a known amount of indicator much smaller than could be conveniently weighed directly. The hydrogen fluoride could then be distilled in, and water or other diluent added. Additions were made to a partially filled cell without significant loss or exposure of the contents to the atmosphere. This was accomplished by pinching the tubing shut, and making the addition to the length of tubing above the closure. After capping the cell, the pinch clamp was opened and the solution mixed. In other cases, the indicator was dissolved in dilute hydrofluoric acid whose concentration was determined by titration with standard base. The indicator concentration in this stock solution was usually determined optically. A known weight of this acid was added to the cell and anhydrous hydrogen fluoride distilled in to yield the desired concentration.

Hydrofluoric acid concentrations were determined by titration below 50% and by direct weighing in the cell in the 50 to 98% region. Above 98% the most convenient determination of water content was found to be that based on optical absorbancy at 1.95 μ described below.

The solutions of indicator as prepared were all stable for at least 24 hours. In preliminary experiments where optical cells with nickel bodies were employed, the nitro aromatic indicators were decolorized slowly on standing, presumably by reduction of the nitro group. Indicators in the acid form usually could be destroyed by heating the solution, yielding in most cases deeply colored compounds, that did not behave as indicators at least in similar acidity ranges. The composition or nature of these colored materials was not investigated further. Solutions of the basic form of the aniline type indicators used appear to be stable indefinitely when stored in all plastic containers.

The Spectrum of Anhydrous Hydrogen Fluoride.

—Anhydrous hydrogen fluoride is a water-white liquid, essentially completely transparent in the visible region of the spectrum. While the infrared spectrum in the region above 2 μ appears to have been studied adequately by Maybury, Gordon and Katz,[16] their data below 2 μ are not adequate and the earlier values reported by Safari[17] for this region appear to be entirely incorrect. A portion of Safari's curve is drawn with a dotted line and it is not clear that any significant measurements were made by him below 2 μ. There seems to be no doubt about the existence of the 1.45 μ peak which might readily be expected as the overtone of the 2.9 μ polymer peak. The 0.98 μ overtone is shown by Safari, but slightly displaced and with much too high an extinction coefficient. While we cannot account for the difference between our spectrum and that reported by Safari, the curve given in Fig. 1 has been obtained repeatedly on a number of different samples of purified hydrogen fluoride. In the region above 2 μ, Fig. 1 agrees perfectly with data reported by Maybury, Gordon and Katz for different samples, with different cells using silver fluoride rather than polychlorotrifluoroethylene windows, using a Perkin–Elmer spectrophotometer rather than a Beckman DK.

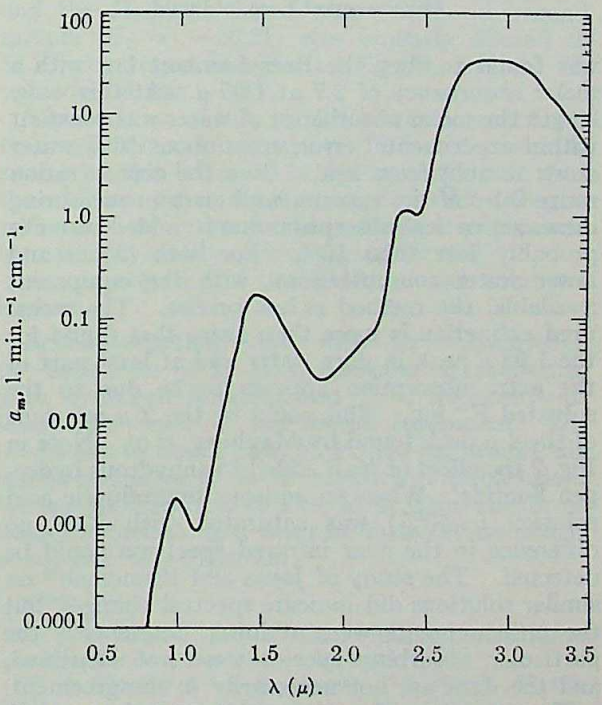

Fig. 1.—Near infrared absorption spectrum of anhydrous liquid hydrogen fluoride.

The Effect of Water and Sodium Fluoride on the Hydrogen Fluoride Spectrum.

—These observations are summarized in Fig. 2. Since water has a significant absorption peak near 1.9 μ where hydrogen fluoride is relatively transparent, it appeared reasonable to develop an analytical method for water content based on this difference in behavior. This proved to be possible, since water as a solute

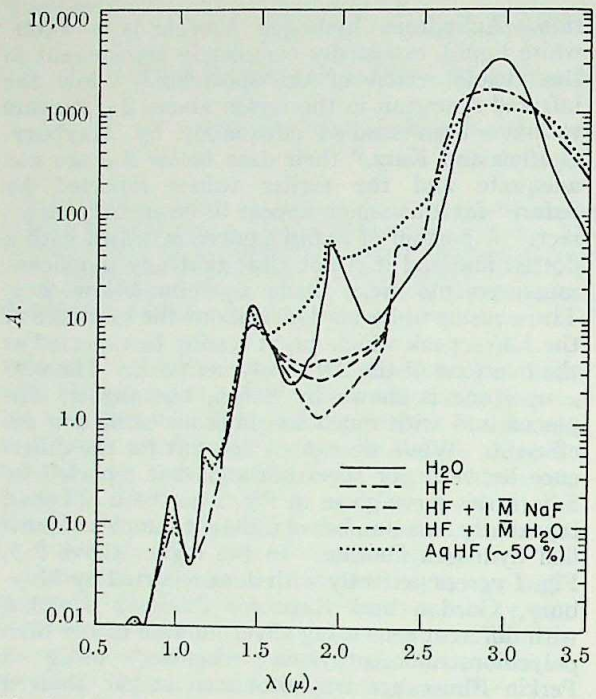

Fig. 2.—Near infrared spectrum of some fluoride solutions. Absorbancy of 1 cm. of liquid.

was found to obey the Beer–Lambert law with a molar absorbancy of 2.7 at 1.95 μ. At this wave length the molar absorbancy of water was constant within experimental error, from about 50% water down to anhydrous acid. Over the concentration range 0.1–2M the experimental error in measuring increased optical absorption due to added water is probably less than 10%. For both higher and lower water concentrations, with the equipment available, the method is less precise. The measured extinction is more than twice that found for the 1.92 μ peak in pure water and at least part of the extra absorption appears to be due to the solvated F^- ion. This could be the 2 μ overtone of the 4 μ peak found by Maybury, *et al.* Note in Fig. 2 the effect of NaF added to anhydrous hydrogen fluoride. When an aqueous hydrofluoric acid solution (~50%) was saturated with NaF, no difference in the near infrared spectrum could be detected. The study of Jones and Penneman[18] on similar solutions did indicate spectral changes, but the measurements were at lower frequencies, the particular absorbing species were not identified, and the data are not necessarily in disagreement.

The Acidity Function.—All solutions were scanned in the visible region and the percentage of acid or basic form calculated in the usual way from the optical density near the peak of the colored species.

The measured H_0 values are summarized in Tables IA and B. In Fig. 3 these values are combined with those of Bell to give the H_0 values for 0–100% hydrofluoric acid and compared with the sulfuric acid values. All of the hydrogen fluoride points plotted were selected from indicator measurements in the 10% acid to 10% basic range (± 1 H_0 unit).

[a] Concentration determined by optical absorption at 1.95 μ. [b] The indicator used in this set of measurements was 2,4,6-trinitroaniline, $pK = -9.41$.

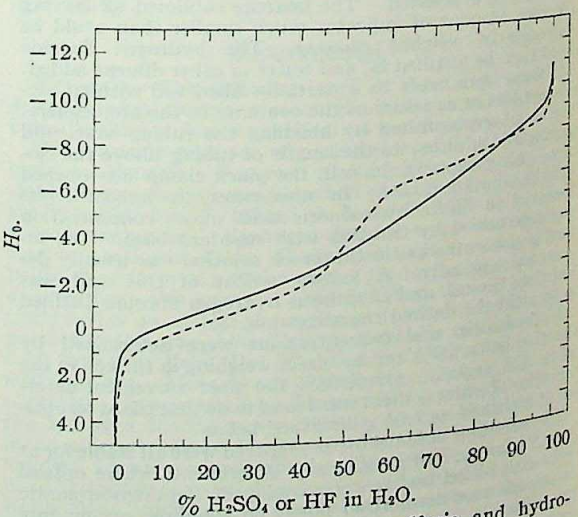

Fig. 3.—The H_0 function for aqueous sulfuric and hydrofluoric acids: ———, H_2SO_4; - - - - - - - -, HF.

On the whole hydrogen fluoride is a weaker acid than sulfuric. The dryest hydrogen fluoride obtainable by us had an H_0 value of −10.2 while 100% sulfuric acid has an H_0 value of −11.0. Due to the lower molecular weight of hydrogen fluoride, however, a 60–80% hydrogen fluoride solution in water is more acid than a similar weight

% H_2SO_4 solution, although on an equivalent concentration basis, sulfuric acid is always stronger.

Neither gram nor moles of hydrogen fluoride per unit volume are satisfactory units for plotting hydrogen fluoride concentration in aqueous solutions. The density increases rapidly as water is added to hydrogen fluoride to a maximum near 75% hydrogen fluoride.[19] This is reflected in a maximum in the molar hydrogen fluoride concentration well below 100%.

A plot of acidity *vs.* weight or mole % hydrogen fluoride rises steadily and shows no such maximum. However it is not a smooth continuous curve from pure water to pure HF. In fact there appear to be several separate regions in this plot. In dilute aqueous solutions, the actual acidic species present is H_3O^+, according to the equation

$$HF + H_2O \rightleftarrows H_3O^+ + F^-$$

Even for infinitely strong acids, the acidity of a solution in which the concentration of H_2O molecules exceeds that of the acid molecule cannot exceed a value fixed by the inherent acidity of H_3O^+. In this region, hydrofluoric acid solutions are significantly less acid than equal concentrations of any of the group of strong acids studied by Hammett but the acidity rises more rapidly with concentration. Of these strong acids, only sulfuric acid has been studied by anyone in the range where there are fewer water molecules than acid molecules. In hydrogen fluoride, as the 1-1 point is approached the acidity rises sharply, then increases steadily until a region close to 100% acid, where it again rises sharply.

Bell[13] has discussed the rise in acid strength below 50 mole % in terms of increasing concentration of HF_2^-, $H_2F_3^-$, and even longer chains as the HF concentration is increased. Several authors have commented on the occurrence of such polymeric ions.[18,20] Presumably as the 1-1 point is passed, the much more acidic species HF_2^+ appears, and acidity then increases regularly with concentration. At the high hydrogen fluoride end of the scale a further sharp rise in acidity is encountered which may also be correlated with the occurrence of polymer chains stabilized by ionization. In this case, however, the increase in chain length serves to decrease the acidity.

As water is added to hydrogen fluoride, the acidity of the solution is reduced by substituting H_3O^+ for H_2F^+. The equilibria involved may be represented as

$$H_2O + nHF \rightleftarrows H_3O^+ + F^-(HF)_{(n-1)}$$

$$HF + nHF \rightleftarrows H_2F^+ + F^-(HF)_{(n-1)}$$

The relative effect of H_2O is enhanced beyond its molar concentration as n is increased. The observed anomalous density behavior of hydrofluoric acid solutions mentioned above may well be correlated with this hypothesis. We hope to discuss the subject more fully elsewhere.

The effect of water on acidity is probably not specific since sodium fluoride is a slightly stronger base as is shown in Table II.

TABLE II

H_0 VALUE FOR HF–NaF SOLUTION

Solution	H_0
100% HF	−10.13
0.447% NaF = 0.103 $\bar{M}$	−9.62
4.32% NaF = 1.0 $\bar{M}$	−8.4

Qualitatively other reagents such as ethyl alcohol similarly yield the basic form of trinitroaniline when added in small amounts to a solution of this indicator in anhydrous hydrogen fluoride.

The addition of liquid SO_2 has little effect. Anhydrous hydrogen fluoride ($H_0 = -10.25$) was diluted to 82.3% hydrogen fluoride, 17.7% SO_2 and the H_0 value found was −9.98. A second sample ($H_0 = -10.21$) was similarly diluted to 81.7% hydrogen fluoride, 18.3% SO_2 and the H_0 value found was −9.93.

The addition of SO_3 to 100% sulfuric acid leads to a regular increase in acidity. There is no simple analog of this behavior in hydrogen fluoride, but the addition of fluoride ion acceptors such as boron trifluoride or antimony pentafluoride might well increase the acidity of hydrogen fluoride.[21–23]

An investigation of the acidity of such solutions is planned.

Acknowledgment.—We wish to acknowledge the assistance of L. A. Quaterman in preparing pure hydrogen fluoride, and J. R. Pickhardt in fabricating much of the special equipment. We would like to thank Prof. R. P. Bell for making his results available to us in advance of publication. We are also indebted to Drs. M. A. Paul and F. A. Long for furnishing a draft of their review article in advance of publication.

Isotopic Exchange Reactions of Neptunium Ions in Solution. V. The Np(V)–Np(VI) Exchange in D_2O[1]

BY J. C. SULLIVAN, DONALD COHEN AND J. C. HINDMAN

RECEIVED DECEMBER 3, 1956

From studies in mixed electrolyte systems the conclusion is drawn that the perchlorate ion does not participate in the Np(V)–Np(VI) exchange reaction. The data do indicate that there are two possible reaction paths, one acid dependent and the other acid independent. The substitution of deuterium for hydrogen decreases the rate of the acid independent path, indicating that hydrogen atoms are involved in the mechanism for the exchange process. The hydrogen ion dependent path probably involves specific hydronium ion catalysis.

Previous communications[2-4] have reported the results of investigations of various factors affecting the rate of the Np(V)–Np(VI) isotopic exchange reaction. It has been demonstrated that the rate of the reaction is negligibly affected by the variation of the macroscopic dielectric constant in perchlorate media containing ethylene glycol or sucrose.[4] Although these results demonstrate the inapplicability of the model for exchange by electron tunneling, for the present system, in the form presented by Marcus, Zwolinski and Eyring,[5,6] they do not conclusively show that the exchange proceeds by a mechanism other than direct electron transfer.

It has been suggested for the present reaction and for similar reactions[7,8] that the exchange in perchlorate solution proceeds by a mechanism involving hydrogen atom transfer. In principle this can be demonstrated by examination of the isotope effect, *e.g.*, by carrying out the reaction in a D_2O solution. Hudis and Dodson[9] have used this technique to gain support for the view that a hydrogen atom transfer mechanism is probable for the Fe(II)–Fe(III) system. Similar measurements are reported here for the Np(V)–Np(VI) system.

In addition, evidence was sought that would indicate whether or not there was a possibility that perchlorate ion might be involved as a bridging group in the activated complex. In principle, if perchlorate enters the complex one would expect to find a dependence of the rate of the reaction with perchlorate ion concentration at constant ionic strength. Anion effects of this nature were reported by Olson and Simonson[10] for a number of reactions in dilute solution. On the other hand, in perchlorate solutions at higher ionic strengths, Silverman and Dodson[11] found that the rate of the Fe(II)–Fe(III) exchange was unaffected by the anion concentration as long as the ionic strength was unchanged. Recently, Sutcliffe and Weber,[12] working at comparable ionic strengths, obtained results that led them to postulate that the perchlorate ion was involved in the oxidation–reduction reaction between Ce(III) and Co(III).

Experimental

The salt solutions were prepared as follows; sodium perchlorate solutions were made by dissolution of the carbonate in perchloric acid. Magnesium and lanthanum perchlorate solutions were prepared by addition of an excess of the respective oxides to perchloric acid. The filtered solutions had a final *p*H of approximately 5. The authors wish to thank Miss I. Fox of the Analytical Group for performing the analyses of these solutions.

Deuteroperchloric acid was prepared in the following manner: first, deuterosulfuric acid was prepared by dissolution of anhydrous SO_3 in D_2O (99.25%). The sulfate was removed from the approximately 13 *M* D_2SO_4 by addition of barium perchlorate and centrifugation of the precipitated barium sulfate. The deuteroperchloric acid (99 ± 0.3% deuterium content) was purified by vacuum distillation. Only the center fraction of the constant boiling mixture was used for preparation of the dilutions.

Stock solutions of Np(V) and Np(VI) were prepared in $DClO_4$. The exchange reactions were carried out in solutions containing a maximum of 99% deuterium. The authors are grateful to Dr. H. Crespi for the determination of the isotopic content of the deuterated solvent solutions.

The majority of the experiments were performed at a temperature of 5.00°, employing the experimental techniques and procedures previously described.[2-4] Solvent extraction separation of the Np(VI) from Np(V) was done using theonyltrifluoroacetone in toluene for the extractant in 0.1 *M* acid and tributyl phosphate for the extractant at higher acid concentrations.

Results and Discussion

The exchange reaction previously has been found to be bimolecular.[2,3] The rate of the exchange may be expressed by the equation

$$R = k[\mathrm{Np(V)}]\,[\mathrm{Np(VI)}] \qquad (1)$$

The specific rate constant, k, is determined from the exponential rate law for a radioactive exchange written as

$$t = \frac{\ln (1 - F)}{([\mathrm{Np(V)}] + [\mathrm{Np(VI)}])k} \qquad (2)$$

where F is the fraction exchanged at time, t. Details of the method of treatment of the data are given in an earlier communication.[2]

The Influence of Ionic Strength and Hydrogen Ion Concentration.—The effect of ionic strength is depicted graphically in Fig. 1. Table I shows the effect of varying the hydrogen ion at constant

ionic strength. The following conclusions may be drawn from these data: first, the invariance of the rate at constant ionic strength in the sodium, magnesium and lanthanum perchlorate solutions, up to $\mu = 3$, indicates that the perchlorate ion participates neither in an equilibrium prior to the rate-determining step nor in the activated complex. In this respect the results are similar to those observed for the Fe(II)–Fe(III) system by Silverman and Dodson.[11] Second, the data in Fig. 1 suggest that an alternate exchange path involving hydrogen ion becomes increasingly important at high acidities. In an earlier communication observations at lower temperatures also suggested this possibility.[3] The results shown in Table I strongly support this hypothesis. The observed rates can be reproduced by a rate law of the form

$$k_{obsd} = k_1 + k_2[H^+] \quad (3)$$

TABLE I

THE EFFECT OF HYDROGEN ION CONCENTRATION ON THE EXCHANGE RATE AT $\mu = 3.0$, $t = 4.5°$

H^+ moles/l.	k_{obsd} (l. mole^{-1} sec.$^{-1}$)	k_{calcd} (l. mole^{-1} sec.$^{-1}$)
0.1	75	75
1.0	86	88.5
1.55	90	96.5
2.17	109	106
3.00	118	118.5

where k_1 is the specific rate constant for the acid independent path and k_2 the specific rate constant for the acid dependent path. At 4.5°, $k_1 = 73.5$ and $k_2 = 15$. From the earlier data[3] at 0° we would estimate $k_1 = 50$ and $k_2 = 10$. Calculation yields a value of 12 ± 5 (95% confidence level) for the activation energy of the acid independent path and 15 ± 7 kcal. for the acid dependent path. There is the implicit assumption in these calculations that the ionic strength data given in Fig. 1 can be interpreted to mean that the activity coefficients remain essentially constant at ionic strengths up to 3.0 M with changes in the medium composition.

The Effect of Deuterium Concentration.—Table II summarizes the data on the effect of deuterium

TABLE II

SUMMARY OF RELATIVE RATES OF REACTION AND ENERGIES OF ACTIVATION FOR THE EXCHANGE IN H_2O AND D_2O SOLUTIONS

$t = 5°$, $[Np(V)] = [Np(VI)] = 2 \times 10^{-5}$ M

H^+ (mole/l.) (μ)	k_{H^+}/k_{D^+}	E_{expt} ($HClO_4$) (kcal./mole)	E_{expt} ($DClO_4$)[a] (kcal./mole)
0.1	1.4 ± 0.1	11.6 ± 0.8	12.1 ± 1.6
1.0	1.3 ± .1	10.6 ± .8	11.6 ± 1.0
3.0	1.2 ± .1	10.6 ± .8

on the rate of the reaction under different conditions. Table III shows the effect of varying the deuterium content for the 0.1 M acid solutions, where the effect of replacing $[H^+]$ by $[D^+]$ is maximal. The uncertainties given are for the 95% confidence level. The fact that the rate of the exchange is slower by a factor of 1.4 in the 0.1 M acid solutions in the presence of deuterium we interpret as evidence for the participation of hydrogen in the

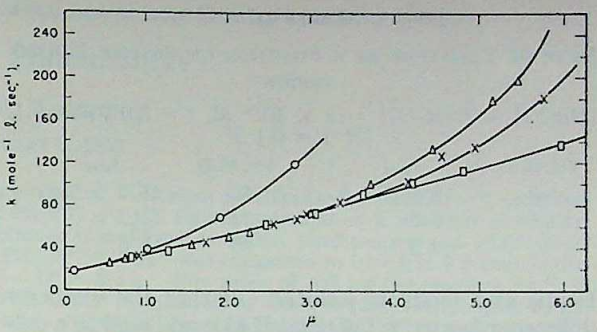

Fig. 1.—The effect of ionic strength and hydrogen ion concentration on the Np(V)–Np(VI) exchange. $[Np(V)] = [Np(VI)] \cong 2 \times 10^{-5} M$; t, 5.00°: O, $[H^+]$; $[H^+]$ 0.1 M and Δ, $NaClO_4$, × $Mg(ClO_4)_2$, □ $La[ClO_4]_3$.

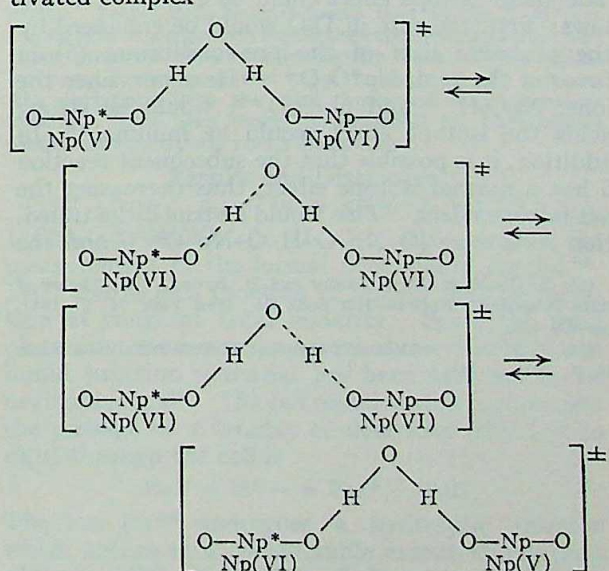
exchange process for the acid independent reaction path. Various suggestions for hydrogen transfer processes involving participation of the solvent have been made.[7,8,13] All involve some kind of group transfer. The isotope factor observed for the present case is minimal for a process involving transfer of hydrogen atoms and corresponds to the situation where the bonding in the activated complex is as strong as in the reactants or to the case where a new bond is formed as the old bond is broken.[14] This suggests that we might visualize the electron transfer process through a water bridge as one which does not involve group transfer but only a stretching of bonds. One possible representation of such a process is depicted schematically as

$$Np^*O_2^+ + NpO_2^{++} + H_2O \rightleftharpoons [X^{+3}]^\ddagger \longrightarrow NpO_2^+ + Np^*O_2^{++} + H_2O \quad (4)$$

where the electron transfer could be considered as involving the internal rearrangements in the activated complex



The dotted lines indicate stretching of bonds to conform to the transfer of an electron to a proton to approach the configuration of a hydrogen atom.

In their discussion of the interpretation of the deuterium effect on the Fe(II)–Fe(III) exchange,

TABLE III

RATE OF EXCHANGE AS A FUNCTION OF VOLUME % DEUTERIUM

$[Np(V)] = [Np(VI)] = 2 \times 10^{-5}\ M$, $t = 5.0°$, $\mu = 0.1$, $[H^+] = 0.1\ M$

Vol. % D	k_{obsd}	Vol. % D	k_{obsd}
0	18.3 ± 1.2	50	15.5 ± 1.2
5	16.0	75	14.7
10	16.2	99	13.5

Hudis and Dodson[9] pointed out that the viscosity difference between D_2O and H_2O could lead to a collision frequency difference of about 20%. However, for reactions involving activation energies of the order of magnitude under consideration diffusion cannot be the rate-determining step, hence viscosity differences will be of little importance.[15] This view is supported in the present case by the experimental results in mixed solvent systems.[4] In these systems, despite much larger viscosity differences the rate was not affected.

The decrease in the k_{H^+} to k_{D^+} ratio with increasing acid concentration indicates a difference in the isotope effect between the acid independent and acid dependent reaction paths. The rate of the reaction for the acid dependent path appears to be more rapid in D_2O solution ($k_{D^+}/k_{H^+} \sim 1.1$). This result suggests that this reaction path involves specific hydronium ion catalysis.[14,16] A reasonable mechanism would involve the two step process

$$Np^*O_2^+ + H^+ \rightleftarrows Np^*O_2H^{++} \qquad (5)$$

and

$$NpO_2^{++} + Np^*O_2H^{++} \rightleftarrows [X^{+4}]^\ddagger \longrightarrow Np^*O_2^{++} + NpO_2H^{++} \qquad (6)$$

The small isotope effect could be explained as follows: first, the rate in D_2O would be enhanced by the probable shift of the pre-equilibrium (5) in favor of the acid, $Np^*O_2D^{++}$. However, since the ions, NpO_2H^{++} and NpO_2D^{++}, would be strong acids the isotope effect would be minimal.[14] In addition, it is possible that the subsequent reaction 6 has a normal isotope effect, thus decreasing the net isotope effect. This would be true if the transition state were $[O–Np–O–H–O–Np–O^{4+}]^\ddagger$ and the exchange process involved the transfer of a hydrogen atom.

Virtues of the mechanism as written are: (1) the transition state is symmetrical. (2) The formation of the transition state would involve the minimum of rearrangement of configuration for the reacting ions. (3) The products of the reaction are the same as the reactants. It should also be pointed out that the normal isotope effect could be small for the mechanism as written since a simultaneous making and breaking of bonds could occur. The net isotope effect would require that the normal isotope effect be small if the isotope effect on the pre-equilibrium (5) is minimal.

A different interpretation has been advanced by Duke and Pinkerton[17] to explain the isotope effect on the rate of the U(V) disproportionation, a reaction similar to that under discussion. A k_{D^+}/k_{H^+} ratio of 1.7 was found. They attribute the enhanced rate in D_2O to a shift in the equilibrium

$$UO_2^+ + H^+ \rightleftarrows UO_2H^{++} \qquad (5a)$$

They consider, however, that the transfer of a proton is unlikely and that the reaction more probably involves a hydroxyl atom transfer

$$O–U–OH^{++} + O–U–O^+ \rightleftarrows [X^{+3}]^\ddagger \longrightarrow O–U^{++} + H–O–U–O_2^+ \qquad (7)$$

If we consider the possibility of hydroxyl atom transfer for the present reaction we have

$$O–Np^*–OH^{++} + O–Np–O^{++} \rightleftarrows [X^{+4}]^+ \longrightarrow O–Np^*–OH^{+3} + O–Np–O^+ \qquad (8)$$

Examination of reaction 8 reveals that OH cannot be transferred in the exchange process. Basically the reaction would have to be considered as an electron transfer through a bridging hydroxyl ion. Little or no isotope effect might be expected in this step. To have a OH transfer in the present case we would have to assume the formation of the less probable species of Np(VI), $O–Np–OH^{+3}$, in the pre-equilibrium step and the reaction

$$O–Np–O–H^{+3} + O–Np^*–O^+ \rightleftarrows [X^{+4}]^\ddagger \rightleftarrows O–Np^{+3} + H–O–Np^*–O_2^+ \qquad (9)$$

This mechanism would involve the breaking of a Np–O bond. In view of the great stability of the O–Np–O structure this is considered a highly unlikely process.

The Hydrolysis of Plutonium(IV)[1]

BY SHERMAN W. RABIDEAU

RECEIVED FEBRUARY 8, 1957

The hydrolysis quotient, $(PuOH^{+++})(H^+)/(Pu^{+4})$, has been evaluated in lithium perchlorate–perchloric acid solutions at a constant total molarity of two from measurements of the Pu(III)–Pu(IV) formal potential as a function of acidity. The temperature dependence of this hydrolysis quotient was obtained from formal potential measurements at 14.88, 25.00 and 34.35°; the value of ΔH for the reaction $Pu^{+4} + H_2O \rightleftarrows PuOH^{+++} + H^+$ was computed to be 7.3 ± 0.5 kcal./mole. At 25° the value of ΔF is 1.73 ± 0.01 kcal./mole; hence, ΔS = 19 ± 2 e.u. The value of ΔH for the reaction $Pu^{+3} + H^+ \rightleftarrows Pu^{+4} + {}^1/_2H_2$, in 2 *M* perchloric acid at 25° was found to be 13.3 ± 0.5 kcal./mole which is very nearly equal to the value obtained previously for this reaction in molar perchloric acid. Virtually identical Pu(III)–Pu(IV) formal potentials were obtained in those cases in which sodium perchlorate was used to replace lithium perchlorate as the added salt to maintain an ionic strength of two in the solutions. Thus, it would appear that the concentration of the perchlorate ion plays a more significant role than the sodium or lithium ion in determining the value of the activity coefficient ratio $\gamma^5_{\pm Pu(ClO_4)_4}/\gamma^4_{\pm Pu(ClO_4)_3}\ \gamma^2_{\pm HClO_4}$.

Introduction

In the study of the isotopic exchange between Pu(III) and Pu(IV) Keenan[2] observed that his results indicated that the hydrolyzed species of Pu(IV), $PuOH^{+++}$ appeared to be involved in the reaction mechanism. The present work was directed toward the evaluation of this hydrolysis quotient in the media in which the exchange experiments were performed, *i.e.*, lithium perchlorate–perchloric acid mixtures, and the determination of some of the thermodynamic quantities applicable to the hydrolysis reaction, $Pu^{+4} + H_2O \rightleftarrows PuOH^{+++} + H^+$. The hydrolysis of Pu^{+4} has been studied previously[3-5] by spectrophotometric and potentiometric methods at ionic strengths ranging from 0.5 to 1.1. However, none of these previous studies included measurements of the temperature coefficient of the hydrolysis quotient. Hindman[6] has considered the evaluation of the degree of hydrolysis of some trivalent and tetravalent ions, including plutonium, from a theoretical point of view in which an attempt is made to calculate the electrostatic free energy involved in the hydrolytic reaction. However, this treatment appears to be semi-quantitative in scope.

Experimental

The experimental apparatus has been described previously.[7] The Pu^{+3} solutions were prepared by dissolving weighed quantities of oxide-free metal in Mallinckrodt Analytical Reagent grade 70% perchloric acid, then diluting with water redistilled from alkaline permanganate. The lithium perchlorate was prepared by neutralizing C.P. lithium carbonate with perchloric acid followed by recrystallization of the salt from water as the trihydrate. This salt was analyzed for perchlorate content by precipitation with tetraphenylarsonium chloride, and for water content by heating to about 160° to form the anhydrous salt. Electrolytic grade hydrogen was purified by passing the gas through a uranium furnace heated to 600°. The gas was saturated with the cell solution in a bubbler maintained at the temperature of the cell; then the gas was passed into the hydrogen electrode compartment. Dual hydrogen and bright platinum electrodes were used and intercompared to assure proper electrode behavior. The plutonium solutions of known (Pu(IV))/(Pu(III)) ratio were prepared by adding weighed aliquots of a standard potassium dichromate solution to the Pu^{+3} solutions. The same acid–salt concentration was used in both the dichromate and Pu^{+3} solutions to maintain the ionic strength at two during the potentiometric titration. The temperature of the plutonium solutions was maintained at ±0.01° during the course of an experiment and was obtained from measurements of the resistance of a type 20D Western Electric thermistor which was calibrated against a platinum resistance thermometer certified by the National Bureau of Standards. A voltage of 1.0000 was impressed upon the thermistor by using a voltage divider and Mallory type 302157 mercury batteries to maintain the resistance–temperature calibration over a period of several months.

To correct the hydrogen electrode for the partial pressure of hydrogen gas, the vapor pressure of the lithium perchlorate–perchloric acid solutions was required. Since it appeared that the vapor pressure data required had not been published previously, the vapor pressures of the acid–salt solution were measured between 5 and 25° by using a high vacuum line and a mercury manometer. The air was removed from the solutions during repeated freezing–melting cycles. Pearce and Nelson[8] found that in the 2 *M* perchloric acid concentration region the experimentally observed vapor pressures differed only slightly from the theoretical fractional lowering of the vapor pressure of the solvent. The deviations from the ideal theoretical vapor pressure lowerings have been found to be small for the lithium perchlorate–perchloric acid solutions also.

Results and Discussion

The cell Pt; Pu^{+3}, Pu^{+4}, $HClO_4(c_1)$, $LiClO_4(c_2)$; $LiClO_4(c_2)$, $HClO_4(c_1)$; H_2, Pt was used in the measurement of the formal potential of the Pu^{+3}–Pu^{+4} couple as a function of acidity and temperature at constant total molarity. Since the total plutonium concentrations were about 8×10^{-3}, the liquid junction potential has been assumed to be negligibly small. The cell reaction that occurs upon the passage of a faraday of electricity from left to right through the cell is

$$Pu^{+3} + H^+ \longrightarrow Pu^{+4} + {}^1/_2H_2$$

The ion Pu^{+4} undergoes a hydrolytic reaction which occurs to a considerable extent in solutions of low acidity (*ca.* 35% hydrolyzed in 0.1 *M* perchloric acid at 25°, *vide infra*)

$$Pu^{+4} + H_2O \rightleftarrows PuOH^{+3} + H^+$$

The concentration quotient, K, for this hydrolysis reaction is

$$K = (PuOH^{+3})(H^+)/(Pu^{+4})$$

The formal potential of the Pu^{+3}–Pu^{+4} couple is given by the expression

$$E^{0\prime} = E_{cell} + RT/F \ln \Sigma Pu(IV)/Pu(III) + RT/F \ln p_{H_2}^{1/2}/(H^+)$$

This formal potential is related to the concentration quotient, K, by the formula

$$E^{0\prime} = E^0 - RT/F \ln [(H^+)/\{(H^+) + K\}] - RT/F \ln \frac{\gamma^5_{\pm Pu(ClO_4)_4}}{\gamma^4_{\pm Pu(ClO_4)_3}\gamma^2_{\pm HClO_4}}$$

If it is assumed that the activity coefficient ratio $\gamma^5_{\pm Pu(ClO_4)_4}/\gamma^4_{\pm Pu(ClO_4)_3}\gamma^2_{\pm HClO_4}$ is constant in perchloric acid–lithium perchlorate solutions of constant ionic strength, the value of the concentration quotient, K, can be evaluated from a plot of the formal potential of the Pu^{+3}–Pu^{+4} couple *versus* log $[(H^+)/(H^+) + K]$. This plot should result in a straight line relation with a slope of $-2.303RT/F$ if the assumption with reference to the constancy of the activity coefficient ratio is valid. It appears that this assumption is justified since reasonably good straight lines do result from plots of the formal potentials *versus* log $[(H^+)/(H^+) + K]$.

In Table I are given the formal potentials of the Pu^{+3}–Pu^{+4} couple in lithium perchlorate–perchloric acid solutions as a function of temperature and of acidity at a total constant molarity of two.

The uncertainty of the formal potentials is about ±0.0002 volt. The values of the hydrolysis quotients were obtained as shown in Fig. 1 by adjusting the value of K in the plot of $E^{0\prime}$ *vs.* log $[(H^+)/(H^+) + K]$ until the theoretical slope of $-2.303RT/F$ was obtained. The values of K are considered to have an uncertainty of ±0.001.

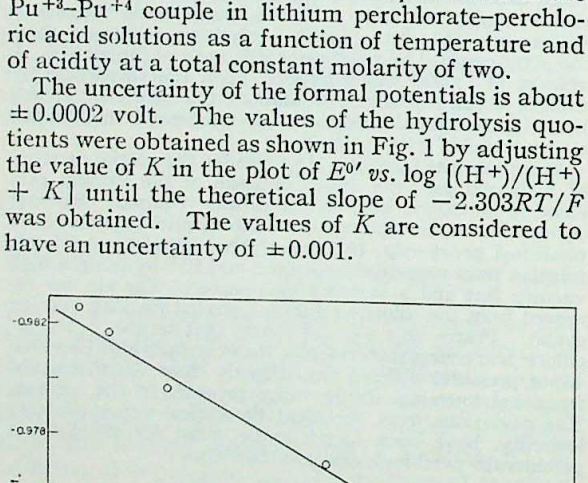

Fig. 1.—Evaluation of hydrolysis quotient of plutonium(IV) from potentiometric measurements in lithium perchlorate–perchloric acid solutions at 25° and at an ionic strength of two.

From the temperature coefficient of the hydrolysis quotient a value of +7.3 ± 0.5 kcal./mole was obtained for ΔH. Since at 25° the value of ΔF equals 1.73 ± 0.01 kcal./mole, the increase in entropy accompanying the hydrolysis of Pu^{+4} is +19 ± 2 e.u. The data given in Table II were used in the evaluation of the heat of the hydrolysis reaction. It is of interest to compare the thermodynamic quantities for the hydrolysis of Pu^{+4} with those reported[9,10] for U^{+4}. With spectrophotometric methods these authors obtained values which were in essential agreement. Values of ΔH = 11.0 kcal./mole and ΔS = 33 e.u. were obtained for the reaction $U^{+4} + H_2O \rightleftarrows UOH^{+3} + H^+$. These values refer to the hydrolysis reaction at zero ionic strength whereas in the hydrolysis of Pu^{+4} the ionic strength of two was used.

TABLE II

DETERMINATION OF ΔH FOR HYDROLYSIS OF Pu(IV)

T, °K.	$1/T \times 10^3$	K	log K
288.05	3.472	0.039	−1.409
298.16	3.354	.054	−1.263
307.51	3.252	.088	−1.056

The value of ΔH for the reaction $Pu^{+3} + H^+ \rightleftarrows Pu^{+4} + {}^1/_2H_2$ also was determined since values of the formal potential of the Pu^{+3}–Pu^{+4} couple in 2 M perchloric acid as a function of temperature were measured. From a plot of $E^{0\prime}/T$ *vs.* $1/T$ a value of 13.3 ± 0.5 kcal./mole was computed for ΔH for this reaction at 25°. This value is very nearly equal to the value reported[11] for this reaction in molar perchloric acid.

A point of interest was examined in connection with changes in activity coefficient ratios in mixed electrolytes at constant ionic strength as sodium perchlorate is substituted for lithium perchlorate. In Table III are given the formal potentials of the Pu^{+3}–Pu^{+4} couple as a function of acidity in the presence of either sodium or lithium perchlorate.

Thus, as evident from a comparison of the formal potentials of the Pu^{+3}–Pu^{+4} couple in sodium or lithium perchlorate–perchloric acid solutions, the alteration of the hydrolysis quotient with the change in added salt is very small. It would seem that the activity coefficient ratio $\gamma^5_{\pm Pu(ClO_4)_4}/\gamma^4_{\pm Pu(ClO_4)_3}\gamma^2_{\pm HClO_4}$ is not very sensitive to the substitution of lithium ions for hydrogen ions, or to

the substitution of sodium ions for lithium ions in these solutions of constant ionic strength.

It might have been predicted from the treatment of Robinson and Stokes[12] that the above activity coefficient ratio would be significantly altered in the solution of mixed electrolytes since the osmotic coefficients and the hydration numbers of sodium perchlorate and lithium perchlorate are appreciably different. However, it appears that this difference is not observed experimentally in view of the small changes noted in the formal potentials of the Pu^{+3}–Pu^{+4} couple.

The Composition and Formation of Cobalt Complexes with 1-Nitroso-2-naphthol

BY I. M. KOLTHOFF AND EINAR JACOBSEN

RECEIVED MARCH 7, 1957

Controversial statements are found in the literature on the composition and the mode of formation of the complex which precipitates upon addition of a solution of 1-nitroso-2-naphthol (HR) to a cobalt(II) solution in an acetate buffer. The precipitate is soluble in benzene and acetonitrile (AN). From its polarographic properties in AN, from amperometric titrations in water and AN, and from gravimetric studies it was concluded that the complex has the formula $Co(III)\,R_3{\cdot}H_2R'$, $H_2R\cdot$ being the semiquinone obtained by a one-electron reduction of HR. $H_2R\cdot$ is unstable in a vacuum at 110°. $H_2R\cdot$ is soluble in 40% acetic acid; the precipitate obtained from this medium has the composition $Co(III)R_3$. It is proposed that $Co(II)R_2$ is the first reaction product which, in acid medium, decomposes rapidly according to the equation: $2Co(II)R_2 \rightarrow Co(III)R_3 + H_2R\cdot + Co(II)$. A precipitate of $Co(II)R_2$ is obtained from neutral and slightly alkaline aqueous medium. When dissolved in AN which contains acid, the reaction products of the disproportionation are found in the solution. The polarographic properties of some other metal–HR complexes have been determined.

Ilinsky and v. Knorre[1] reported in 1885 that upon addition of excess cobalt(II) to a neutral aqueous solution of the sodium salt of 1-nitroso-2-naphthol (designated in this paper as HR) a brown-red precipitate is formed. By addition of acid to the mixture and heating, the precipitate is transformed to a purple-red compound. The purple complex is also obtained when the precipitation is carried out in acid medium. The percentage of cobalt in the complexes was determined and the formulas CoR_2 and CoR_3 for the brown-red and purple-red complexes were suggested.

During this century HR has been recommended by a number of investigators for the determination of cobalt. The precipitate has been reported to be of variable composition, and for this reason is ignited to and weighed as Co_3O_4 or the oxide is reduced with hydrogen to the metal.[2,3]

Mayer and Feigl[4] suggest that divalent cobalt is partly oxidized by the reagent to the trivalent state and claim that the precipitate formed by addition of HR to an acid solution of divalent cobalt is not a pure compound but contains both divalent and trivalent cobalt. In order to obtain all cobalt in the trivalent form they first convert cobalt(II) into cobaltic hydroxide by addition of hydrogen peroxide and sodium hydroxide. The hydroxide is dissolved by heating in a fairly concentrated solution of acetic acid to yield a complex trivalent cobalt acetate. After dilution the cobalt(III) is precipitated with the reagent and the precipitate weighed as $CoR_3{\cdot}2H_2O$. It is not realized by these authors that on heating of a cobalt(III) solution in aqueous acetic acid reduction to cobalt(II) occurs.

Kolthoff and Langer[5] titrated divalent cobalt in acetate buffer amperometrically with HR. The ratio of cobalt to HR in the purple-red precipitate was found to be 1:4 and they suggested the formula $CoR_2{\cdot}2HR$.

In a discussion of these results Feigl[6] suggested that HR reacts with cobalt(II) salts to form an inner complex containing trivalent cobalt. He suggests that the precipitate is composed of the trivalent cobalt complex with one molecule of coördinated reagent. No experimental evidence however was presented and no simple reaction mechanism would account for this suggestion.

From the above review it is evident that the composition of the red cobalt complex and its mode of formation are not yet clear. In the present paper experiments are described which establish the composition of the red precipitate and the reactions leading to its formation.

It was observed that some of the metal complexes with HR, which are precipitated from aqueous medium, are soluble in benzene and acetonitrile (designated in this paper as AN). In AN as solvent or in mixtures of AN with benzene well-de-

fined polarographic waves of the metal complexes were obtained. A polarographic study of the cobalt complexes indicated that cobalt is present in the trivalent form. Evidence is presented that cobalt(II) reacts in an acetate buffer or in other acid medium with RH to form $Co(II)R_2$ which rapidly is transformed into $Co(III)R_3$ and $H_2R{\cdot}H_2R{\cdot}$ having properties of a semiquinone. In dilute acetic acid medium $H_2R{\cdot}$ precipitates quantitatively with the red compound, which has the overall composition $CoR_3{\cdot}H_2R{\cdot}$. At higher concentrations of acetic acid the semiquinone is soluble and the precipitate is composed of CoR_3. This interpretation was supported by gravimetric and amperometric experiments.

Experimental

Materials Used.—C.P. chemicals were used unless otherwise stated. Standard solutions of HR were prepared and standardized as recommended by Kolthoff and Langer.[5] Unless otherwise stated, 0.1 *M* sodium perchlorate prepared from the anhydrous salt served as supporting electrolyte in AN as solvent.

Technique.—The conventional type of dropping mercury electrode and of electrolysis cell were used. Current–voltage curves were recorded with a Sargent Recording Polarograph Model XXI. Oxygen was eliminated from the solutions by bubbling pure nitrogen through the cell for 10 min. and passing it over the solution during the electrolysis. Further details on the polarographic technique in AN are found in a recent paper.[7]

Results

Polarography.—Irreproducible and poorly defined current–voltage curves of the reagent and its metal complexes in AN were obtained in acid-free solutions of sodium perchlorate. By addition of acetic acid or perchloric acid well-defined and reproducible polarograms were observed.

Current–voltage curves of 10^{-3} *M* HR in AN of different acidity are plotted in Fig. 1. The diffusion current was found not to be affected by concentration and kind of acid present and to be proportional to concentration of HR, the value of $i_{d/c}$ being equal to 16.0 μa./mmole HR/liter. By assuming a reasonable value for the diffusion coefficient of HR, it was inferred that its reduction involves four electrons. This corresponds to a reduction of the nitroso group to the amine. The half-wave potential is shifted to more positive values with increasing concentration of acetic acid, while the stronger acid perchloric in 0.1 *M* solution has a much greater effect than 1.5 *M* acetic acid. Identical waves were obtained when the reagent was extracted with benzene from aqueous acetic acid solution and the benzene solution diluted with AN which contained the appropriate amount of acid and salt.

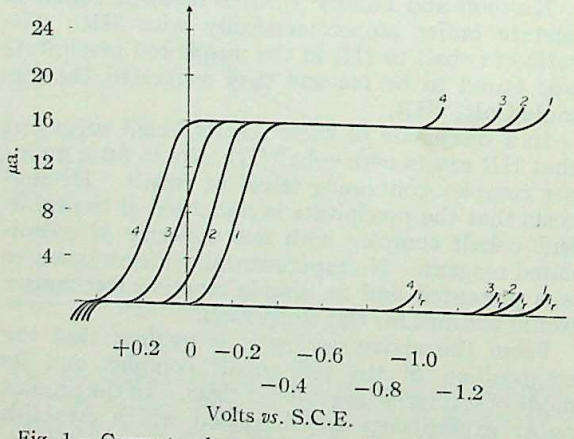

Fig. 1.—Current-voltage curves of 10^{-3} *M* HR in 0.1 *M* sodium perchlorate in acetonitrile: (1) 0.1 *M*; (2) 0.5 *M*; (3) 1.5 *M* in acetic acid; (4) 0.1 *M* in perchloric acid.

Complexes of various metals with HR were prepared by adding a known volume of the reagent in 60% acetic acid to aqueous 0.2 *M* sodium acetate solutions containing an excess (50 to 100%) of the metal salts. The precipitates formed were extracted with benzene and an aliquot part of the extract diluted with AN, which was 0.5 *M* in acetic acid and 0.1 *M* in sodium perchlorate, shortly before recording the polarograms. Current–voltage curves of the metal complexes are plotted in Fig. 2. Diffusion currents and $E_{1/2}$ values are reported in Table I.

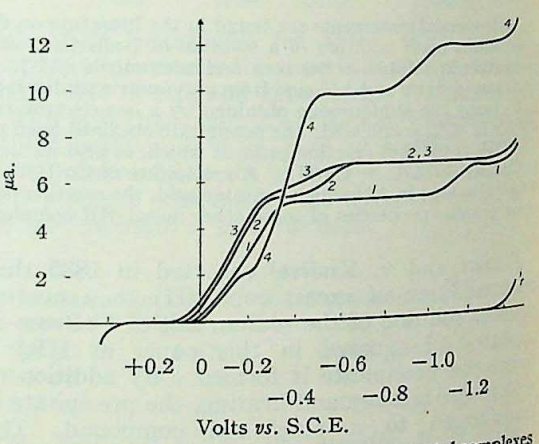

Fig. 2.—Current-voltage curves of various metal complexes with HR in AN (0.5 *M* in acetic acid and 0.1 *M* in $NaClO_4$): 1) 2×10^{-4} *M* $Fe(II)R_2$; (2) 2×10^{-4} *M* $Ni(II)R_2$; (3) 2×10^{-4} *M* $Cu(II)R_2$; (4) 2×10^{-4} *M* $Co(III)R_3{\cdot}R$.

Solutions of the metal complexes also were prepared by mixing together equivalent amounts of the metal perchlorates and the reagent in acetonitrile which was 0.5 *M* in acetic acid. Current–voltage curves of these solutions were identical with those in Fig. 2 and the i_d values were proportional to the concentration of the respective complexes.

The polarograms of copper(II), nickel(II) and the iron(II) complexes exhibit two waves. The first wave corresponds to reduction of the reagent in the complex, the second wave to reduction of the metal ion to amalgam. The half-wave potentials of the second wave of the nickel and ferrous iron complexes are practically identical with the observed $E_{1/2}$ value of the corresponding metal/perchlorates in the same medium (Table I). The $E_{1/2}$ value of the second wave of the copper complex is close to that of copper(I) to copper amalgam. The copper(II) in the complex is held firmly and cannot be reduced until all the reagent is destroyed, whereupon the reduced reagent also

TABLE I

DIFFUSION CURRENTS AND $E_{1/2}$ VALUES OF 2×10^{-4} M META . COMPLEXES WITH HR IN ACETONITRILE

Complex	Color	i_{d1}	i_{d2}	Ratio i_{d2}/i_{d1}	$E_{1/2}$ 2nd wave	$E_{1/2}$ of Me(ClO_4)$_2$	
NiR_2	Brown	5.30	1.30	1:4.1	−0.54	Ni(II)–Ni(0)	−0.55
FeR_2	Green	5.20	1.30	1:4.0	−1.12	Fe(II)–Fe(0)	−1.11
CuR_2	Brown	5.40	1.35	1:4.0	−0.42	Cu(I)–Cu(0)	−0.40
$CoR_3 \cdot R\cdot$	Purple-red	9.85	1.96	1:5.0	−0.93	Co(II)–Co(0)	−0.68

stabilizes the copper(II). Considering that the reduction of one molecule of reagent involves 4 electrons and that of one metal(II) 2 electrons, the ratio i_{d_2}/i_{d_1} should be 1:4 for MR_2. As seen from Table I, this ratio is found experimentally.

The polarogram of the cobalt complex differs from the others. The half-wave potential of the second wave was found to be 0.25 volt more negative than the $E_{1/2}$ for reduction of uncomplexed cobalt(II) ions in the same medium. This difference might be attributed to complex formation of cobalt with the reduced reagent. If the complex had the composition $CoR_2 \cdot 2HR$, the ratio of i_{d_2}/i_{d_1} should be 1:8, while the ratio should be 3:16 or 1:5.33 if the formula were $CoR_3 \cdot HR$. Actually, a ratio of 1:5.00 was found, which corresponds to a formula $Co(III)R_3 \cdot R\cdot$, in which $R\cdot$ is the semiquinone of HR, which would require 3 electrons per molecule for its reduction. From Fig. 2 it is seen that the reagent wave of the cobalt complex is composed of two waves, the first wave being about 2 μa., and the second wave 7.9 μa. According to the formula $Co(III)R_3 \cdot R\cdot$ the ratio of the waves should be 1:5.0, which is actually found.

In order to get further information on the formation and composition of the cobalt complex several amperometric titrations and gravimetric determinations have been carried out.

The Amperometric Titrations.—Cobalt(II) chloride in 0.2 M aqueous acetate buffer was titrated amperometrically with HR dissolved in 60% acetic acid. The diffusion current of the reagent was measured at an applied potential of −0.6 volt *vs.* S.C.E. The titration curve is plotted in Fig. 3 curve 1. In agreement with Kolthoff and Langer[5] the ratio Co:R in the precipitate at the end-point was found to be exactly 1:4.00. When the titration was carried out in 40% acetic acid, a current passed immediately upon addition of reagent, this current increased linearly with the volume of reagent added until the end-point. After the end-point the increase in current became much greater (curve 2, Fig. 3). Again, the end-point was found at a ratio of Co:R of 1:4.00.

Several titrations were carried out by first precipitating the cobalt as cobaltic hydroxide and dissolving the precipitate in hot acetic acid solution according to Mayer and Feigl's[4] procedure for preparation of the trivalent cobalt acetate. In agreement with Kolthoff and Langer[5] the results were found somewhat variable; in several titrations the ratio Co:R in the precipitate at the end-point varied between 1:3.70 and 1:3.90, indicating that most of the cobalt(III) was reduced to the divalent

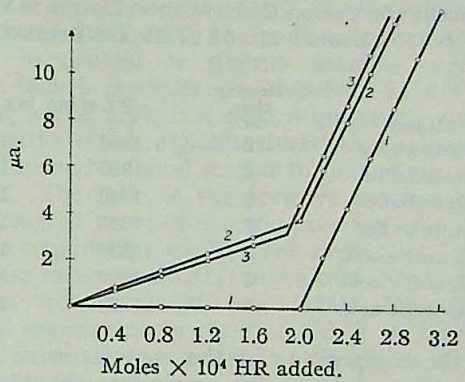

Fig. 3.—Amperometric titration of cobalt with 0.1 M HR in 60% acetic acid at −0.60 volt: (1) 5×10^{-5} M cobalt(II) in 50 ml. of acetate buffer; (2) in 50 ml. of 40% acetic acid; (3) 5×10^{-5} M "cobalt(III)" in 50 ml. of 35% acetic acid.

form upon dissolution in 40% acetic acid. A typical titration curve is plotted in Fig. 3, curve 3.

Amperometric titrations of the reagent with cobalt(II) perchlorate were carried out in AN which was 1 M in acetic acid and 0.1 M in sodium per-

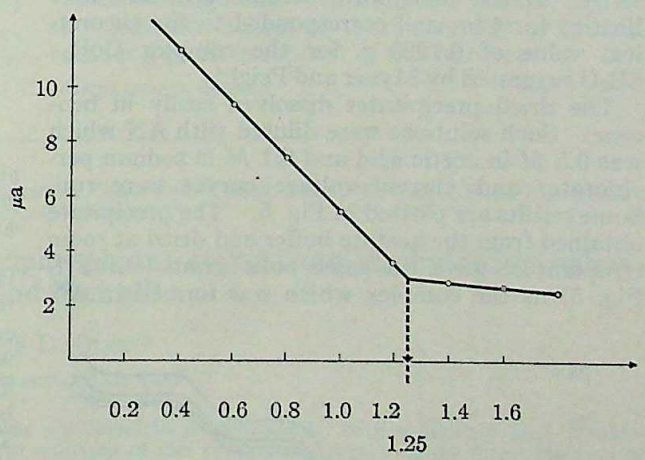

Fig. 4.—Titration of 5×10^{-5} M HR in 50 ml. of acetonitrile which was 1.0 M in acetic acid with 10^{-2} M $Co(ClO_4)_2$ in acetonitrile. Measured at −0.16 volt *vs.* S.C.E.

chlorate. The titrations were carried out at −0.16 volt at which potential the free reagent yields a diffusion current, and the reagent in the complex a very small current only (compare Figs. 1 and 2). A typical titration line is given in Fig. 4. The end-point corresponded again to a ratio of Co:HR of 1:4.00

Gravimetric Determinations.—Several gravimetric determinations were carried out in which cobalt(II) in acetate buffer was partially precipi-

tated with a 0.1 *M* solution of HR. One hundred per cent. excess of cobalt was present in all experiments. The precipitate was filtered, washed with distilled water, and dried in a vacuum oven at 110°. The weight of the precipitate decreased with time of heating. The results of two experiments are reported in Table II.

TABLE II

WEIGHT OF THE COBALT COMPLEX UPON DRYING IN VACUUM OVEN AT 110°, USING 8 ML. 0.1 *M* HR AND EXCESS COBALT (II)

Medium	Heating time, hr.	Wt. of ppt. in g. a	b
Acetate buffer	2	0.1366	0.1370
Acetate buffer	4	.1350	.1352
Acetate buffer	6	.1340	.1341
Acetate buffer	8	.1325	.1323
40% acetic acid	2	.1226	.1228
40% acetic acid	4	.1222	.1223
40% acetic acid	6	.1223	.1222

If the composition of the complex were $CoR_2 \cdot 2HR$, the weight of the precipitate should be 0.1499 g. assuming quantitative precipitation of HR. If 4 moles of the reagent react with 1 mole cobalt(II) to give a complex of the form $CoR_3 \cdot 2H_2O$, the weight of the complex should be 0.1223 g. As seen from Table II the final weight of the precipitate was between these two values.

The precipitation also was carried out in 40% acetic acid as solvent. The precipitate was filtered and washed with 40% acetic acid. The weight of the precipitate became constant after heating for 4 hr. and corresponded to the theoretical value of 0.1223 g. for the complex $CoR_3 \cdot 2H_2O$ suggested by Myaer and Feigl.[4]

The dried precipitates dissolved easily in benzene. Such solutions were diluted with AN which was 0.5 *M* in acetic acid and 0.1 *M* in sodium perchlorate, and current–voltage curves were run. Some results are plotted in Fig. 5. The precipitate obtained from the acetate buffer and dried at room temperature gave the same polarogram (curve 1, Fig. 5) as the complex which was formed in AN

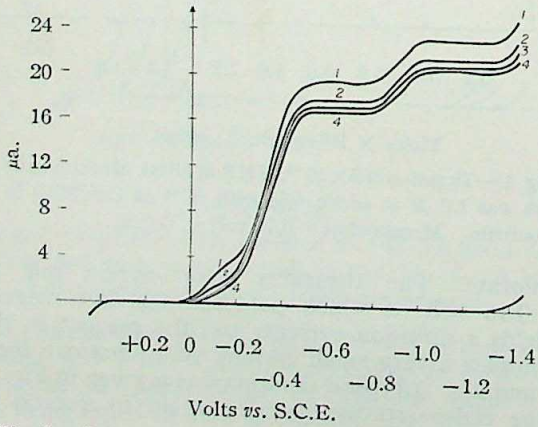

Fig. 5.—Current–voltage curves of 4×10^{-4} *M* Co-complex in acetonitrile which was 0.1 *M* in $NaClO_4$ and 0.5 *M* in acetic acid: (1) precipitate dried at room temperature; (2) dried 2 hr.; (3) 4 hr.; (4) 8 hr.

(Fig. 2). However, on drying, the first wave of the reagent wave decreased markedly. The decrease of the height of the total reagent wave corresponded to the decrease of the prewave. The ratio i_{d_2}/i_{d_1} decreased from 1:4.99 (air-dried) to 1:4.33 after 8 hr. drying at 110°.

The current–voltage curve of the dried complex prepared in 40% acetic acid is plotted in Fig. 6, curve 2. This polarogram does not exhibit a prewave. The ratio i_{d_2}/i_{d_1} was found to be 1:4.02, indicating that the composition of the complex corresponds to $Co(III)R_3$. After precipitation in 40% acetic acid the filtrate was shaken out with benzene and the extract diluted with AN. The polarogram of this solution is plotted in curve 3 of Fig. 6. The height of this wave was 3.8 μa. while the height of the reagent wave in $Co(III)R_3$ was 15.9 μa. (curve 2). The sum of the two is 19.7 μa. and exactly equal to the total height of the total reagent wave in the complex prepared in dilute acetate buffer (curve 1). This agreement, combined with the

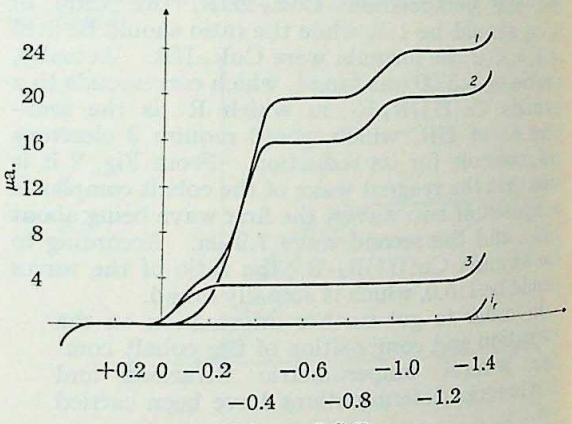

Fig. 6.—(1) Current–voltage curves of 4×10^{-4} *M* Co-complex in acetonitrile; (0.5 *M* in acetic acid and 0.1 *M* in sodium perchlorate); (2) of 4×10^{-4} *M* complex, prepared in 40% acetic acid; (3) of extract of the 40% acetic acid filtrate.

fact that the wave in curve 3 occurs in the same potential region as the prewave in curve 1, allows the conclusion that the prewave is given by the species which is soluble in 40% acetic acid. This was confirmed by preparing a complex from dilute acetate buffer and extracting it with hot 40% acetic acid. The resulting complex now gave a polarogram identical with that in curve 2 (Fig. 6) instead of that in curve 1, while the soluble species after extraction gave a wave identical with curve 3.

Composition and Formation of Cobalt Complexes with HR.—On the basis of the experimental results presented in the previous section it is possible to present the equations of formation and the composition of cobalt complexes with HR. The precipitate obtained from an acetate buffer is evidently not a pure compound and contains some "coprecipitated reagent." This "coprecipitated reagent" is soluble in warm 40% acetic acid. After extraction of the precipitate with 40% acetic acid its formula is $Co(III)R_3$. This compound is obtained directly when the precipitation is carried out in 40% acetic acid as was

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

indicated by the results of polarographic and gravimetric experiments and amperometric titrations.

The precipitate obtained from dilute acetate buffer contains cobalt and reagent in the molecular ratio 1:4.00. After extraction with 40% acetic acid this ratio becomes 1:3.00 ($Co(III)R_3$). The extracted reagent requires only 3 electrons per molecule in its reduction, while HR requires 4 electrons. This is strong evidence that the extra molecule of reagent is a free radical, denoted as $H_2R\cdot$, which is an intermediate and stable product formed in the reduction of HR

$$HR + H^+ + e^- \longrightarrow H_2R\cdot$$

It is not plausible to assume that the precipitate in dilute acetate buffer is formed by the sequence of reactions

$$Co(II) + HR \longrightarrow Co(III) + H_2R\cdot \quad (1)$$

$$Co(III) + 3HR \longrightarrow Co(III)R_3 + 3H^+ \quad (2)$$

$$Co(III)R_3 + H_2R\cdot \longrightarrow CoR_3\cdot H_2R\cdot \quad (3)$$

In amperometric titrations of cobalt(II) with the reagent in acetate buffer and in the reverse titration it was found that at any stage of the titration before and after the end-point the over-all composition of the precipitate corresponded to 1:4.00. In 40% acetic acid the reaction ratio in both types of titration also was at any stage 1:4.00, although the precipitate had the composition $Co(III)R_3$. Finally, from the identical polarographic behavior in AN of the precipitate formed from dilute acetate buffer and of the reaction product obtained by mixing cobalt(II) and HR in AN, and also from amperometric titrations in AN it appears impossible that the formation of the final reaction product occurs by the sequence of reactions 1 and 2. It is postulated that this sequence of reactions accounts for the observed results

$$Co(II) + 2HR \longrightarrow Co(II)R_2 + 2H^+ \quad (4)$$

$$2Co(II)R_2 \longrightarrow Co(III)R_3 + H_2R\cdot + Co(II) \quad (5)$$

The cobalt(II) complex formed according to eq. 4 is transformed rapidly in acid medium. In dilute acetate buffer $H_2R\cdot$ is insoluble and coprecipitates with $Co(III)R_3$. In 40% acetic acid $H_2R\cdot$ is soluble and only $Co(III)R_3$ precipitates. In AN both $Co(III)R_3$ and $H_2R\cdot$ are soluble.

As stated by Ilinski and v. Knorre[1] and confirmed in this Laboratory $Co(II)R_2$ precipitates on mixing cobalt(II) with the sodium salt of the reagent in neutral or slightly alkaline medium. When such a precipitate is dissolved in AN containing acetic acid, it should disproportionate according to eq. 5. Qualitatively the polarogram should be and is found similar to that of curve 1 in Fig. 6. The ratio of the prewave to that of the total reagent wave minus the prewave was found 1:4, as required by eq. 5. The ratio of i_{d_2} (cobalt wave, in this case Co(III) and Co(II)) to i_{d_1} (total reagent wave) should be 1:3.00. Actually in several experiments a ratio of 1:2.97 ± 0.03 was found, in excellent agreement with the postulated interpretation.

The gravimetric data (Table II) and Fig. 5 indicate that coprecipitated $H_2R\cdot$ can be volatilized more or less completely in a vacuum oven at 110°. The reason why Mayer and Feigl[4] could obtain such good results is not because they first oxidized cobalt from the divalent to trivalent state, but because they carried out the precipitation in fairly concentrated acetic acid medium in which $H_2R\cdot$ is soluble.

The Synthesis of Tetrakis-(dichloromethylphosphine)-nickel from Methyldichlorophosphine and Nickel[1a]

BY LOUIS D. QUIN[1b]

RECEIVED FEBRUARY 23, 1957

The reaction of bulk nickel with methyldichlorophosphine was found to proceed readily to give high yields of tetrakis-(dichloromethylphosphine)-nickel. This represents the first synthesis of this type of compound by the direct reaction of nickel and a trivalent phosphorus compound. A small amount of a black unidentified solid adhering to the residual nickel is also formed. Similar conditions were not effective for causing phosphorus trichloride or phenyldichlorophosphine to react with nickel. The properties of tetrakis-(dichloromethylphosphine)-nickel were in general similar to those of related compounds.

Several compounds of the type $Ni(PY_3)_4$ have been prepared in recent years by the reaction of nickel tetracarbonyl[2-5] or other $Ni(PY_3)_4$ compounds[2,3] with trivalent phosphorus compounds. Their preparation by the direct reaction of nickel with phosphorus compounds has not yet been successful, although evidence of a reaction has been obtained with phosphorus trichloride.[2] Phosphorus trifluoride showed no reaction with nickel.[3,6] We now wish to report the facile synthesis of the new compound tetrakis-(dichloromethylphosphine)-nickel, $Ni(CH_3PCl_2)_4$ (I), by the reaction of methyldichlorophosphine and elemental nickel.

The reaction has been affected by several tech-

niques, the best of which involves refluxing methyldichlorophosphine through a column packed with bulk nickel as turnings or wire. Under these conditions, the reaction proceeds relatively rapidly, as large surface area of nickel can be exposed to the methyldichlorophosphine. The product is very soluble in methyldichlorophosphine and accumulates in the pot; it is isolated by vacuum distillation of the unreacted methyldichlorophosphine and recrystallization of the residue. The pot temperature provides a good indication of the extent of reaction; the operation has generally been stopped when the temperature has risen from the boiling point of pure methyldichlorophosphine (81–82°) to 102–104°. Beyond this point, the solution becomes so concentrated in I that its crystallization commences; any material deposited on the walls of the flask is decomposed on continued heating. The conversion of methyldichlorophosphine to I at the usual stopping point is about 60–70%; the yields based on either consumed methyldichlorophosphine or nickel exceed 90%. With equipment properly sized for a charge of 250 g. of methyldichlorophosphine, a production rate of I of 40–50 g. per hour has been obtained. This rate is dependent primarily on the amount of nickel in the column.

Another technique for conducting this reaction involves merely refluxing methyldichlorophosphine in a flask containing nickel. In this case the reaction of a given amount of methyldichlorophosphine is considerably slower than that in the column. The product of this reaction appears to be less pure than that obtained by the column reaction. We have also found that Raney nickel will react with methyldichlorophosphine at room temperature to produce I, but this method of preparation has not been explored in detail.

In the preparation of I, bulk nickel slowly acquired a light powdery coating of an unidentified black by-product II which contains Ni, Cl and P (and probably C and H). There was no evidence of this coating decreasing the rate of production of I. That II was not an intermediate in the formation of I was shown by the fact that a small residue of II remained when a sample of nickel was completely consumed by prolonged refluxing with methyldichlorophosphine.

Compound I was found to be attacked readily by oxygen. When solutions of I were exposed to air or oxygen, precipitation of tan solids commenced immediately. These solids have not yet been sufficiently investigated to permit their identification. A report[2] on $Ni(PCl_3)_4$ implies instability of its solutions on exposure to air also.

Compound I reacted readily with phenyldichlorophosphine to affect replacement of all CH_3PCl_2 groups. The $Ni(C_6H_5PCl_2)_4$ so produced was of high purity; it melted at a temperature slightly higher than that previously reported.[5] In general other properties of I were similar to those of related compounds and are described in the Experimental section.

Attempts were made to apply the most favorable conditions for preparing I to the direct synthesis of $Ni(PCl_3)_4$ and $Ni(C_6H_5PCl_2)_4$. After prolonged refluxing of phosphorus trichloride and phenyldichlorophosphine through nickel-packed columns, there was no indication of a reaction and not a trace of the corresponding nickel complex could be isolated. The reduced availability of the electron pair on the phosphorus atom in these cases may be of importance in interpreting their lack of reactivity. Further study of the structural requirements of trivalent phosphorus compounds for undergoing the reaction with elemental nickel is contemplated.

Experimental[7]

Preparation of $Ni(CH_3PCl_2)_4$ (I).—A 1.8 cm. i.d. heated column with a 37-cm. section packed with 258 g. of chopped nickel turnings of average size 0.4 mm. × 5 mm. × 6 mm. was attached to a flask containing 274 g. (2.34 moles) of CH_3PCl_2. The top of the column was fitted with a reflux condenser. The system was flushed with nitrogen before the reaction and protected from the atmosphere thereafter. The CH_3PCl_2 was then boiled (81–82°) at a rate slightly below that causing flooding in the column. A yellow color developed in the pot after a few minutes; the nickel was noticeably blackened after 1–2 hr. operation. The pot temperature rose slowly at first and then rapidly as the relative change in content of solute (I) with respect to solvent (CH_3PCl_2) became greater. After 6 hr., the pot temperature had reached 100° and the reaction was stopped. On cooling, large crystals of I formed in the pot. The residual CH_3PCl_2 was removed by vacuum distillation. The crude I so obtained weighed 198 g. (0.376 mole). The conversion from CH_3PCl_2 charged was 64.3%. In the distillation there was recovered 88.2 g. (0.754 mole) of CH_3PCl_2; the yield of I from CH_3PCl_2 consumed was therefore 94.6%. The nickel packing was found to have lost 24.5 g. (0.417 mole); the yield of I based on this value was 90%. The crude I was recrystallized from dry diethyl ether or *n*-pentane at about −50° in the absence of air.

Anal. Calcd. for $C_4H_{12}Cl_8NiP_4$: C, 9.13; H, 2.30; Cl, 53.89; Ni, 11.2; P, 23.5. Found: C, 8.77; H, 2.35; Cl, 54.46; Ni, 11.2; P, 23.7.

Isolation and Properties of Black Ni–CH_3PCl_2 Product (II).—The nickel from an experiment such as that above was washed twice with dry, air-free *n*-pentane to remove residual I and CH_3PCl_2. The nickel was dried in a stream of nitrogen and transferred to a bottle. The bottle was shaken vigorously to cause detachment of the black coating on the nickel. The powder so obtained was removed through a sieve. Analysis of two different samples of II gave the following inconclusive data: Cl, 26.0 and 33.1; Ni, 49.1 and 33.8; P, 12.9 and 18.0, respectively. II was insoluble in all solvents investigated. It had no melting point but released a small amount of a volatile substance above 100°. No attempt has yet been made to identify this substance other than to ascertain that it is not CH_3PCl_2. II did not react with CH_3PCl_2 on prolonged refluxing in the presence or absence of nickel, indicating it not to be an intermediate in the formation of I. II has occasionally shown ferromagnetic properties, but this is possibly due to the presence of some elemental nickel.

Properties of $Ni(CH_3PCl_2)_4$. (a) **Thermal Stability.**—At room temperature, I appeared relatively stable when protected from the atmosphere, although it developed a strong CH_3PCl_2 odor. In a capillary, I slowly blackened over the range 170–185°; no melting point was observed. A 6.8-g. sample of I was heated to 240° in 15 minutes. There distilled 4.5 g. of dark blue liquid, which was redistilled to remove the trace of colored impurities. The liquid was found to be almost pure CH_3PCl_2 (74% yield) by its infrared spectrum. The pyrolysis flask was partially mirrored with nickel. The rest of the residue was a black powder, partly soluble in water.

(b) **Solubility.**—I was very soluble in organic solvents. The solutions were relatively stable at room temperature when protected from the atmosphere; at elevated temperatures, decomposition generally occurred to give dark brown or green mixtures. I was insoluble in cold water, though a slow reaction occurred over a period of several days to give a green solution. With boiling water, a green

(7) All melting points are uncorrected.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

solution rapidly resulted; no solid separated on cooling. Similarly, the lower alcohols appeared to dissolve I with reaction on boiling. Hot sodium hydroxide (2 *N*) and ammonium hydroxide (concd.) rapidly gave dark brown mixtures with I.

(c) **Reaction with Oxygen.**—Most solutions of I deposited a light tan solid unless carefully protected from oxygen. When air was purposely passed for one hour through a solution of 1.49 g. of I in 25 ml. of *n*-pentane at room temperature, precipitation of the solid commenced immediately and a thick slurry resulted. The solid was recovered by filtration and washed with benzene. It weighed 0.30 g. Reliable analytical data have not yet been obtained for this compound. It was soluble in water (solution strongly acid) and alcohols and insoluble in organic solvents. It did not melt but darkened at a high temperature. Pentane-soluble products of the oxidation were not examined. Exposure of solid I to the atmosphere results in partial conversion to a pentane-insoluble solid which may be similar to the material described above.

(d) **Reaction with Phenyldichlorophosphine.**—A solution of 6.0 g. (0.0114 mole) of I in 40 g. (0.22 mole) of phenyldichlorophosphine was agitated at 70–80° at 35 mm. for 3 hr. CH_3PCl_2 replaced and volatilized was collected in a trap chilled by a bath of Dry Ice and trichloroethylene. The trap was found to contain 5.1 g. of pure CH_3PCl_2. This recovery represented 96% of theory. Excess phenyldichlorophosphine was removed by vacuum distillation of the orange reaction product, leaving an oil which readily crystallized. This residue was washed with *n*-pentane to remove residual phenyldichlorophosphine and then recrystallized from diethyl ether. The recovery of bright yellow product was rather low (57% yield) due to its great solubility in the solvent. It is believed the true yield of $Ni(C_6H_5PCl_2)_4$ was nearly quantitative. The product melted at 91–94°; since the reported value is 86.5°,[5] the solid was recrystallized again. It then melted at 93–94° after sintering at 91–92°. Analysis indicated it to be high purity $Ni(C_6H_5PCl_2)_4$.

Anal. Calcd. for $C_{24}H_{20}Cl_8NiP_4$: Cl, 36.6; Ni, 7.58; P, 16.0. Found: Cl, 36.4; Ni, 7.40; P, 15.9.

Kinetic Studies of Thiourea Derivatives. II. The Dimethylthioureas[1]

By William H. R. Shaw and David G. Walker

Received February 11, 1957

unsym-Dimethylthiourea isomerizes in aqueous solutions at elevated temperatures to form dimethylammonium thiocyanate. Experimental first-order rate constants for this reaction under a variety of conditions have been obtained. The isomerization is *p*H independent over a wide range and no effect of ionic strength was observed. At high *p*H, however, a complicating parallel reaction takes place. The behavior of *sym*-dimethylthiourea also has been examined. This compound decomposes to form methylamine and methyl isothiocyanate as primary products. Additional reactions by the product species occur. Rate constants and Arrhenius parameters for the isomerization of *unsym*-dimethylthiourea and for the decomposition of the symmetrical derivative are reported. All of the findings are discussed in terms of a possible mechanism.

Introduction

A few papers[2,3] on the chemistry of the dimethylthioureas have recently become available, but no work concerned with the kinetic behavior of these compounds could be found in the literature. Since data on both symmetrical and unsymmetrical dimethylthiourea would be of obvious value in any theoretical interpretation of the relative reactivity of thiourea derivatives, the present[4–7] study was undertaken.

Experimental

Apparatus and Technique.—The apparatus and technique used in the kinetic runs have been described in detail in earlier publications.[5–7]

Analytical Methods.—Ammonium, methylammonium and dimethylammonium ions were separated from the reaction mixture by passing the experimental solution through a cation-exchange column as previously described. Elution was effected by 20 ml. of 0.1 *N* NaOH, at the usual flow rate. This slight modification was necessary to ensure quantitative elution of the dimethylamine. After elution aliquots of the neutralized elutriate were used to determine ammonia,[5] methylamine[7] and dimethylamine[8] by spectrophotometric analyses described in detail elsewhere.

The ammonia analysis was not affected by dimethylamine in the concentrations encountered. As previously reported, however, methylamine exerted a moderate interference but suitable corrections could be made.

The methylamine analysis was unaffected by the ammonia and dimethylamine concentrations prevailing in the reaction mixtures. The dimethylamine analysis was similarly uninfluenced by ammonia and methylamine.

Thiocyanate ion was determined spectrophotometrically as before.[6] No significant interference by ammonia, methylamine, dimethylamine or the dimethylthioureas was encountered.

The average deviation of a set of 12 analyses of 0.3 m*M* dimethylamine was 7.0%. The average deviations for the other analyses have been reported in earlier work.

Compounds.—*sym*-Dimethylthiourea (1,3-dimethyl-2-thiourea) was prepared by the addition of methylamine to methyl isothiocyanate.[9] The product was separated as an oil from water solution twice and then finally crystallized, m.p. 64° (lit.[10] 61°) from benzene which had been partially distilled to remove the last traces of moisture.

Anal. Calcd. for $C_3H_8N_2S$: C, 34.6; H, 7.79; N, 26.9. Found: C, 34.8; H, 7.78; N, 27.0.

unsym-Dimethylthiourea (1,1-dimethyl-2-thiourea) was prepared by the addition of H_2S to dimethylcyanamide.[11]

Results

The rates of formation of four possible reaction products: (1) thiocyanate ion, (2) ammonia, (3) methylamine, and (4) dimethylamine were followed; corresponding empirical first-order rate constants: k_1, k_2, k_3 and k_4 were calculated by the initial rate equation presented before.[7]

The decomposition of *sym*-dimethylthiourea in water solution at elevated temperatures gave methylamine as one reaction product. Carbon oxysulfide also was formed. No thiocyanate, ammonia or dimethylamine could be detected by our rather sensitive analytical techniques. If these products were formed at all, the empirical constants: k_1, k_2 and k_4 characterizing their rate of formation at 100° must be less than: 10^{-10} sec.$^{-1}$, 10^{-9} sec.$^{-1}$ and 10^{-9} sec.$^{-1}$, respectively. Consequently the only rate constants reported for this compound are based on the rate of methylamine formation divided by two. At 100.0 ± 0.1° for reaction times varying from 6.75 to 24.0 hr. the numerical value for k_3 was found to be $2.50 \pm 0.16 \times 10^{-7}$ sec.$^{-1}$. This value was obtained with average *sym*-dimethylthiourea concentrations ranging from 19.4 to 992 mM in solutions that were also 0.005 M in H_2SO_4. Thus, in acidic media, the empirical first-order constant, k_3, was found to be independent of average *sym*-dimethylthiourea concentration, $\bar{u}$, and reaction time, t. Consequently the decomposition of this compound can be regarded as a first-order reaction producing methylamine and carbon oxysulfide as ultimate products in acid solution.

In neutral and alkaline media more complex behavior was observed (Fig. 1), and a faint precipitate of mercuric sulfide was detected at *p*H 9.1 by our usual test. The amount of precipitate increased with increasing *p*H. These findings are analogous to results reported with methylthiourea.[7] Thus the *p*H dependence of k_3 in basic solutions can be rationalized by postulating the occurrence of a significant amount of reverse reaction (synthesis of reactant from products); and the formation of sulfide can be explained by assuming the onset of a base-catalyzed parallel reaction (see Discussion).

Runs were also made at different temperatures (Table IA) and in acid media of varying ionic strength. Samples initially 40 mM in *sym*-dimethylthiourea and 12 mM in H_2SO_4 were subjected to a reaction time of 16.8 hr. at 100°. These samples also contained added sodium sulfate ranging in concentration from 0.00 to 0.50 M. No salt effects were encountered.

unsym-Dimethylthiourea was studied in a similar fashion. Two reaction products: thiocyanate and dimethylamine were found in all reaction mixtures. The empirical constants k_1 and k_4 based on these products were independent of $\bar{u}$, t and *p*H (Fig. 2) over a wide range. These findings are in sharp contrast to results noted above with *sym*-dimethylthiourea. The behavior of k_1, however, is similar to that of analogous constants obtained with methylthiourea and thiourea. No conversion of thiocyanate to ammonia was observed in the low *p*H range. This conversion has been noted before; but, because the increased reactivity of *unsym*-dimethylthiourea made a shorter reaction time possible, this reaction was not important in the present work. No methylamine was detected in any of the experimental solutions. At *p*H 12.6, however, ammonia was observed ($k_2 = 38 \times 10^{-7}$ sec.$^{-1}$), the rate of dimethylamine production increased ($k_4 = 54 \times 10^{-7}$ sec.$^{-1}$), and a strong positive test for sulfide ion was obtained. Neither ammonia nor sulfide ion was detected in solutions of lower *p*H. All of these results point, as in previous work, to the onset of a base-catalyzed parallel reaction that produces ammonia and dimethylamine in equimolar amounts.[12] In acid media, neutral solutions, and solutions up to *p*H 11.4, however, k_1 and k_4 were extremely well behaved constants. At 100 ± 0.1° the numerical values for k_1 and k_4 were: $16.7 \pm 1.5 \times 10^{-7}$ sec.$^{-1}$ and $16.9 \pm 1.20 \times 10^{-7}$ sec.$^{-1}$, respectively. The fact that $k_1 = k_4$ within experimental error over this wide range of conditions established the stoichiometry of the reaction rather rigidly. Moreover, a neutral 42.6 mM solution of *unsym*-dimethylthiourea when heated for 90 hours at 127° gave the

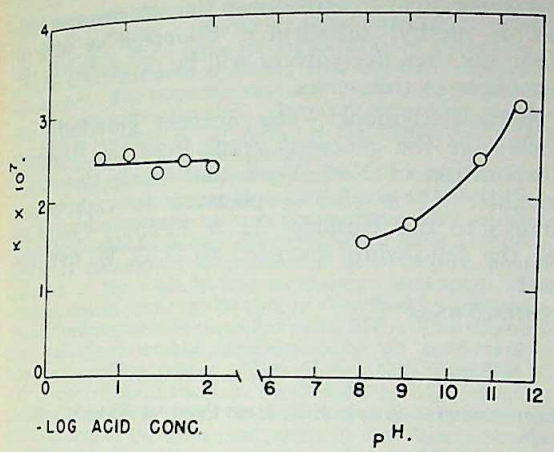

Fig. 1.—Empirical first-order rate constant obtained with *sym*-dimethylthiourea as a function of acid concentration. The constant k_3 is based on the rate of formation of methylamine divided by two. Runs above *p*H 7 were made in buffered 0.071 *M* borax solutions. Results recorded below *p*H 7 were made in H_2SO_4 solutions. All solutions were initially 0.040 *M* in *sym*-dimethylthiourea. Reaction times were 16.83 hours for the high *p*H run and 24.0 hours for the low *p*H run. All measurements were made at 100°.

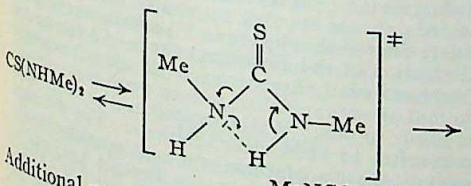
following analysis: thiocyanate, 42.3 ± 0.5 m*M*; dimethylamine, 39 ± 3 m*M*. Thus, like thiourea, the synthesis of the parent compound from the decomposition products in aqueous media must be very slight. In the absence of solvent, however, equilibrium mixtures of *unsym*-dimethylthiourea and dimethylammonium thiocyanate have been reported[13] to contain 16.9% *unsym*-dimethylthiourea and 80.4% dimethylammonium thiocyanate at 130°. In summary, then, the decomposition of *unsym*-dimethylthiourea is a first-order reaction producing dimethylammonium thiocyanate. The decomposition[14] is not catalyzed by hydrogen or hydroxide ions and is unaffected by ionic strength. Rate constants for this reaction at different temperatures also were obtained (Table I).

Discussion

By analogy to previous work[6] a plausible reaction mechanism for *sym*-dimethylthiourea can be written as



$$MeNCS + MeNH_2 \quad (1)$$

Additional reactions by the products include

$$MeNCS + H_2O \longrightarrow MeNH_2 + COS\uparrow \quad (2)$$

$$MeNH_2 + H^+ \rightleftharpoons MeNH_3^+ \quad (3)$$

$$MeNCS + MeNH_2 \longrightarrow CS(NHMe)_2 \quad (4)$$

In acid solution the experimental rate constant, k_3, is presumably the result of reaction 1 followed quickly by reactions 2 and 3. Reaction 4 does not occur, being suppressed by the rapid occurrence

(13) H. Salkowski, *Ber.*, **26**, 2497 (1893).

(14) The hydrolytic reaction[12,15] is, however, catalyzed by hydrogen ions.

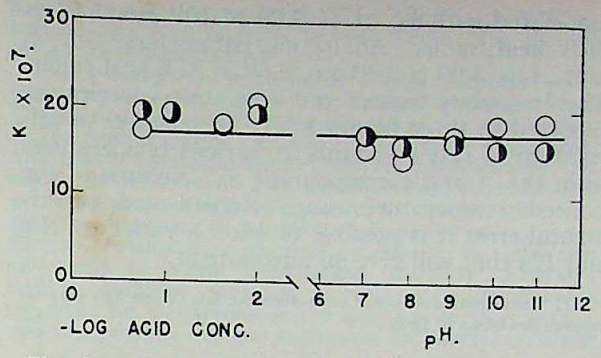


Fig. 2.—Empirical first-order rate constants obtained with *unsym*-dimethylthiourea as a function of acid concentration. The constants k_1 (O) and k_4 (◑) are based on the rate of formation of thiocyanate and dimethylamine, respectively. Runs above *p*H 7 were made in buffered 0.008 *M* borax solutions. Results recorded below *p*H 7 were made in HNO_3 solutions. An initial concentration of 42.7 m*M* *unsym*-dimethylthiourea was used with reaction times of 5.47 hours on the acid side and 4.17 hours on the high *p*H side. All data were collected at 100°.

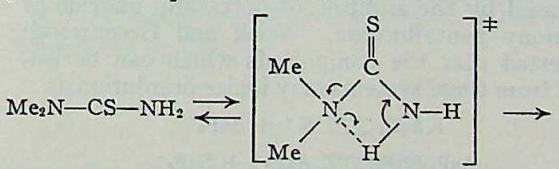
of reactions 2 and 3. In neutral and basic solutions, however, reaction 4 does take place. In alkaline media, a parallel base-catalyzed reaction, producing H_2S and an unstable fragment[15] which further decomposes to yield methylamine, is also present.

A similar mechanism for *unsym*-dimethylthiourea would predict two primary reaction products produced in equimolar amounts



$$Me_2NH + HNCS \quad (5)$$

Also

$$HNCS \longrightarrow H^+ + NCS^- \quad (6)$$

$$Me_2NH + H^+ \rightleftharpoons Me_2NH_2^+ \quad (7)$$

No significant synthesis (reverse of reaction 5) is possible in aqueous media since HNCS is a strong acid. The rate constants (Fig. 2) are, consequently, *p*H independent.

The absence of methylamine in *unsym*-dimethylthiourea reaction mixtures and the lack of dimethylamine in *sym*-dimethylthiourea reaction solutions is strong experimental proof that the methyl groups do not migrate during reaction. Thus all products can be predicted by assuming intramolecular hydrogen transfer and dissociation of the activated complex as indicated (reactions 1 and 5).

Over the temperature range studied, the rate constants for the decompositions of the dimethylthioureas follow the simple Arrhenius relationship. A least squares analysis of the data presented in Table I gave the following Arrhenius parameters[16]

(15) Perhaps a carbodiimide is formed which undergoes further reaction with the solvent. See for example: H. G. Khorana, *Chem. Revs.*, **53**, 145 (1953).

(16) These parameters will reproduce the rate constants in Table IA within the average deviation at 3%.

associated with k_3: $A = 3.69 \times 10^{14}$ sec.$^{-1}$, $E = 36.3$ kcal./mole. Analogous parameters[17] for k_1 are: $A = 3.90 \times 10^{14}$ sec.$^{-1}$, $E = 34.6$ kcal./mole. The frequency factors and activation energies are reported to three figures solely for purposes of calculation of rate constants at various temperatures from the A and corresponding E. Because of the limited temperature range studied and experimental error it is possible to select a variety of A's and E's that will give an adequate fit.

(17) These parameters will reproduce the k_1's (Table IB) with an average deviation of 10%.

A theoretical discussion of the relative reactivities of methyl substituted thioureas as well as other thiourea derivatives will be presented in the last paper of this series.

Fluoroarsenites

BY E. L. MUETTERTIES AND W. D. PHILLIPS

RECEIVED MARCH 21, 1957

The interactions of several inorganic fluorides with arsenic trifluoride were examined and a physical characterization of some of these systems was made. Some monovalent fluorides formed solids of the composition $MAsF_4$. The stability of these fluoroarsenites appeared to be inversely related to the polarizing power of the cation. Dissociation of the fluoroarsenites was very high in the fused state, and in arsenic trifluoride solution they underwent rapid fluorine exchange. The existence of the tetrafluoroarsenite anion in melts and in solution could therefore not be established by n–m–r data. A bridged structure is suggested for the antimony pentafluoride complex: $F_4Sb(F)_2AsF_2$.

Introduction

The conductivity of arsenic trifluoride is greatly increased by the addition of potassium fluoride or antimony pentafluoride. Woolf and Greenwood[1] suggested that the compounds which can be isolated from these systems may ionize in solution as

$$KAsF_4 \rightleftharpoons K^+ + AsF_4^-$$

$$AsF_3 \cdot SbF_5 \rightleftharpoons AsF_2^+ + SbF_6^-$$

This present study was undertaken to gain a more general understanding of the behavior of arsenic trifluoride toward inorganic fluorides and an attempt also was made to determine the structure of the complex fluorides obtained from some of these systems.

Experimental

Materials and Apparatus.—Arsenic trifluoride was stored in contact with sodium fluoride and was distilled (b.p. 60.3° (760 mm.)) prior to use. Commercial samples of the alkali metal and thallous fluorides were used. These fluorides all totaled at least 98% metal and fluorine after vacuum drying at 100–250°. Baker and Adamson antimony pentafluoride was distilled before use. Matheson tank boron trifluoride was stored over sodium fluoride to remove any traces of hydrogen fluoride.

Dissociation pressures were determined in an isoteniscope. With this apparatus, cathetometer readings of the manometer had a precision of ±0.5 mm. which proved to be much better than the reproducibility of the actual dissociation pressures of various samples. The fluorine magnetic resonance spectra were obtained using a Varian high resolution n–m–r spectrometer and electromagnet[2] at a frequency of 30 Mc. and a magnetic field of 7,500 gauss. Spectra were calibrated in terms of displacements in cycles per second (c.p.s.) from the fluorine resonance of CF_3COOH. Positive frequency displacements indicate resonances occurring at lower fields than the fluorine resonance of CF_3COOH. Calibration was accomplished by superimposing an audio-frequency on the sweep field to produce side band peaks to the CF_3COOH resonance.[3]

Preparation of Fluoroarsenites.—The fluorides of potassium, rubidium, cesium and thallium all reacted spontaneously and quite exothermally with arsenic trifluoride. Because the products of these reactions had limited solubility in arsenic trifluoride, the fluoroarsenites were prepared in pressure vessels at 80° to ensure complete reaction. Three hour reaction periods proved satisfactory for quarter-mole quantities of the metal fluoride; a 300% excess of arsenic trifluoride was used. The products, which were slurries, were filtered and the solids were recrystallized from arsenic trifluoride.

Anal. Calcd. for $KAsF_4$: K, 20.6; As, 39.4; F, 40.0. Found: K, 19.91; As, 39.21; F, 39.45. Calcd. for $CsAsF_4$: Cs, 46.8; As, 26.4; F, 26.8. Found: Cs, 47.3; As, 26.96; F, 27.06. Calcd. for $TlAsF_4$: Tl, 57.6; As, 21.1; F, 21.4. Found: Tl, 57.61; As, 21.59; F, 20.61.

Lithium and sodium fluorides did not react with arsenic trifluoride. Treatment of these fluorides with liquid arsenic trifluoride at temperatures up to 160° in pressure vessels yielded only the starting materials. Analyses of the solid products showed that less than 1% arsenic was present.

Characterization of the Fluoroarsenites.—All the fluoroarsenites were extremely hygroscopic: 30 seconds exposure to fairly humid air was sufficient to turn tenth-gram quantities of the solids to oils. Water reacted exothermally with the fluoroarsenites to yield clear solutions. The F^{19} magnetic resonance spectra of these solutions consisted solely of a rather broad resonance in the fluoride ion region. There was no evidence for a fluoroarsenite ion, *e.g.*, AsF_4^- or $AsOF_2^-$, in aqueous solution, but such an ion could be present in very low concentration and in equilibrium with fluoride and arsenite ions.

Saturated solutions of the fluoroarsenites in arsenic trifluoride at 30° contained 2% K, 6% Rb, 8% Cs and 11% Tl, respectively. Such solutions had a F^{19} magnetic resonance spectrum that consisted of a single resonance, shifted slightly from that of arsenic trifluoride toward a position denoting higher shielding: δ for AsF_3 = 1050 c.p.s. and δ for $KAsF_4$ in AsF_3 = 1025 c.p.s. The absence of two or

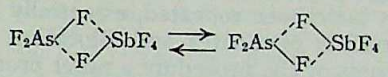
more resonances indicated that fluorine exchange was taking place in this system. (Exchange phenomena of sufficiently high frequency have been shown capable of collapsing a two-line spectrum into a single, concentration-dependent resonance.[4]) The exchange rate was too fast to be "frozen out" by cooling the solutions. It was therefore not possible to establish whether F^- or AsF_4^- is the major conducting species in arsenic trifluoride solution.[5]

The F^{19} magnetic resonance spectrum of a melt of $KAsF_4$ consisted of a single rather broad resonance at +940 c.p.s. The tetrafluoroarsenite anion is isoelectronic with selenium tetrafluoride and thus may be expected to have a trigonal bipyramid structure. The absence of structure in the spectrum of the melt is due to fluorine exchange. The exchange mechanism may be simply described by a dissociation of the fluoroarsenite into AsF_3 and MF. This dissociation was demonstrated tensimetrically at temperatures below the melting points. The dissociation pressures at 100° ranged from 0.18 atm. for $KAsF_4$ to 0.07 atm. for $CsAsF_4$. Equilibria were attained slowly. Because of slight etching of the glass equipment by the fluoroarsenites at 100°, the dissociation pressures are considered to be approximate values.

Covalent Fluorides.—Nuclear magnetic resonance spectra of binary systems of covalent fluorides and arsenic trifluoride were examined in an attempt to gain structural information. Samples were prepared by condensing the fluorides in 5 mm. o.d. Pyrex tubes which were then sealed. Approximately equimolar quantities of the fluorides were used except where excess arsenic trifluoride was necessary to prevent solid formation.

Although boron trifluoride slightly increases the conductivity of arsenic trifluoride, no evidence for interaction of these two liquids was obtained at temperatures up to ~ −10° or between liquid arsenic trifluoride and gaseous boron trifluoride up to 30°. The characteristic resonances of the components were observed. Woolf and Greenwood[1] have suggested the possibility of an unstable $AsF_2^+BF_4^-$ compound in such mixtures but the n–m–r data give no support to this suggestion.[6]

The F^{19} magnetic spectrum of arsenic trifluoride–antimony pentafluoride consisted of a single resonance peak. The position of the peak was between the resonance positions of the pure fluorides and was concentration dependent. Any type of compound formed between the antimony and arsenic fluorides would have non-equivalent fluorines and would present two or more peaks in the fluorine spectrum. Absence of structure in the spectrum is attributed to a rapid fluorine exchange (low temperature did not slow the rate sufficiently to permit a structural analysis). Although lacking conclusive evidence, a bridge-type structure is suggested for this system in the liquid state since such a structure provides a simple mechanism for fluorine exchange



A bridge structure is supported by related data. Bridge-type structures have been cited as intermediates for fluorine exchange in halogen fluorides.[7] Antimony pentafluoride appears to have bridge-bonding[8] and a bridge intermediate has been proposed for chlorine exchange between antimony (III) and antimony(V).[9] It should be noted that a simple coördination complex $F_5Sb–AsF_3$ is not acceptable as an intermediate for exchange since dissociation of such a complex would not involve cleavage of As–F or Sb–F bonds.

(4) H. S. Gutowsky and A. Saika, *J. Chem. Phys.*, **21**, 1688 (1953).

(5) Although the fluoroarsenites are undoubtedly composed of M^+ and AsF_4^- aggregates in the solid state, it does not necessarily follow that the tetrafluoroarsenite anion is the major anion in AsF_3 solution. The equilibrium for AsF_4^-(soln) ⇌ AsF_3 + F^-(soln) may be far to the right.

(6) It should be noted that an $AsF_2^+BF_4^-$ intermediate could be present to concentrations involving approximately 5% of the total fluorine and not be detected. However, if this intermediate is present, rapid equilibration between the components and the intermediate does not occur. Rapid equilibration would yield a single F^{19} resonance rather than the observed, non-perturbed resonances of the components.

Di-*t*-butylberyllium and Beryllium Hydride[1]

By E. L. Head, C. E. Holley, Jr., and S. W. Rabideau

Received December 6, 1956

Methods are described for the preparation of pure di-*t*-butylberyllium and for the preparation of beryllium hydride (approx. 80 wt. %) by the pyrolysis of both pure di-*t*-butylberyllium and its etherate. Pure di-*t*-butylberyllium is a clear, colorless, mobile liquid with a density of 0.65 g./cc. and a freezing point of −16°. When freshly prepared it has a vapor pressure of about 35 mm. at 25°; on standing it undergoes slow decomposition at room temperature with the evolution of isobutene. Beryllium hydride prepared by pyrolysis of di-*t*-butylberyllium has a density of about 0.57 g./cc., evolves hydrogen slowly at 190 to 200° and rapidly at 220°, is relatively inert to laboratory air, and reacts slowly with water and rapidly with acid. It was analyzed by chemical and microscopic methods. It gave no X-ray pattern.

Introduction

The preparation of beryllium hydride has been announced by a number of workers. In view of the apparently tenuous nature of some of the published results, the present authors, with others,[2] have investigated these procedures in considerable detail. Attempts to prepare beryllium hydride by heating beryllium in atomic hydrogen by the method of Pietsch[3] were unsuccessful. A surface reaction between excess lithium hydride and beryllium chloride in ether solution was observed as described by Wiberg and Bauer,[4] but separation of the product, which contained organic material, from the excess lithium hydride could not be accomplished and analysis was not possible. There seems to be little direct evidence for identifying this material as beryllium hydride.

(1) This work was done under the auspices of the Atomic Energy Commission.

(2) Some 30 staff members of this Laboratory have contributed to the program to a greater or lesser extent. In addition to procedures mentioned here, preparation of beryllium hydride was attempted by many other methods, including direct combination of the elements under various conditions, reduction of inorganic salts and reduction of beryllium alkyls with various reducing agents. Experiments on the reaction between lithium aluminum hydride and dimethylberyllium in diethyl ether essentially confirm the results of Schlesinger and co-workers.[5] Our best product, out of some 30 preparations, contained 60+% BeH_2,[6] and was contaminated with several per cent. each of lithium hydride and aluminum hydride, or possibly lithium aluminum hydride, and ether, which was the major impurity.

Recently Coates and Glockling[7] reported the preparation of beryllium hydride by the pyrolysis of di-*t*-butylberyllium etherate to give a product containing 71% BeH_2 (96.5 mole %). These experiments have been repeated, essentially confirming the results of Coates and Glockling, and by modifications of the procedure a purer product was obtained. Also, a method for the preparation of ether-free di-*t*-butylberyllium has been developed. These latter experiments are described below along with the results of the determination of some of the properties of the beryllium hydride thus obtained.

Preparation of Di-*t*-butylberyllium Etherate.—The di-*t*-butylberyllium etherate was prepared from *t*-butylmagnesium chloride and beryllium chloride in diethyl ether solution following the directions of Coates and Glockling[7] as closely as possible. The product was analyzed by hydrolysis and found to contain 51 to 52 mole % di-*t*-butylberyllium, the remainder being ether, as compared to 55.4 mole % obtained by Coates and Glockling.

Preparation of Ether-free Di-*t*-butylberyllium.—Attempts to increase the di-*t*-butylberyllium content to higher values according to the directions of Coates and Glockling were unsuccessful. An investigation was then made of the effect on the etherate of etherphilic substances such as $AlCl_3$, BF_3 and $BeCl_2$. The first two gave complicated reactions but treatment with anhydrous beryllium chloride was successful in giving pure di-*t*-butylberyllium. A typical preparation is described below.

In an inert atmosphere (N_2), approximately 7.5 g. of anhydrous $BeCl_2$ and a glass-enclosed iron stirring bar were put into a reaction flask fitted with a stopcock and ground joint for attaching to the vacuum line, and a seal-off constriction and ground joint for introducing the di-*t*-butylberyllium etherate, the latter joint plugged with a rubber stopper. After connecting the flask to the vacuum line, the rubber stopper was removed and the ground joint on the end of a glass ampoule containing approximately 24 g. of di-*t*-butylberyllium etherate (15 g. di-*t*-butylberyllium) was inserted. (These quantities correspond to a 50% excess of $BeCl_2$ if each $BeCl_2$ molecule accepts two ether molecules.) The flask was then evacuated, the stopcock closed, the break-off seal in the end of the ampoule broken, and the di-*t*-butylberyllium allowed to drain into the flask onto the beryllium chloride, the last portion being driven into the reaction flask by heating the ampule with a hair dryer. Upon completion of the transfer the flask was cooled with liquid nitrogen and the ampule and ground joint removed by sealing at the seal-off. This procedure permitted a transfer without exposure to the atmosphere with the possibility of weighing by difference the amount of di-*t*-butylberyllium etherate used.

The contents of the flask were stirred magnetically for several hours at room temperature, usually overnight, after which the stopcock was opened and the contents exposed at room temperature to a −80° trap followed by a −195° trap to collect the volatile constituents. In addition to di-*t*-butylberyllium, some isobutane and isobutene were formed, which were soluble in it but which could be separated from it and collected in the −195° trap by alternate freezing and thawing. Some of this gas may have been present in the original di-*t*-butylberyllium etherate, but some probably was formed during the reaction with beryllium chloride or by subsequent slow decomposition of the ether-free di-*t*-butylberyllium.

The yield of ether-free di-*t*-butylberyllium was about 40% of the amount expected on the basis of the di-*t*-butylberyllium content of the starting material.

A by-product of the treatment with beryllium chloride was a volatile white solid which melted at about 50° and sublimed under vacuum at temperatures just below this. From analysis it was apparently *t*-butylberyllium chloride etherate but it was not otherwise characterized.

Some Properties of Di-*t*-butylberyllium and its Etherate.—Di-*t*-butylberyllium etherate containing 51 to 52 mole % of di-*t*-butylberyllium is a clear, colorless liquid with a density of 0.78 g./cc. Its vapor pressure is a few millimeters at room temperature, and it gave no evidence of decomposition.

The freshly prepared ether-free material is a clear, colorless, mobile liquid with a density of 0.65 g./cc.; and a freezing point of −16°. The freshly prepared material had a vapor pressure of about 35 mm. at 25°. A reliable figure could not be obtained since at room temperature the compound decomposed slowly with the liberation of isobutene and apparently with the polymerization of the remaining liquid. After standing for seven weeks under its own vapor, it could not be distilled quantitatively.

Pyrolysis of Di-*t*-butylberyllium and its Etherate.—When the pyrolysis of di-*t*-butylberyllium etherate was carried out as described by Coates and Glockling,[7] using a closed vessel up to a temperature of 150° and a vacuum at higher temperatures, considerable amounts of ethane were formed and a product containing only 40% BeH_2 was obtained. The pyrolysis was repeated using a vessel equipped with a cold finger maintained at −20°. The di-*t*-butylberyllium was refluxed under vacuum by means of an oil-bath which was slowly raised to 200°. The volatile decomposition products were collected in a liquid nitrogen cold trap and thus prevented from possible reaction with beryllium hydride. The product analyzed 80% BeH_2, the remainder being mostly ether. This is equivalent to 97 mole %, assuming ether to be the only impurity. Between 190 and 200° the loss of hydrogen from the product was detectable, but negligible in 1 hr.; at 220° the hydrogen loss was rapid.

Pyrolysis of ether-free di-*t*-butylberyllium could not be carried out in this apparatus because of its high volatility. Since no ether was present to react with the beryllium hydride, it could be pyrolyzed, first in a closed system until its volatility became negligible, and then under vacuum. In this way a product was obtained which again contained about 80% BeH_2, the impurity probably being unreacted *t*-butyl groups, however, instead of ether.

Vapor phase pyrolysis of pure di-*t*-butylberyllium was attempted by passing it repeatedly through a hot tube. This was not successful. At temperatures between 150 and 210° most of the material passed through the tube and condensed as a liquid of low volatility, and above 210° the beryllium hydride decomposed rapidly.

Analyses.—Samples of di-*t*-butylberyllium and its pyrolysis products were hydrolyzed, and the resulting gases were measured and analyzed with the mass spectrometer. The solutions from the hydrolyses were analyzed for beryllium and chlorine and in the case of the di-*t*-butylberyllium etherate, for magnesium also. A combustion analysis for carbon and hydrogen also was carried out on some of the pyrolysis products using the method of Head and Holley.[8]

Some typical analytical results with a possible interpretation follow.

1. **Hydrolysis of Di-*t*-butylberyllium Etherate.**—A typical sample (weighing approximately 0.6 g.) on hydrolysis was found to contain 36.1% ether, and isobutane and isobutene (4:1 molar ratio) equivalent to 61.7% di-*t*-butylberyllium, or a total of 97.8% of the original sample.

Analysis of the hydrolysis solution showed beryllium equivalent to 66.6% di-*t*-butylberyllium or, including the ether, a total of 102.7% of the original sample. On a molar basis the sample was about 51% di-*t*-butylberyllium.

Several points deserve comment. First, isobutene was always evolved on hydrolysis. If its origin is the decomposition of di-*t*-butylberyllium, a corresponding amount of hydrogen should be observed. Although hydrogen was occasionally found, it was not observed in this instance. Second, the discrepancies in material balance are probably within experimental error, since the individual analyses are accurate, at best, to only 1%. It was observed in each of five different preparations that the ether content was slightly less than 50 mole %.

2. **Hydrolysis of Beryllium Hydride Prepared by the Pyrolysis of Di-*t*-butylberyllium Etherate.**—A sample (approximate weight 19 mg.) of the best preparation of beryllium hydride from di-*t*-butylberyllium etherate was found on hydrolysis to liberate hydrogen equivalent to 81% BeH_2. Analysis of the hydrolysis solution showed beryllium equivalent to 79% BeH_2. The check between the beryllium found and the hydrogen observed is within the expected analytical error, so the major impurity is not a beryllium compound and is probably ether. In this sample the hydrolysis gases were not analyzed for ether and isobutane. In other samples both ether and isobutane in varying ratios were found in addition to the hydrogen. The purity of most preparations was between 76 and 80%.

3. **Combustion Analysis of Beryllium Hydride Prepared by the Pyrolysis of Di-*t*-butylberyllium Etherate.**—A sample (weight 33 mg.) on combustion gave CO_2 equivalent to an ether content of 21%. The hydrogen (determined as water) in excess of the stoichiometric amount required for ether corresponded to a BeH_2 content of 76%. Analysis of this material by the hydrolysis procedure also indicated a BeH_2 content of 76%. The ether and BeH_2 calculated in this manner account for 97% of the original sample weight.

4. **Hydrolysis of Di-*t*-butylberyllium.**—Hydrolysis of a sample of the best di-*t*-butylberyllium (weight 225.2 mg.) gave isobutane and isobutene (molar ratio 60:1) equivalent to 101% di-*t*-butylberyllium. (Half as much hydrogen was observed as isobutene.) Analysis of the hydrolysis solution showed an equivalent amount of beryllium (17.5 mg. found, 16.8 mg. expected).

5. **Hydrolysis of Beryllium Hydride Prepared by Pyrolysis of Di-*t*-butylberyllium.**—A sample weighing 17.9 mg. gave, on hydrolysis, hydrogen equivalent to 80.5% BeH_2 and isobutane equivalent to 17.8% di-*t*-butylberyllium, giving a total of 98.3% of the sample. Analysis of the hydrolysis solution showed beryllium equivalent to 99% of the beryllium calculated from the gas analysis (the di-*t*-butylberyllium contributes a minor amount of beryllium to the solution). This is the best sample of beryllium hydride prepared by pyrolysis of ether-free di-*t*-butylberyllium.

Properties of Beryllium Hydride.—The density of the product was estimated from the fact that it sank in liquid ethane at −110°, but floated at lower temperatures. The density of ethane is 0.561 g./cc. at −100°,[9] and the density of the product is estimated to be 0.57 ± 0.02 g./cc. at −110°. Since the product is 97 mole % BeH_2, it is probable that the density of pure BeH_2 would not differ significantly.

Beryllium hydride prepared by pyrolysis is relatively inert to laboratory air. A 26-mg. sample containing 76% BeH_2 gained 0.8 mg. on exposure to laboratory air for eight days and the BeH_2 content decreased to 72%. The product reacts slowly with water but vigorously with dilute mineral acid.

The product prepared from ether-free reagent was not altered by treatment with ethereal $LiAlH_4$.

A microscopic examination of the product prepared from the etherate showed it to be heterogeneous, consisting of optically isotropic grains, with refringence near 1.58, which contained optically anisotropic inclusions with much lower refringence, densely but non-uniformly distributed. The grain size of the inclusions was several tenths of a micron. The two constituents appeared to be present in approximately equal amounts.

X-Ray examination of the product prepared from di-*t*-butylberyllium gave no lines attributable to BeH_2.

Acknowledgments.—The authors wish to express their appreciation to J. F. Lemons for his encouragement and helpful suggestions; C. Apel, A. W. Mosen, and G. Warren for chemical analyses; F. H. Ellinger for X-ray analyses; E. Staritzky for microscopic analyses; and P. Fain, R. Kandel and E. D. Loughran for mass spectrometric analyses.

Electrolyte Catalysis. III. The Cleavage of Benzyl Phenyl Ether by Hydrogen Bromide in Nitrobenzene, Chloroform and Carbon Tetrachloride

BY A. V. DRUMMOND AND A. M. EASTHAM

RECEIVED AUGUST 27, 1956

The kinetics of the cleavage of benzyl phenyl ether by hydrogen bromide in nitrobenzene and chloroform have been determined and the effects of five substituted ammonium bromides on the rate of reaction in these solvents examined. The rate of cleavage in carbon tetrachloride solution is negligibly small but is subject to heterogeneous catalysis by several solid salts. Mechanisms are suggested for the cleavage and its catalysis by electrolytes.

Earlier work in this Laboratory[1,2] showed that several reactions involving the cleavage of a C–O bond were catalyzed by electrolytes in non-aqueous solvents. The salts had considerable specificity in their catalytic powers and it was suggested that the electrolyte facilitated the charge transfers which occurred during the reaction.

In order to obtain more information about this type of catalysis, the cleavage of ethers by hydrogen bromide has now been studied. Walvekar, *et al.*,[3] have reported that this reaction is catalyzed by amine salts in carbon tetrachloride and *n*-hexane. It was first necessary to establish the kinetics of the uncatalyzed reaction for, although the similar cleavage by hydrogen iodide is widely used, little work has been done on the mechanism of this type of reaction.[4]

Since cleavage of ethers by hydrogen bromide is much slower than that by hydrogen iodide, benzyl

phenyl ether was used throughout the work in order to obtain a convenient rate of reaction. The solvents nitrobenzene and chloroform were chosen for their widely different dielectric constants and good solvent properties. The salts used as catalysts were necessarily all bromides in order to avoid uncertainty as to the acid species present.

Experimental

Materials.—Technical nitrobenzene was steam distilled from 2 *N* sulfuric acid, washed with water and dried over calcium chloride. After standing for 12 hr. over phosphorus pentoxide it was filtered and distilled rapidly at *ca.* 10 mm. pressure. The distillate was shaken with dry activated alumina for 8 hr. and filtered before carefully fractionally distilling at *ca.* 5 mm. The product was pale yellow and did not darken on standing over phosphorus pentoxide for 24 hr., $n^{25}D$ 1.5499–1.5500.

C.P. chloroform was shaken with a large amount of calcium chloride. After filtering, it was refluxed over phosphorus pentoxide in an atmosphere of dry nitrogen for 2–3 hr. and was allowed to cool with nitrogen bubbling through. It was then decanted on to fresh phosphorus pentoxide and, after flushing out very thoroughly with nitrogen, was fractionally distilled. The pure chloroform was collected and stored in blackened vessels under nitrogen. The infrared and mass spectra showed no trace of ethanol. After removing the ethanol present in C.P. chloroform it is essential to keep the liquid out of contact with air; accordingly, all vessels were thoroughly flushed out with dry nitrogen before being used with chloroform solutions.

C.P. carbon tetrachloride was passed down silica and alumina columns and was fractionally distilled.

Anhydrous hydrogen bromide was obtained both from a cylinder (The Matheson Co.) and by dropping bromine into dry tetralin. It was stored in solution or in a cold trap at −180°. Benzyl phenyl ether (m.p. 38.9°) was prepared in the usual way[5] from reagent grade phenol and benzyl chloride.

Pyridinium bromide was prepared as previously described.[1] Tri-*n*-butylamine hydrobromide and tetra-*n*-butylammonium bromide were recrystallized from ethyl acetate (m.p. 75.2–75.9° and 117–118°, respectively). Tetra-*n*-propylammonium bromide was recrystallized from ethyl acetate containing 10% absolute ethanol. (*Anal.* Calcd. for $C_{12}H_{28}NBr$: C, 54.15; H, 10.53; N, 5.26; Br, 30.06. Found: C, 54.10; H, 10.58; N, 5.31; Br, 30.09.) Tetraethylammonium bromide was recrystallized from absolute ethanol. (*Anal.* Calcd. for $C_8H_{20}NBr$: C, 45.73; H, 9.59; N, 6.66; Br, 38.03; Found: C, 45.65; H, 9.61; N, 6.70; Br, 38.05.)

Analytical Methods.—Samples of solutions of hydrogen bromide in organic solvents were taken from a buret with the tip held under the surface of 30–40 ml. of aqueous alcohol (60–70% ethanol). They were titrated with standard alkali (brom cresol green indicator) or silver nitrate solution (Ag/AgCl electrode; Fisher Titrimeter). In the latter method alcohol was added during the titration to prevent separation of the solvent. The alkali titration was not affected by small amounts of phenol but the bromide estimation was the more reliable in the presence of appreciable amounts of amine salts.

Kinetics Measurements.—The kinetics of the reaction were determined by measuring the initial rate of consumption of hydrogen bromide. The reaction vessel consisted of a 25-ml. buret fitted with a jacket through which water circulated from a thermostat controlled to within ±0.005°. This buret was sealed to a capillary tube and glass joint with reduced ends, so that it could be filled from the mixing vessel.

Reaction mixtures (30 ml.) were made up in a small flask fitted with a ground joint to take the buret, the solution of ether being in a small sealed bulb. This flask was attached to the elongated buret tip by the ground joint, zero time was taken on breaking the sealed bulb and, after stirring magnetically, the solution was forced up into the reaction buret by nitrogen pressure.

Samples were taken by running out 2 ml. of the solution from the buret. Immediately before sampling, 0.5 ml. of solution was run out and discarded to ensure that the sample came from the main thermostated body of the solution. The first reading was taken after 5 min. and a total of 9 samples was analyzed during the first 5–10% reaction. The initial concentration of hydrogen bromide [HBr] was determined by extrapolating the (straight) line through the experimental points back to zero time. The slope of this line was taken as the initial rate of reaction.

In some experiments in carbon tetrachloride solution a solid salt was placed between two plugs of glass wool at the bottom of the reaction buret. When filling the reaction vessel, all the solution came in contact with the salt. By withdrawing a sample normally, solution which had been standing in contact with the salt was obtained while discarding 2.5 ml. of solution before sampling gave a solution which had had only a short time of contact with the salt. For other experiments with this solvent, the flask in which the reactants were mixed was modified to permit filtering the reaction mixture through sintered glass while forcing it into the buret.

In order to test the quantitative nature of the reaction 22.9 g. of benzyl phenyl ether in nitrobenzene (2.38 *M*) was saturated with hydrogen bromide and left 3 weeks. The solution was extracted with alkali and the phenol estimated by bromide–bromate titration; 6.7 g. of phenol (equivalent to 13.1 g. ether) was found. The organic layer was distilled under reduced pressure yielding 3 fractions: (a) mainly nitrobenzene, (b) 7.9 g. of benzyl phenyl ether, (c) 2.1 g. of high boiling residue. 21 g. (92%) of the original ether was thus found and the remainder was presumed to be in fraction (c). Phenol was therefore formed essentially quantitatively. The other expected product, benzyl bromide, which was detected by its lachrymatory effects, would have distilled in fraction (a) and was not estimated.

Vapor Pressure Measurements.—A modification of the apparatus of Howland, Miller and Willard[6] was used. An all-glass system which could be thoroughly evacuated was constructed and hydrogen bromide was supplied from a cold trap. The solvent was stirred magnetically and surrounded by a water-bath at 10.0 ± 0.06°.

Samples were taken into a sealed, evacuated trap which was attached to the solvent flask by a ground joint. This trap had a calibrated stem in which the volume of solution was measured. The solvent and hydrogen bromide were frozen in liquid nitrogen, the trap removed and excess standard alkali was placed over the sample. After melting, the hydrogen bromide was determined by back titration.

Results

The Reaction in Nitrobenzene at 25.0°.—At least in its initial stages the cleavage of benzyl phenyl ether is second order with respect to the concentration of hydrogen bromide and first order with respect to the concentration of ether. The kinetics of the reaction are expressed by the equation

$$-\frac{d[HBr]}{dt} = k[HBr]^2[C_6H_5OCH_2C_6H_5]$$

in which, at 25°, $k = 0.058 \pm 0.002$ l.^{2} mole^{-2} min.$^{-1}$.

Figure 1 shows the vapor pressure of hydrogen bromide at 10.0° over pure solvent and over solutions of pyridinium, tetra-*n*-propyl- and tetra-*n*-butylammonium bromides. A stable complex MBr·HBr is formed with each salt and these complex salts have distinct "salting-in" effects on the "free" hydrogen bromide in the solution. Within the limits of experimental error, the vapor pressure of hydrogen bromide over solutions of benzyl phenyl ether (up to 0.25 *M*) is the same as that over pure solvent. The salt complex, MBr·HBr, in the ab-

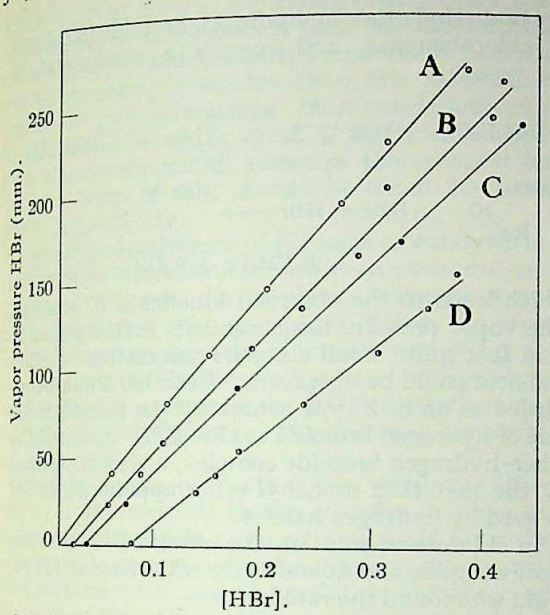

Fig. 1.—Vapor pressure of HBr over nitrobenzene: B, 0.018 *M* tetra-*n*-propylammonium bromide; C, 0.031 *M* pyridinium bromide; D, 0.075 *M* tetra-*n*-butylammonium bromide; A, no added salt.

sence of free HBr reacts only very slowly, if at all, with the ether.

At constant salt concentration the kinetics of the catalyzed cleavage of the ether have the same form as before, *i.e.*

$$-\frac{d[HBr]}{dt} = k'[HBr]^2[C_6H_5OCH_2C_6H_5]$$

where [HBr] is taken as the concentration of hydrogen bromide, outside the MBr·HBr complex. The dependence of k' on the electrolyte concentration is shown in Fig. 2. The catalytic effects of the five salts increase in the order: $C_5H_5NHBr \cong n\text{-}Bu_3NHBr < n\text{-}Bu_4NBr < n\text{-}Pr_4NBr < Et_4NBr$.

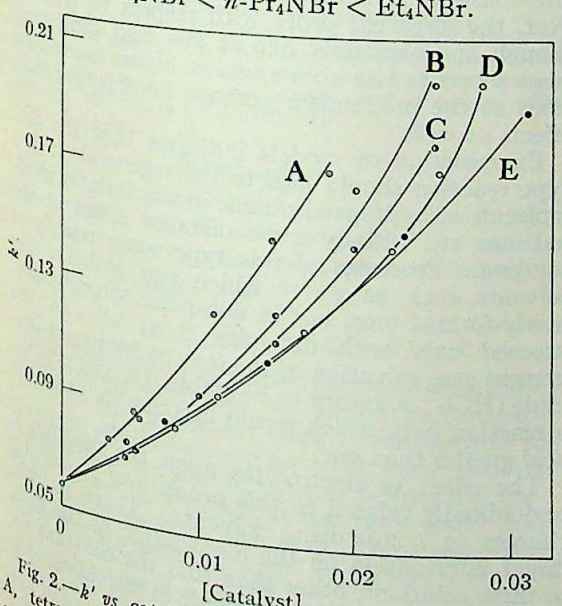

Fig. 2.—k' *vs.* catalyst in nitrobenzene; ether = 0.35 *M*: A, tetra-ethylammonium bromide; B, tetra-*n*-propylammonium bromide; C, tetra-*n*-butylammonium bromide; D, tri-*n*-butylammonium bromide; E, pyridinium bromide.

Water, ethanol and phenol also catalyze the reaction. Phenol, a product of the reaction, is less active than the other compounds and did not cause significant error in the initial rate measurements.

Reaction in Chloroform at 40.0°.—The cleavage is much slower in chloroform than in nitrobenzene and experiments were therefore done at a higher temperature. Initial rates for the uncatalyzed reaction were again first order with respect to the concentration of ether but showed a complex dependence of the initial rate upon the initial concentration of hydrogen bromide. It was impossible, with the experimental method used, to maintain a fixed and reproducible initial concentration of hydrogen bromide, so the initial rates were corrected to a chosen standard concentration of hydrogen bromide. The corrections, which very rarely exceeded 5–10%, were made on the basis of curve A in Fig. 3. The "standard" concentration

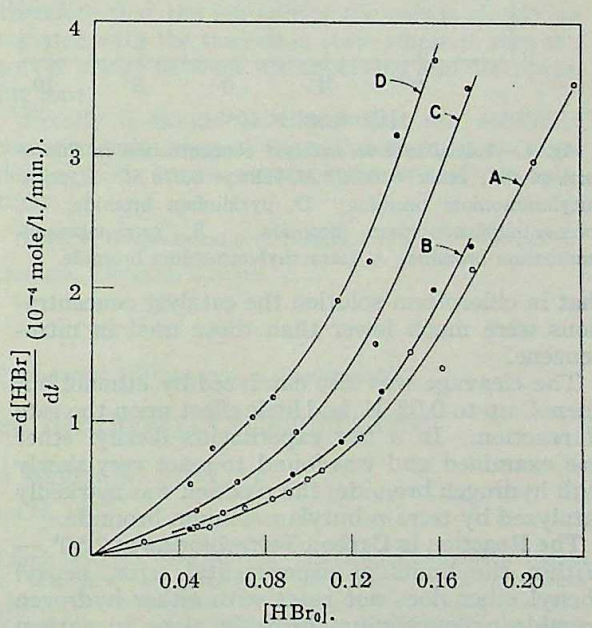

Fig. 3.—Initial rate *vs.* HBr concentration in chloroform; ether = 0.367 *M*, all salts 3.03×10^{-4} *M*: A, no added salt; B, tri-*n*-butylammonium bromide; C, pyridinium bromide; D, tetra-*n*-propylammonium bromide.

of hydrogen bromide was chosen to lie in the most accurate region of the rate *vs.* [HBr] curve. Similar corrections were applied to the results of Fig. 4 on the basis of the experiments of Fig. 3.

In the presence of a constant amount of a catalyst the cleavage is again a complex function of the concentration of hydrogen bromide as is shown by curves B, C and D of Fig. 3. Experiments in which the concentration of hydrogen bromide was varied also were performed using constant amounts of tetraethylammonium and tetra-*n*-butylammonium bromides as catalysts but the results were too close to those for tetra-*n*-propylammonium bromide to be shown on the graph. At a fixed concentration of hydrogen bromide the initial rate of reaction varies linearly with the amount of catalyst up to 10^{-3} *M* (Fig. 4). The five salts increased in catalytic activity in the order *n*-Bu_3NHBr < PyHBr < *n*-Bu_4NBr < *n*-Pr_4NBr < Et_4NBr. It may be noted

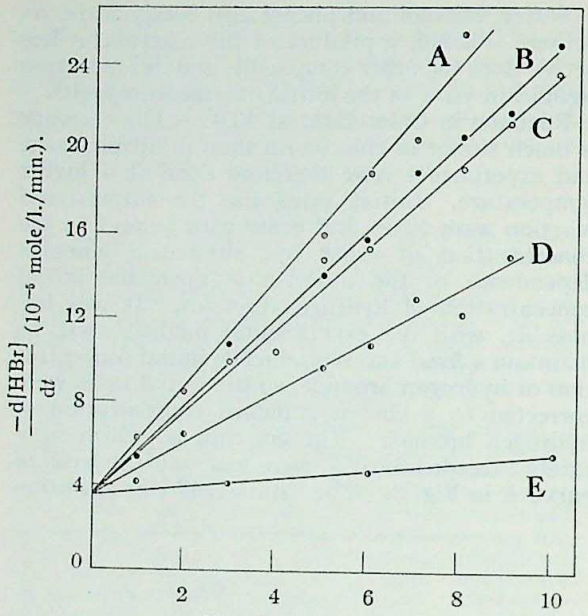

Fig. 4.—Initial rate *vs.* catalyst concentration in chloroform at 40°; ether = 0.367 *M*, HBr = 0.076 *M*: E, tri-*n*-butylammonium bromide; D, pyridinium bromide; C, tetra-*n*-butylammonium bromide; B, tetra-*n*-propylammonium bromide; A, tetraethylammonium bromide.

that in chloroform solution the catalyst concentrations were much lower than those used in nitrobenzene.

The cleavage was also catalyzed by ethanol but phenol, up to 0.02 *M*, had little effect upon the rate of reaction. In a few experiments diethyl ether was examined and was found to react very slowly with hydrogen bromide; the reaction was markedly catalyzed by tetra-*n*-butylammonium bromide.

The Reaction in Carbon Tetrachloride at 2.50°.—Within the limits of experimental error, benzyl phenyl ether does not react with either hydrogen bromide or pyridinium bromide alone in carbon tetrachloride. However, solid pyridinium bromide, which is insoluble in carbon tetrachloride solutions of hydrogen bromide or of benzyl phenyl ether, catalyzes the cleavage of the ether by hydrogen bromide. After stirring a solution of ether and hydrogen bromide with pyridinium bromide for $^1/_2$ hr. and then filtering, the filtrate did not react further but a considerable amount of the hydrogen bromide had reacted during the stirring. The insoluble salts LiBr, NaBr, KBr, NH_4Br, Me_4NBr, LiCl, NaCl, KCl, Na_2SO_4 and K_2SO_4 behave similarly to pyridinium bromide but glass surfaces do not act catalytically. Very finely divided sodium chloride (*ca.* 15 m.²/g.) is a more powerful catalyst than an ordinarily ground specimen. There can be little doubt that in all these experiments in carbon tetrachloride the cleavage of the ether occurred on the surface of the solid salt.

Discussion

The results obtained in nitrobenzene are in agreement with those of Mayo, *et al.*,[7] for the cleavage of diethyl ether by hydrogen bromide in toluene or chlorobenzene, and suggest a mechanism of the type

$$R_1CH_2OR_2 + HBr \overset{K}{\rightleftharpoons} R_1CH_2(R_2)O\cdots\cdots HBr \quad (1)$$

$$R_1CH_2(R_2)O\cdots\cdots HBr + HBr \xrightarrow{k_1} R_1CH_2Br + R_2OH + HBr \quad (2)$$

which leads to the observed kinetics if K is small. The vapor pressure measurements indicate that K is in fact quite small since no association of ether and acid could be observed. Reaction 2 can be regarded as an S_N2 type attack by the second molecule of hydrogen bromide at the $-CH_2-$ group of the ether–hydrogen bromide complex, a view supported by the fact that diphenyl ether apparently is not cleaved by hydrogen halides.[8]

In chloroform solution the observed kinetics are more complex and do not agree with those of Mayo, *et al.*, who found the rate law

$$-\frac{d[HBr]}{dt} = k[HBr]^{3/2}[ether]^{1/2}$$

for the cleavage of diethyl ether. In the present work the apparent order with respect to acid increases with concentration, an effect not due to polymeric molecules of hydrogen bromide since Henry's law is obeyed.[6]

One must suppose that the mechanism suggested for reaction in nitrobenzene would also apply to some extent in chloroform. It seems possible, however, that the ether–hydrogen bromide complex may also decompose in a unimolecular fashion since Hart and Eleuterio[9] have observed retention of configuration in the cleavage of α-phenylethyl phenyl ether by hydrogen chloride in solvents of low dielectric constant and high acid concentration. However, the apparent order with respect to HBr although approximately one at low acid concentrations seems to rise above two at higher concentrations so the mechanism perhaps involves medium effects as well.

Examination of models indicates that the S_N2 type reaction should lead to the regeneration of a molecule of hydrogen bromide in which the individual ions are initially some distance apart in the solution. Processes of this type occur readily in solvents such as water which can stabilize the newly-formed ions, but in non-polar solvents they proceed only with difficulty if at all. In the present case solvation of the ions by hydrogen bromide (HCl_2^- is known to be stable[10]) might provide a reaction path which would account for orders in acid greater than one.

The effect of electrolytes upon the reaction is undoubtedly related to this problem of separating charges in non-ionizing solvents. There is little direct information on the dissociation of the salts in these solutions, other than that the constant for tetra-*n*-butylammonium bromide in nitrobenzene is

1.6×10^{-2} at 25°.[11] By analogy with other systems, however, it is apparent that the constants for tetra-*n*-propyl- and tetraethylammonium bromide will be successively smaller than this value while those for pyridinium and tri-*n*-butylammonium bromides will be of the order of 10^{-4}. In chloroform the corresponding values of the constant for the two types of salts should be about 10^{-9} and 10^{-14}, respectively.

Since the effectiveness of the salts as catalysts increases with decreasing dissociation constant and dielectric constant, the catalysis probably is not due to free ions in solution. Also, it does not seem to result from an increase in the activity of the reactants since the "salting in" of the hydrogen bromide indicates a decrease in activity which is not likely to be outweighed by an increase in the activity of the ether.

The equilibrium of reaction 1 in which the ether and hydrogen bromide form a complex involves an increase in the dipole moment associated with the HBr and the presence of other ions and dipoles will tend to increase K and so accelerate the observed cleavage of the ether. However, it is doubtful if such an increase in K would account for more than a small part of the catalysis. Walvekar, *et al.*,[12] found no correlation between the values of K for different ethers and their rates of cleavage as measured by Ghaswalla and Donnan.[13] However, the very slow cleavage of diethyl ether in chloroform is markedly catalyzed by tetra-*n*-butylammonium bromide. Since diethyl ether certainly forms an oxonium complex much more readily than benzyl phenyl ether, it must be stage 2 of the reaction, cleavage of the complex, which is significantly affected by the catalyst.

It seems then that the catalysis is due to the ion pairs in solution accelerating the rate of cleavage of the C–O bond, a process which probably is closely related to the heterogeneous catalysis observed in carbon tetrachloride. The catalysis by ionic crystals is of such a general nature that it must be due primarily to the electrical inhomogeneity of the crystal surface but in solution specific ion effects must be of considerable importance because the catalytic activities of the salts do not seem to be related to the dipole moments. It seems probable therefore that the ion pair of the salt is closely associated with the transition state where it acts as a sort of bridge between the appearing and disappearing ions.

Finally it should be noted that our solubility measurements suggest that Walvekar, *et al.*, were dealing with heterogeneous systems and not solutions.

Studies of Some Methyl-substituted Benzhydryl Carbonium Ions

BY HILTON A. SMITH AND BURCH B. STEWART

RECEIVED MARCH 16, 1957

The behavior of the following methylbenzhydrols in 100% sulfuric acid has been studied: 2,2′,3,4,5,6-hexamethylbenzhydrol, 2,2′,4,6-tetramethylbenzhydrol and 3-methylbenzhydrol. The first two compounds gave fairly stable carbonium ions; the last gave a less stable and more reactive carbonium ion. The properties were investigated utilizing *i*-factors, ultraviolet and near-visible spectra, titration studies, and chemical studies, all using sulfuric acid. Evidence for the steric effect of three *ortho*-methyl groups and the "buttressing" effect of methyl groups in the 3- and 5-positions of the hexamethylbenzhydryl carbonium ion is discussed.

Introduction

It has been shown that many benzhydrols[1-4] ionize in 100% sulfuric acid to give stable carbonium ions. The ionization can be represented as

$$(C_6H_5)_2CHOH + 2H_2SO_4 \longrightarrow (C_6H_5)_2\overset{+}{C}H + 2HSO_4^- + H_3O^+ \quad (1)$$

Actually benzhydrol is rather unstable in sulfuric acid and undergoes rapid polymerization and sulfonation.[1] In the present work it was desired to find out the effect of certain methyl-substitutions on the formation and stabilization of benzhydryl carbonium ions. In addition, it had been noted that benzhydryl carbonium ions with two or less *ortho*-methyl substituents formed benzhydryl ethers, while those with four *ortho*-methyl substituents formed benzhydrols when poured into water. It was therefore of interest to ascertain the behavior of such ions when three *ortho*-methyl substituents were present.

Results

i-Factors.—Table I gives the *i*-factors as extrapolated to zero time for the compounds studied. For the hexamethyl and tetramethyl compounds, solution was rapid, and the first *i*-factors could be determined within 10 or 15 minutes after addition of the benzhydrol to the sulfuric acid. The freezing points slowly changed as sulfonation took place. The *i*-factor of approximately 4.0 obtained by extrapolation to zero solution time is that expected for ionization according to eq. 1. For 3-methylbenzhydrol, however, solution in the sulfuric acid was very slow, for an insoluble polymer was formed which dissolved slowly as sulfonation occurred

TABLE I

CHARACTERISTICS OF BENZHYDROLS IN SULFURIC ACID

Benzhydrol	Color in sulfuric acid	Initial i-factors (extrapolated)	% Yield Methyl ether	M.p., °C.[a]	Methyl ether analyses,[b] % Carbon Calcd.	Carbon Found	Hydrogen Calcd.	Hydrogen Found
2,2′,3,4,5,6-Hexamethyl	Red-brown	3.9	65[c]	69.5–70.1	85.05	85.60	9.28	9.12
2,2′,4,6-Tetramethyl-	Red-purple (iridescent)	3.9–4.0	64[d]	61.7–62.2	84.99	84.94	8.72	8.69
3-Methyl-	Red-brown (with polymer)	5.0–5.1[e]	0	(Polymer; no methyl ether isolated)				

[a] Melting points were taken on an aluminum melting point block and are uncorrected. [b] Analyses were done by Galbraith Microanalytical Laboratories, Knoxville, Tennessee. [c] Based on the crude compound. [d] Based on the purified product; the crude product was an oil and not weighed. [e] Obtained by extrapolation of the slow sulfonation curve.

After five or six hours, complete solution was achieved, and i-factors could be determined. Extrapolation of these slowly increasing values to zero solution time gave the figure of 5.0 recorded in Table I. Polymerization gives lower values and sulfonation gives larger values. The polymerization reaction can be represented for benzhydrol as

$$(n + 2)(C_6H_5)_2CHOH + (n + 3)H_2SO_4 \longrightarrow C_6H_5\overset{+}{C}HC_6H_4[CH(C_6H_5)C_6H_4]_n\ CH(C_6H_5)_2 + (n + 2)H_3O^+ + (n + 3)HSO_4^- \quad (2)$$

The i-factor would be $(2n + 6)/(n + 2)$ for dissolved polymer if no sulfonation occurred. For dimerization, $n = 0$, and $i = 3.0$. For dimerization and monosulfonation of two rings the i-factor would be 5.0. After this sulfonation complete solution should be achieved, with further sulfonation occurring rather slowly. Higher polymers with more extensive sulfonation could also give i-factors around five.

Chemical Studies. Methyl Ether Preparations.—The preparation of alkyl ethers from benzhydryl carbonium ions, as described later, is not only an important synthetic method, but gives excellent confirmation that the sulfuric acid solutions actually contain carbonium ions. The ordinary acid-catalyzed etherification of a highly methylated carbinol would yield essentially no ether in the reaction times used.

The yields are given in Table I for the methyl ethers prepared. Both polymethylated-benzhydrols gave the methyl ethers. However only a polymeric material melting at 150–160° and a small amount melting at 200–210° could be obtained from the 3-methylbenzhydrol.

Reactions of Carbonium Ions with Water.—It has been demonstrated that four *ortho*-methyl groups on a benzhydryl carbonium ion are sufficient to prevent the formation of the bis ether.[1,4] Both hexamethyl- and tetramethylbenzhydrol have three *ortho*-methyl groups and therefore are sterically hindered so that formation of the bis ether is prevented. The original carbinol is obtained when the sulfuric acid solution is added to water.

A solution obtained by adding 0.25 g. of 2,2′,3,4,5,6-hexamethylbenzhydrol to 18 g. of 100% sulfuric acid and stirring for one minute was poured into an ice–water mixture. A 96% yield of the original carbinol (identified by mixed melting point) was obtained. The solution of the same benzhydrol which had stood for 21 hours in the process of cryoscopic determinations was also poured into an ice–water mixture to give a product which was completely water soluble and was not identified.

A solution obtained by the addition of 0.25 g. of 2,2′,4,6-tetramethylbenzhydrol to 18 g. of 100% sulfuric acid was stirred for one minute and then poured into an ice–water mixture to give a 100% yield of the original carbinol which was identified by mixed melting point. The solution from a 24-hr. cryoscopic run was poured into water to give an essentially clear solution.

Six solutions of 3-methylbenzhydrol in 100% sulfuric acid solution (generally in the ratio of 1 g. of benzhydrol per 100 g. of acid) were allowed to stand for times of from 10 seconds to 15 minutes and subsequently poured into ice–water mixtures. Yellow gums with different melting ranges between 130 and 250° were obtained. For one gum, some softening was noted at 50° which is close to the melting point of 3-methylbenzhydrol. The solution from a 27 hour cryoscopic run when poured into an ice–water mixture gave a clear solution. Yields of 46–90% for the gums indicate that rapid sulfonation must have occurred to give water-soluble products. This material probably gives a protonated species initially, but this undergoes a rapid reaction with undissolved benzhydrol to give a polymer which is not very soluble in sulfuric acid. Subsequently, the polymer is slowly sulfonated and is finally completely dissolved. No conditions were found where any bis ether was obtained when the sulfuric acid solution was poured into ice-water. Only polymeric materials and the original carbinol were found in the water-insoluble products. The yellow polymeric gums could be separated into two portions by extraction with ligroin, methanol or ethanol. A small fraction of insoluble, brittle material melted over the range of 180–250°, while the large fraction of soluble material melted between 130–160°.

Titrations to Form Carbonium Ions.—Titrations of the compounds dissolved in an inert solvent and water mixture using 96% sulfuric acid were made to obtain the relative stabilities from the minimum

TABLE II

TITRATION TO FORM CARBONIUM IONS WITH SULFURIC ACID

percentage of sulfuric acid necessary for the permanent appearance of the characteristic carbonium ion color. The procedure has been described previously.[4] It was found in the present work that a suitable choice of concentration is needed to achieve satisfactory reproducibility. Reducing the concentration of the carbinol one-fifth did not affect the results appreciably whereas increasing the concentration fivefold gave very low results. Temperature control during titration is also necessary. Titration results are shown in Table II.

Experimental

Factors.—The apparatus, technique and solvent for the cryoscopic measurements have been described previously.[1,5] Trial runs using triphenylcarbinol as the solute gave values of 4.02 and 3.96. Since the rates of possible side reactions, such as sulfonation, increase with increasing temperature, it is very important that the temperature of the solutions used remain as low as possible. The range actually encountered was 7–14°. Also the maintenance of a fairly constant temperature minimizes the amount of moist air drawn into the cryostat through the silicone-lubricated sleeve and stirring stem.

For the run with 3-methylbenzhydrol the polymer formed was very slow to dissolve, and the freezing point measurements were not commenced until the compound was dissolved. The cryostat, with a ground glass stopper, was fitted with an outside rubber stopper which was inserted into the container of a motor-driven shaker. Powdered solid carbon dioxide and crushed ice were added to the bottom of the shaker container to maintain a small amount of frozen solvent and to ensure that the temperature was held essentially constant. After five hours of shaking at 180–200 c.p.m., the Beckmann thermometer was inserted and the freezing run was begun.

Preparation of Methyl Ethers.—A 0.25-g. sample of carbinol was dissolved in approximately 18 g. of 100% sulfuric acid, and the solution was added immediately to 100 ml. of absolute methanol. This solution was then poured into 125 g. of an ice–water mixture and extracted quickly with two 100-ml. portions of ether. After drying the ether extracts over Drierite, evaporation of the ether gave the methyl ether which was then purified by recrystallization from ethanol.

Reactions of Carbonium Ions with Water.—A sample of carbinol was dissolved in 100% sulfuric acid. After a definite reaction time the solution was poured into an ice–water mixture and extracted with several portions of ether. After drying the ether extracts with solid sodium hydroxide pellets, evaporation of the ether gave the products. The solid was purified by recrystallization from ethanol. The polymers were extracted with methanol, ethanol or ligroin in the attempt to separate any bis ether which might have been formed. No bis ether was indicated in the products.

Titrations to Form Carbonium Ions.—The carbinol was dissolved in 10 ml. of carbon tetrachloride and this solution added to 50 ml. of water. This mixture was then titrated to the barely visible carbonium ion end-point with 96% sulfuric acid. The acid was added very slowly with constant stirring of the mixture which was maintained at approximately room temperature. From the volume of acid required, the percentage of acid necessary for visible carbonium ion formation in the aqueous layer was determined.

Spectra.—The ultraviolet and near-visible spectra were obtained using a Beckman DU spectrophotometer and quartz cells 1 cm. thick. A hydrogen discharge lamp was used for the range 250–350 mμ; a tungsten filament lamp was used for the range 350–600 mμ. For 3-methylbenzhydrol a solution in cyclohexane was prepared and added to sulfuric acid contained in a volumetric flask. The cyclohexane was evaporated under the vacuum produced with a water aspirator while the flask was swirled to effect extraction of the compound into the sulfuric acid layer. The flask was then filled to the mark with sulfuric acid. By this procedure solid polymer did not form and the spectrum could be measured. The reference solvent was treated exactly as just described. The spectra are shown in Fig. 1.

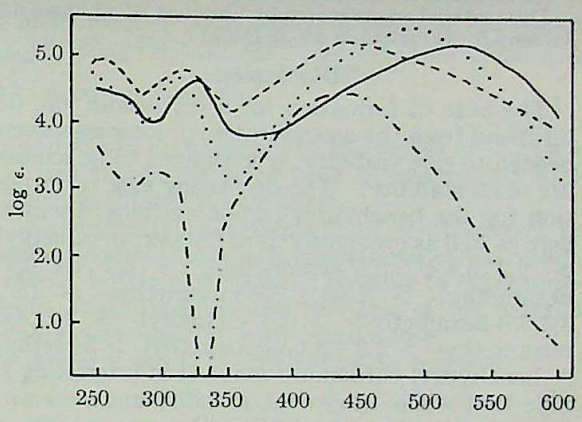

Fig. 1.—Absorption spectra of benzhydryl carbonium ions in 100% sulfuric acid: — · —, 3-methyl; . . . ., 2,2′,4,6-tetramethyl; ———, 2,2′,4,4′,6,6′-hexamethyl; – – – –, 2,2′,3,4,5,6-hexamethyl.

Preparation of Compounds. 2,2′,3,4,5,6-Hexamethylbenzophenone.—This compound was prepared by the reaction of pentamethylbenzene and 2-methylbenzoyl chloride in the presence of anhydrous aluminum chloride; carbon disulfide was used as the solvent. After the addition of the acid chloride to the reaction mixture, the mixture was refluxed for two hours before hydrolysis. The ketone was purified by recrystallization from ethanol. A yield of 80.3% was obtained of white crystals very soluble in benzene; soluble in ether, ethanol and acetone; and slightly soluble in carbon disulfide. The compound melted at 155.5–155.7°.

Anal. Calcd. for $C_{19}H_{22}O$: C, 85.73; H, 7.61. Found: C, 85.44; H, 7.58.

2,2′,3,4,5,6-Hexamethylbenzhydrol.—The hexamethylbenzophenone was reduced for two hours using a fourfold excess of ethereal lithium aluminum hydride. After hydrolysis of the complex with 10% hydrochloric acid, and separation of the ether layer, evaporation gave a white solid in 99.3% yield which melted at 132.7–133.0°. Using excess lithium aluminum hydride to reduce a sterically hindered ketone evidently gives excellent yields of the carbinol. A less sterically hindered ketone, 4,4′-dimethylbenzophenone, gave an unsatisfactory yield of the carbinol but the bis ether was obtained in 70% yield.[4]

Anal. Calcd. for $C_{19}H_{24}O$: C, 84.95; H, 8.39. Found: C, 84.73; H, 8.19.

2,2′,4,6-Tetramethylbenzophenone.—This ketone was prepared in 48% yield by the reaction of 2-methylbenzoyl chloride with mesitylene in the presence of anhydrous aluminum chloride; carbon disulfide was used as the solvent. After addition of the acid chloride to the reaction mixture, the mixture was refluxed for two hours, before hydrolysis. Evaporation of the carbon disulfide layer gave the ketone which was purified by recrystallizations from ethanol. The melting point was 111.9–112.2°. A melting point of 111° has been reported.[6]

Anal. Calcd. for $C_{17}H_{18}O$: C, 85.67; H, 8.32. Found: C, 85.44; H, 8.50.

2,2′,4,6-Tetramethylbenzhydrol.—The tetramethylbenzophenone was reduced for two hours using a four-fold excess of ethereal lithium aluminum hydride. A white solid melting at 123.5–124.5° was obtained. The yield was 99.2%. This compound is sterically hindered also and is obtained in an excellent yield with no bis ether impurities.

Anal. Calcd. for $C_{17}H_{20}O$: C, 85.02; H, 9.01. Found: C, 85.01; H, 9.16.

3-Methylbenzhydrol.—This compound was prepared by the Grignard reaction using *m*-tolylmagnesium bromide and

benzaldehyde. The compound melted at 53.0–53.3° and was obtained in 80% yield. The literature gives melting points of 53°[7] and 61°.[8] In this work the higher melting compound could not be obtained.

Anal.[9] Calcd. for $C_{14}H_{14}O$: C, 84.82; H, 7.11. Found: C, 84.75; H, 7.29.

2,2′,4,4′,6,6′-Hexamethylbenzhydrol (Dimesitylcarbinol).—This material was prepared by "Method B" of Fuson and Jackson.[10] It melted at 150.6–151.4°.

Discussion

The ease of formation for a carbonium ion, determined from the concentration of ionizing solvent needed to give visibility, is considered to be a measure of its stability. The decreasing ease of formation for the benzhydryl carbonium ions discussed here as well as previously[1] is as follows: decamethyl- > 2,2′,3,4,4′,5,6,6′-octamethyl- > 2,2′,4,4′,6,6′-hexamethyl- > 2,3,4,4′,5,6-hexamethyl- > 2,2′,-3,4,5,6-hexamethyl- > 4,4′-dimethyl- > 2,2′,4,6-tetramethyl- > 2,3,4,5,6-pentamethyl- > 3-methyl- > benzhydryl carbonium ion. It is interesting to note that while, in general, stability increases with increasing methyl substitution, the accumulation of methyl groups is not so effective when all substituents are on one ring as when they are distributed over both rings.

Another interesting comparison involves compounds which should show the "buttressing effect."[11] According to Newman and Deno[12] resonance in the mesityldimethylcarbonium ion is sterically hindered by the introduction of methyl groups in the 3- and 5-positions to form the pentamethylphenyldimethylcarbonium ions. A similar effect should be found when methyl groups are introduced into the 3- and 5-positions of the 2,2′,4,6-tetramethylbenzhydrylcarbonium ion and into the 3,5- and 3′,5′-positions of the dimesitylcarbonium ion. These introductions should give for the relative ease of formation the following orders: 2,2′,-4,6-tetramethyl- > 2,2′,3,4,5,6-hexamethyl- and 2,2′,4,4′,6,6′-hexamethyl- > 2,2′,3,4,4′,5,6,6′-octamethyl- > decamethylbenzhydryl carbonium ions. Exactly the reverse order is noted. One must conclude that the "buttressing" effect is not of considerable importance in these ions. It is possible that steric hindrance is not as great when methyl groups are substituted in the *ortho* positions of the benzhydryl carbonium ions as is found for similar substitution in the benzyldimethyl carbonium ions studied by Newman and Deno. However scale models indicate little difference.

When one studies the absorption spectra of these ions, the opposite conclusions concerning the "buttressing effect" can be drawn. The order of increasing extinction coefficient should be decamethyl- < 2,2′,3,4,4′,5,6,6′-octamethyl- < 2,2′,-4,4′,6,6′-hexamethyl- and also 2,2′,3,4,5,6-hexamethyl- < 2,2′,4,6-tetramethyl. This is the observed order. One might also anticipate that λ_{max} would be shifted toward shorter wave lengths as resonance is hindered by the 3,5-methyl substituents, but the decamethylbenzhydryl carbonium ion has the largest rather than the smallest value.

Gold and Tye[3] attach theoretical significance to the intensity of the second absorption occurring at about 320–340 mμ as compared with the intensity of the principal band for several benzhydryl and α-substituted benzhydryl carbonium ions. They predict greater stability for smaller values of the intensity difference. The differences in the logarithms of the intensities between the principal and secondary bands for 2,2′,4,4′,6,6′-hexamethylbenzhydryl, 2,2′,3,4,5,6-hexamethylbenzhydryl, tetramethylbenzhydryl, methylbenzhydryl and benzhydryl carbonium ions are 0.57, 0.64, 0.87, 1.18 and 1.32, respectively. This order of decreasing stability is in agreement with the titration results.

2,2′,3,4,5,6-Hexamethylbenzhydrol and 2,2′,4,6-tetramethylbenzhydrol gave fairly stable carbonium ions which did not polymerize. The solutions as initially formed reacted with water to give the original carbinol and with methanol to give the methyl ether. These results are explained best by the existence of carbonium ions. Carbonium ions in sulfuric acid when poured into water usually give the bis ether but evidently three as well as four *ortho*-methyl groups prevent this reaction and permit regeneration of the original benzhydrol.

From the cryoscopic runs the rate of sulfonation of the hexamethylbenzhydryl carbonium ion appears to be somewhat faster than that of the tetramethylbenzhydryl carbonium ion. The factors that contribute to carbonium ion stability also increase the tendency for sulfonation as previously noted.[4] It appears that monosulfonation presumably in the unsubstituted ring takes place readily. Further sulfonation, if any, is very slow. Sulfonation of one ring for all molecules is also suggested from the fact that the contents of the cryostat when poured into an ice–water mixture after the cryoscopic run gave a clear solution indicating no unsulfonated material.

The "*i*" value of 5.0 listed in Table I for 3-methylbenzhydrol is believed to correspond to dimerization with monosulfonation in one ring of each unit in the dimer. Obviously the fast initial reaction was polymerization which caused insolubility until sulfonation had occurred. Formation of a trimer followed by sulfonation in each unit would give an "*i*" factor of 4.67. Further sulfonation is apparently quite slow, for the slope in the plot of freezing point *vs.* time after complete solution was less than 0.002° per hour.

Kinetics of the Homogeneous Reaction of NO and H_2[1]

BY WENDELL M. GRAVEN

RECEIVED FEBRUARY 4, 1957

An examination of the kinetics of the reaction of NO and H_2 within the temperature interval of 850–1060° has resulted in information which may be represented by the rate expression $\frac{\Delta H_2O}{\Delta t} = \frac{2.2 \times 10^9 \exp(-41000/RT)[NO]^2[H_2]^{1/2}}{1-3.0\,[H_2]^{1/2}}$. A chain mechanism has been found to be in partial agreement with the experimental data.

Introduction

In each of the gaseous molecular reactions which have been demonstrated kinetically to be of third order nitric oxide is one of the participants.

The interaction of NO and H_2 differs from most of the other reactions in that its rate constant has a higher activation energy and a larger pre-exponential factor.[2] This fact caused Taylor and Tanford[3] to reject the mechanism proposed by Hinshelwood and Mitchell,[4] which involved ternary molecular collisions as well as collisions of molecules with "binary collision complexes." Believing the reaction mechanism to be more complex and probably to involve hydrogen atoms they undertook an investigation of the mercury-photosensitized NO–H_2 reaction. Quite understandably, a different dependence of reaction rate on H_2 and NO pressures was observed.

In view of recent interest in the high temperature behavior of NO–H_2 flames[5,6] a re-examination of the kinetics of the NO–H_2 reaction has been considered to be appropriate.

Before a comprehensive kinetic investigation was initiated an approximate dependence of the rate upon reactant concentrations was determined by a simple and rapid technique which will be described.

For a binary system, the reaction rate of which is ith order in reactant A and jth order in reactant B, the initial rate, R_N, may be expressed in terms of the mole fraction, N, of component A and a pressure-dependent rate constant, k, according to eq. 1

$$R_N = kN^i(1-N)^j \qquad (1)$$

Elimination of k by taking the ratio of the initial rate at mole fraction N to that at some other composition, say the equi-molar mixture, enables one to define the relative rate ratio, R, by means of eq. 2.

$$R = R_N/R_{1/2} = 2^{i+j}N^i(1-N)^j \qquad (2)$$

Equation 2 is applicable to all two-component reaction systems at constant temperature and pressure, provided that the extent of reaction is not greater than several per cent.

A plot of R against N results in a family of curves corresponding to the selected values of the exponents, i and j. Figure 1 shows such a plot in which i and j have been limited to the values of $1/2$, 1 and 2, and the curves have been terminated at mole fractions 0.1 and 0.9 for clarity.

Experimental measurement of R at several reactant compositions and comparison of the results with a master plot makes it possible to determine i and j, and therefore the rate law of the reaction under consideration, with relative ease.

Application of this method to the reaction

$$NO + H_2 = H_2O + {}^1/_2N_2 \qquad (3)$$

yielded results which have been plotted as individual points in Fig. 1, where N represents the mole fraction of NO. It may be observed that the

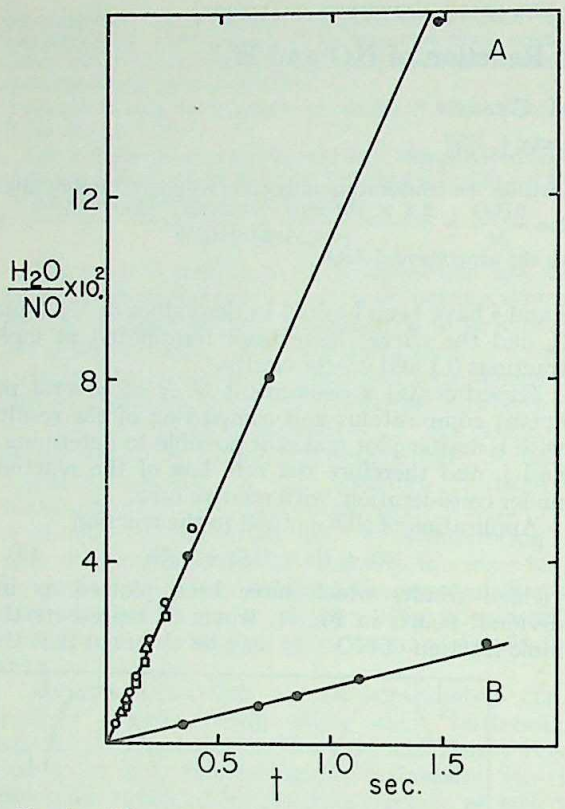

Fig. 2.—Effect of reaction time on extent of reaction. A: $T = 1025°$; ●, vessel II; $[NO] = [H_2]$; ○, vessel I; $[NO] = [H_2]$; □, vessel I; $[NO] = \frac{1}{2}[H_2]$; △, vessel I; $[NO] = [2H_2]$; B: $T = 850°$; ●, vessel II; $[NO] = [H_2]$

experimental points do not coincide with any of the nine curves corresponding to integral or half-integral values of i and j. However, the data are in close agreement with the R values that would be expected if the concentration dependence of the rate were second order in NO and two-third order in H_2. Since alternative complex rate expressions might serve as well, or better, for representing the data it was thought that a more comprehensive investigation was required, particularly in view of earlier reports[2] that the reaction obeyed an over-all third-order rate law.

Experimental

The measurements of reaction rates were made with a flow technique which permitted rapid heating of pre-mixed reactants and diluent and rapid quenching of effluent mixtures. A description of the design of the reaction vessel and the experimental technique has been published previously.[7,8] The use of two quartz reaction vessels, which were similar in every respect except size, permitted a test for homogeneity of the reaction as well as a hundred-fold variation of the extent of reaction. Vessel I had a free volume of 5.60 ml. and an estimated surface/volume ratio of 5.6 cm.$^{-1}$. Vessel II had a free volume of 42.6 ml. and an estimated surface/volume ratio of 2.3 cm.$^{-1}$.

Reaction rates were determined by absorption of water vapor in calcium chloride. Gravimetric measurement of the amount collected during an appropriate time interval permitted a precise estimate of the steam content of the effluent mixture.

Calibrated capillary tube flowmeters facilitated measurement and control of the flow rates of reactants and diluent. Mixing was accomplished with tangential jet mixing chambers.

Mass spectrometric analyses of the compressed N_2, H_2 and He gases showed that the principal impurity (H_2O, N_2, O_2 or CH_4) did not exceed a few tenths of a per cent. Each gas was dried and freed of O_2 by standard catalytic methods. Compressed NO gas which had been passed through ascarite absorbent showed no evidence of NO_2, an amount of N_2O which did not exceed a few tenths of a per cent., and N_2 in an amount that exceeded the maximum impurity stated by the supplier.

The temperature at the center of the reaction vessel, which was situated in an electric furnace, was maintained constant within one degree with a modified "Simplytrol" pyrometer-relay furnished by Assembly Products, Inc. Temperature measurements along the major axis of the larger vessel with a Pt, Pt–Rh thermocouple, which had been calibrated by the Bureau of Standards, indicated a temperature gradient of 11° between the entrance and the center.

The total pressure of the reactant mixture was approximately 77 or 80 cm., depending upon which vessel was being used.

With the use of helium as a diluent to maintain a constant total flow rate it was possible to vary the reactant concentrations independently of one another without changing the reaction time. A total flow rate of 1.5 l./min., which corresponded to a reaction time of about 0.05 sec. in vessel I and 0.4 sec. in vessel II, resulted in about one and 5% reaction, respectively, at the maximum temperatures. Consequently, in all runs except those in which the reaction time was increased deliberately initial rates were being measured and a differential rate law, together with initial reactant concentrations, could be employed in computing rate constants.

Results

Adjustment of the total flow rate permitted a wide variation in the residence time of the gases within the vessel. This was extended further by the use of two vessels with different volumes. Figure 2 shows the results of rate measurements in both vessels at two temperatures with three different compositions of reactants. In each case a linear relationship exists between per cent. reaction and reaction time. Curve A, in which the variation of t covers a 40-fold range, indicates that the linearity persists nearly to 15% conversion. Moreover, the close fit to a single curve of data from two vessels, one having 2.5 times the surface/volume ratio of the other, argues against any significant contribution of heterogeneous reaction.

That N_2 takes no part in that portion of the reaction mechanism which is rate-determining may be seen from the data in Fig. 3. Reaction rates were obtained from runs in which NO and H_2 concentrations remained invariant while N_2 replaced He as diluent at two temperatures with the use of both reaction vessels. The greater scatter of the points in curve A is due in part to the ten-fold magnification of error that arises from the division of product concentrations by the reaction time.

In Fig. 4 the reaction rates obtained from runs at constant H_2 concentration with varying NO concentration have been plotted against the square of the corresponding NO concentrations. Data obtained at three temperatures with both vessels give straight lines over ten-fold variations in NO concentration, thus demonstrating a second-order dependence.

The dependence of the reaction rate upon H_2 concentration was found by preliminary experiments, Fig. 1, to be non-integral and less than first order. By plotting a number of trial functions it

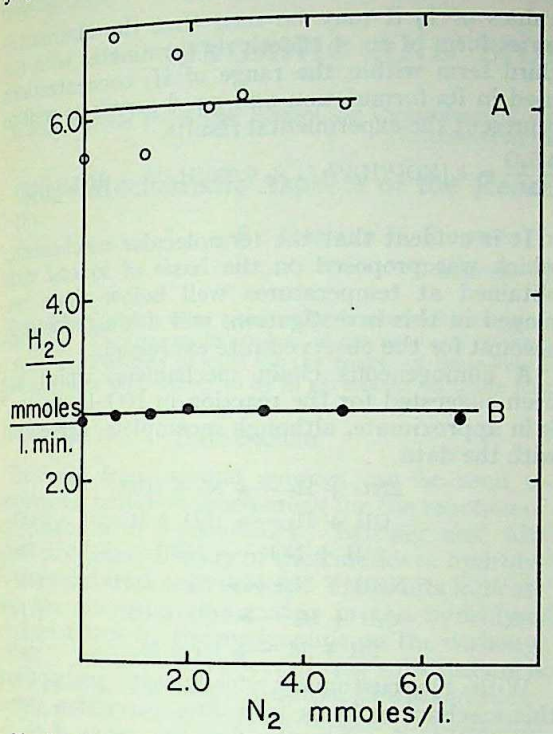

Fig. 3.—Effect of N_2 concentration on rate of reaction. A: $T = 1060°$; vessel I; $t = 0.0469$ sec.; $[NO] = [H_2] = 2.33$ mmoles/l.; B: $T = 1025°$; vessel II; $t = 0.391$ sec.; $[NO] = 1.98$, $[H_2] = 1.32$ mmoles/l.

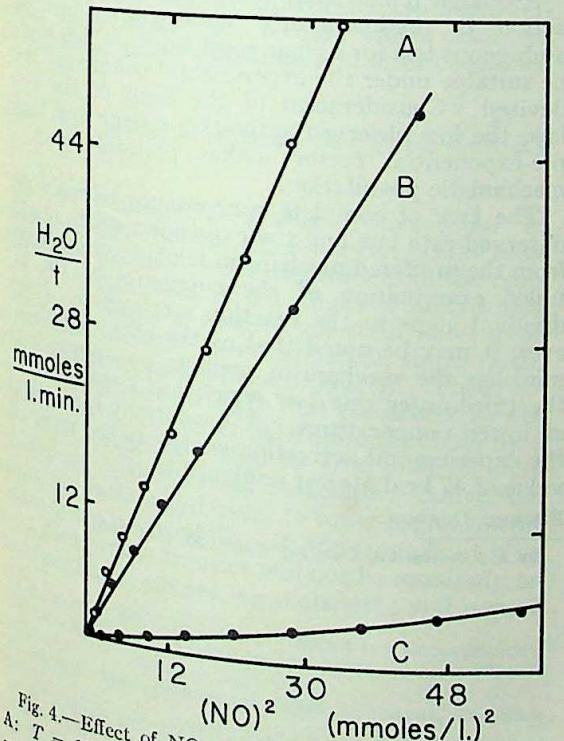

Fig. 4.—Effect of NO concentration on rate of reaction. A: $T = 1060°$; vessel I; $t = 0.0469$ sec.; $[H_2] = 3.49$ mmoles/l.; B: $T = 1025°$; vessel II; $t = 0.391$ sec.; $[H_2] = 3.31$ mmoles/l.; C: $T = 850°$; vessel II; $t = 0.452$ sec.; $[H_2] = 3.79$ mmoles/l.

was ascertained that for runs at constant NO and varying H_2 concentrations a plot of the reciprocals of the reaction rates against the reciprocals of the square roots of corresponding H_2 concentrations yielded a straight line. Figure 5 shows three such plots which span ten-fold variations in H_2 concentration and include data procured at three temperatures with the use of both reaction vessels.

Sufficient information has been provided for the formulation of a tentative rate law which may be expressed in the incremental form

$$\frac{\Delta H_2O}{\Delta t} = \frac{k_1[NO]^2[H_2]^{1/2}}{1 + k_2[H_2]^{1/2}} \qquad (4)$$

The two parameters of eq. 4, k_1 and k_2, can be evaluated from the slopes and intercepts, respectively, of the curves in Fig. 5. It may be observed that k_2 is singular by virtue of being negative and nearly independent of temperature. Thus, at 1025° it is found to be -0.095 (l./mmole)$^{1/2}$, while at 850° where the experimental uncertainty is greater a value of -0.08 is computed.

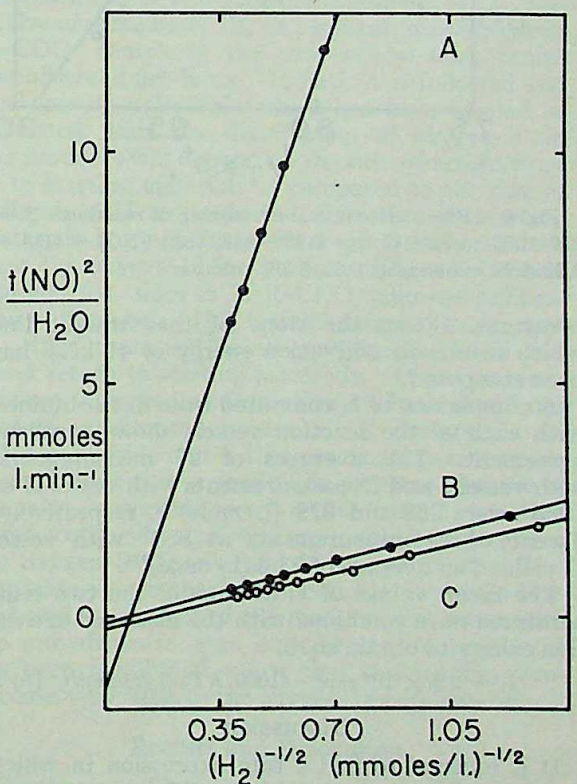

Fig. 5.—Effect of H_2 concentration on rate of reaction. A: $T = 850°$; vessel II; $t = 0.678$ sec.; $[NO] = 4.45$ mmoles/l.; B: $T = 1025°$; vessel II; $t = 0.391$ sec.; $[NO] = 3.31$ mmoles/l.; C: $T = 1060°$; vessel I; $t = 0.0469$ sec.; $[NO] = 3.49$ mmoles/l.

Calculations of k_1 for individual runs were made with the assumption that the value of k_2 was -3.0 (l./mole),$^{1/2}$ independent of temperature. Therefore, the observed temperature dependence of the over-all reaction rate was assigned to k_1.

Rate measurements were made with the larger vessel using an equi-molar reactant mixture and extended over a 200° temperature interval. The data appear in Fig. 6 as a plot of the logarithms of the ratios of k_1 to the square roots of corresponding temperatures against the reciprocals of the tem-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

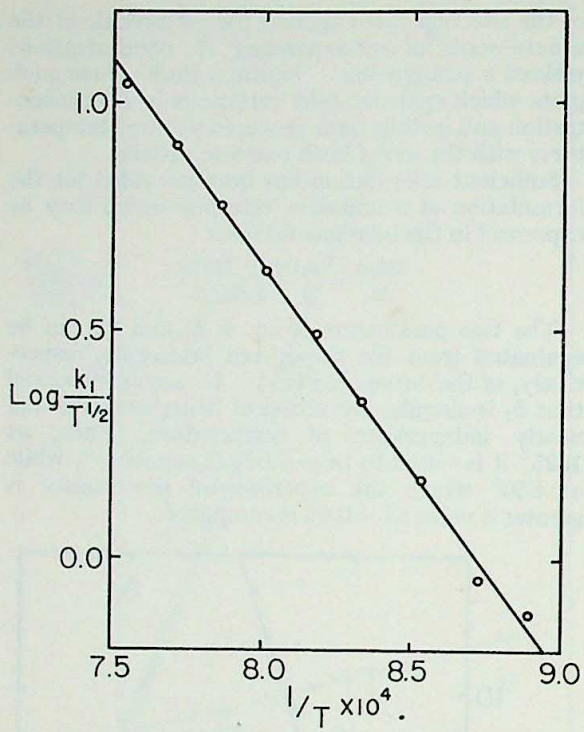

Fig. 6.—Effect of temperature on rate of reaction. T = 850–1053°; vessel II; t = 0.383–0.452 sec.; [NO] = [H_2] = 3.23–3.79 mmoles/l.; 0.33–3.3% reaction.

peratures. From the slope of the straight line which results an activation energy of 41 kcal. has been computed.

A comparison of k_1 computed from data obtained with each of the reaction vessels shows excellent agreement. The averages of 27 measurements with vessel I and 28 measurements with vessel II at 1025° were 268 and 279 (l./mole)$^{1/2}$, respectively. Twenty-three measurements at 850° with vessel II yielded an average of 23.2 (l./mole)$^{1/2}$.

The mean values of k_1 at each of the two temperatures were combined with the observed activation energy to obtain eq. 5.

$$k_1 = 2.2 \times 10^9 \exp(-41000/RT)\ (\text{l./mole})^{1/2} \quad (5)$$

Discussion

It is unusual to find a rate expression in which the denominator consists of the difference between two terms, associated with a non-detonating reaction. However, if use is made of the experimental values of k_2 it may be seen that the alternative series form of eq. 4 effectively terminates with the third term within the range of H_2 concentrations used in its formulation and eq. 6 serves as well to represent the experimental results.

$$\frac{\Delta H_2O}{\Delta t} = k_1[NO]^2[H_2]^{1/2}(1 + 0.095[H_2]^{1/2} + 0.0090\,[H_2]) \quad (6)$$

It is evident that the termolecular mechanism,[2] which was proposed on the basis of kinetic data obtained at temperatures well below those employed in this investigation, will not satisfactorily account for the observed rate expression.

A homogeneous chain mechanism, which has been suggested for the reaction in NO–H_2 flames,[9] is in approximate, although incomplete, agreement with the data.

$$2NO + H_2 \longrightarrow N_2 + 2OH \quad (7)$$
$$OH + H_2 \longrightarrow H_2O + H \quad (8)$$
$$H + NO \longrightarrow NOH \quad (9)$$
$$NOH + NO \longrightarrow N_2 + O_2H \quad (10)$$
$$O_2H + H_2 \longrightarrow H_2O + OH \quad (11)$$
$$2H + M \longrightarrow H_2 + M \quad (12)$$

With the customary steady-state assumptions this mechanism leads to a rate expression corresponding in form to the first two terms of eq. 6, which, it may be observed, account for 95% of the experimental rate of reaction at the highest H_2 concentration employed in this investigation.

Although it has been demonstrated that the reaction is predominantly homogeneous no unambiguous test for a chain mechanism, which would be suitable under the experimental conditions, was devised. Consideration of the form of the rate law, the low observed activation energy and large pre-exponential factor makes plausible such a mechanistic postulation.

The lack of complete concordance between the observed rate law and the expression which results from the proffered mechanism tends to vitiate a detailed examination of the energetics of the individual steps in the reaction mechanism. However, it may be noted that as the chain length diminishes the mechanism predicts an approach to the third-order rate law which has been observed at lower temperatures. A concurrent increase of the experimental activation energy to the reported value of 47 kcal.[4] is not implausible.

Some Mechanistic Aspects of the Reaction of Anhydrides with Nucleophiles[1]

BY DONALD B. DENNEY AND MICHAEL A. GREENBAUM[2]

RECEIVED JANUARY 19, 1957

Anhydrides, which were specifically labeled with oxygen-18, have been treated with various nucleophiles under several conditions. The oxygen-18 content of the products of these reactions coupled with data from the literature can be utilized to define a multi-step process for the course of these reactions. Several reactions have been devised to test this mechanism and have been shown to be in agreement with the postulate.

Introduction

Evidence from several sources can be used to construct a tentative mechanism for the reaction of anhydrides with nucleophiles. Berliner and Altschul[3] have made a study of the kinetics of hydrolysis of several aroyl anhydrides. Their data indicate that the rate-determining step in the hydrolysis involves attack by the nucleophile on the carbonyl carbon. The observed effect of ring substituents is in accord with this view. Bunton, Lewis and Llewellyn[4] have shown by using an oxygen-18 tracer that an intermediate $C_6H_5-C(OH)_2-\overset{\overset{O}{\|}}{C}-C_6H_5$ must be in equilibrium with the starting materials in the aqueous hydrolysis of benzoic anhydride. Gold and Jefferson[5] have studied the tertiary amine catalyzed hydrolysis of acetic anhydride and have concluded that the reactive species is $[CH_3-\overset{\overset{O}{\|}}{C}-\overset{+}{N}(R)_3\ \ {}^{O}_{\|}\ CH_3-C-O^-]$ although rigorous evidence for its formation was not obtained. Emery and Gold[6] have studied the product ratios obtained from the reaction of anilines with mixed aliphatic anhydrides. They have found a marked effect of solvent on these ratios as well as an apparent steric factor which alters the ratio of the products.[7] These observations indicate strongly that the attack by the nucleophile, :NH, on an anhydride proceeds by a slow rate-determining step to give I which is in equilibrium with starting materials. Conversion of I to products will depend to some degree on the nature of the nucleophile. If, for example, it is an anion then proton transfer will not be required; on the other hand, amines, alcohols, etc., will require that a proton be transferred before the products are formed. It is the latter situation which is of concern here. There are two attractive paths for the formation of products from I. Path A involves an ionization of I to give the fragments of II. Reaction of some base, :B, *i.e.*, solvent, nucleophile or $R-COO^-$ completes the process and one obtains the observed products. If Path A is followed and one uses an anhydride which has been labeled as indicated, then the distribution of oxygen-18 in the products will depend on the rate of return from II to starting materials as compared to the rate of collapse of II to products.[8] If return to starting materials is much faster than product formation, then the oxygen-18 in the anhydride will become equilibrated, since in II $R-COO^-$ allows equilibration of the label. If k_4 is much larger than k_{-1} and k_{-2}, then there will be no equilibration, as II will never return to starting materials. It can be readily seen that product formation by Path B will not lead to equilibrated products. If one uses a labeled anhydride and if these two paths are the ones being followed, it is possible to get some measure of the relative importance of return from II as compared to the non-equilibrating routes by measuring the oxygen-18 distribution in the products. Unfortunately, a further complication arises since benzoic acid, a product of the reaction, can react with the anhydride to give equilibrated material. It has been possible to show that this reaction contributes very little to the oxygen-18 equilibration.

Results and Discussion

Synthesis.—The preferred method of preparing the monocarbonyl labeled benzoic anhydride is to allow silver benzoate to react with labeled benzoyl chloride. This reaction affords good yields of specifically labeled anhydride. It was by this procedure that IV was converted *via* the acid chloride to VII (see Table I). Another method used for preparing the monolabeled anhydride was to allow sodium benzoate in water to react with labeled benzoyl chloride (from III) in chloroform. Using this procedure VI was prepared; however, because of the unpredictableness of the method, it cannot be recommended. When labeled benzoic acid, V, was allowed to react with benzoyl chloride and pyridine in ether, an excellent yield of VIII was obtained.

(7) A study in this Laboratory of the ratio of products obtained from mixed aroyl anhydrides as yet has not led to the large solvent effects found by Emery and Gold. Further discussion of the points raised by these experiments will be deferred until a later paper as they do not affect the arguments advanced in this paper.

(8) The reasoning which is being applied here depends upon the fact that the products are not in equilibrium with the starting materials; that this is the case is abundantly demonstrated by qualitative organic chemical data.

It was shown that VIII was partially equilibrated with respect to its oxygen-18, and therefore this method is unreliable.

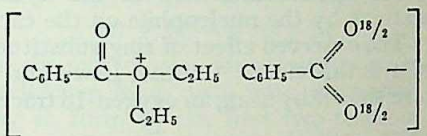
TABLE I

Compound	Atom % O^{18} in labeled position
Benzoic anhydride (VI)	1.32; 1.30
Benzoic anhydride (VII)	1.00; 0.99
Benzoic anhydride (VIII)	1.19; 1.19
Benzoic acid (III)	1.32; 1.31
Benzoic acid (IV)	1.02; 1.01
Benzoic acid (V)	1.19; 1.18
p-Nitrobenzoic anhydride (IX)	1.13; 1.11

Position of Label.—The distribution of oxygen-18 in these anhydrides was elucidated by allowing them to react with ammonia at −33°. The oxygen-18 content of the benzamides and benzoic acids derived from VI and VII indicated that all of the excess oxygen-18 was incorporated in the carbonyl groups. The methods of synthesis limit this excess oxygen-18 to only one of the carbonyls. When VIII was treated in this manner, the results showed that VIII was about 35% equilibrated. This equilibration presumably occurred during the preparation of the anhydride.

The reaction of these anhydrides with ammonia proceeds without any equilibration; therefore, Path B must be operating or no return from II is taking place. Such a finding is not unexpected since the excess ammonia will make the conversion of II to products and of I to III very rapid, thereby eliminating return. It is very interesting to note that at −78° the reaction of the anhydrides with ammonia leads to completely equilibrated products. At this temperature ammonia apparently exists as rather tightly hydrogen bonded oligmers. Diffusion of these large groups to the reaction site will be slow compared to the reaction at −33°, and therefore return from II can compete effectively with the non-equilibrating processes.

Equilibration Paths.—When the labeled anhydrides were allowed to react with aniline in ether, the products showed complete equilibration of the oxygen-18. If the anhydride interacts very rapidly with the ether to give an ion pair, X, then collapse of X to the starting material would lead to equilibration. It has been shown that the equilibration does not take place through X since anhydride which had been dissolved in ether gave the same oxygen-18 distribution as untreated material when they were allowed to react with aniline in water–acetone.



X

Another possible path for the equilibration involves a rapid attack by the benzoic acid being formed in the reaction on unreacted anhydride. That this path contributes little to the equilibration has been shown by allowing molar ratios of benzoic anhydride, aniline, dimethylaniline and benzoic acid-C^{14} to react in ether. The benzanilide contained 15% of the possible carbon-14 calculated on the basis of complete exchange of all benzoyl species. This figure represents an unreal maximum since the concentration of benzoic acid under the normal reaction conditions is much lower than that used here. In the absence of aniline the amount of exchange was considerably higher, 46%.

The other path which can lead to equilibration involves return from II. In order to test this possibility, a molar ratio of anhydride to aniline of 2:1 was allowed to react in ether. The unreacted anhydride was recovered and treated with ammonia. The benzamide contained 38% of the excess oxygen-18 and the benzoic acid 58%. These figures correspond to about 69% equilibration and amply demonstrate that equilibration of the starting materials is taking place.

Effect of Basic Solvent.—An inspection of the proposed reaction scheme shows that in all paths some base :B is required before the products can be formed. In Path A benzoate ion can function as the base and, since it is intimately associated with the cation, it should have ample opportunity to remove the proton. It also has the opportunity to function as a nucleophile and cause return to I. If the benzoate ion acts primarily as a base, then one would expect to find non-equilibrated products, which is not the case in most of the examples studied. The prime function of the benzoate ion therefore appears to be that of a nucleophile, and it attacks on the cation to give return to I.

[a] Analyzed by the method of W. E. Doering and E. Dorfman, THIS JOURNAL, 75, 5595 (1953), as slightly modified by D. B. Denney and M. A. Greenbaum, *ibid.*, 78, 979 (1957). In the case of the anhydrides and products the observed oxygen-18 values appear to be good to ±0.01 atom % oxygen-18. In general, in work of this sort the tendency is to obtain low values for the oxygen-18 content since any dilution or exchange causes a decrease in oxygen-18 content. The deviation from the expected total oxygen-18 content of the products has been listed in the table, and in all cases but one it is equal to or less than ±0.03. These values represent the sum of the errors over three positions. The calculated per cent. equilibration is accurate to about ±8%, in the case of products from VII. In the case of products from VI it is about ±5%. The reason for the difference between VII and VI is because of the greater oxygen-18 content of VI.

The presence of added base in the reaction mixture should lead to a net decrease in equilibration, all other things being equal. This will arise since the rate of conversion of II to products will be increased as will the rate of formation of III. The reaction in ammonia demonstrates the importance of base concentration in controlling the amount of equilibration. In order to find other examples of this behavior, the labeled benzoic anhydride was allowed to react with aniline in acetone–water (1:2). Analysis of the products showed that 23% equilibration had occurred. Under these conditions the water is functioning as a base and therefore decreases the rate of return from II. II is also probably much more stable in this solvent mixture than in solvents of lower dielectric constant, and the ions should therefore be much more loosely bound. Any diffusion away from the cation by benzoate ion will lead to a lowering in the rate of return from II to I.

Prof. Philip A. Vaughan (Rutgers) has derived an equation which relates the ratio of the rate of return from II to the rate of those processes which lead to products, *i.e.*, k_4 and Path B. This equation only applies to those situations in which an effective base is present in excess throughout the course of the reaction. The equation is

$$V = 0.333 + \frac{0.166}{0.75r + 1}$$

where V = the observed excess oxygen-18 content in the product benzoyl species normalized to a starting value of 1.00.

r = the ratio of the rate of return from II to product formation by all paths, and r is also equal to the average number of returns from II.

Using this equation r can be calculated for the reaction in acetone/water and it is 0.22. This result is indicative of the delicate balance of rates between return and product formation.

It was deemed desirable to have an example of the reaction in a basic organic solvent. The choice of such a solvent is rather difficult since they can in general react with the anhydride to cause equilibration. It was found that the reaction of cyclohexylamine with labeled anhydride in dimethylaniline afforded products which were 62% equilibrated. In this example at least some of the equilibration may have been caused by the dimethylaniline. A calculation of r for the above reaction shows it to be 1.4. In this case it is interesting to note that although dimethylaniline is a stronger base than water, more equilibration takes place than occurred in the aqueous solution. At least a part of this effect is due to the lower dielectric constant of dimethylaniline which will cause II to be "tighter" and will facilitate return. When methanol was used as the solvent as well as the nucleophile, the products contained completely equilibrated oxygen-18. Since methanol is a weaker base than either water or dimethylaniline and since its dielectric constant is rather low as compared to water, it is not surprising that one finds complete equilibration in the reaction.

Effect of Deuterium Substitution.—Inspection of the proposed reaction scheme indicates that any diminution in the rate of conversion of II to products or in the rate of Path B should lead to increased oxygen-18 equilibration. Deuterium substitution for hydrogen to give :N–D will lead to intermediates containing deuterium and presumably to a diminution in rate of hydrogen transfer since the energy required to transfer the deuteron will be larger than that required for the proton. When cyclohexylamine–ND_2 was allowed to react with labeled anhydride in dimethylaniline, the products showed complete equilibration of the label. These results are to be compared with the undeuterated material in which the amount of equilibration was 62%. Clearly there is an isotope effect which leads to the predicted behavior.

Effect of Substituent.—When *p*-nitrobenzoic benzoic anhydride-*p*-nitrobenzoyl-*carbonyl*-O^{18} (IX)

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

was allowed to react with aniline in ether, the *p*-nitrobenzanilide contained 52% of the excess oxygen-18. Several factors can contribute to the difference found between the amount of oxygen-18 equilibration in the substituted and unsubstituted cases. One difference is that in the substituted case one can isolate product containing only the original labeled position, *i.e.*, *p*-nitrobenzanilide. In this manner the dilution factor which was present in the symmetrical case is removed. The presence of the *p*-nitro group will enhance the rate of attack at the carbonyl adjacent to the ring bearing the *p*-nitro group. Increased attack at this position causes a slower equilibration than an equal number of statistical attacks. There are considerable complications attendant with any attempt to calculate the number of returns from II in this case, since II now consists of two different ion pairs which are formed at different rates and which have different k_{-1}'s, etc. It is possible to make a very naive calculation if several assumptions are made. It has been assumed that the ratio of the rate of attacks at the substituted benzoyl moiety as compared to the benzoyl is 3:1. This assumption is based on the product ratio, there being 75% *p*-nitrobenzanilide to 25% benzanilide. It is also necessary to assume that k_4 and k_3 are zero until the proper degree of equilibration is reached and then become infinite. Such an assumption leads to a value for the number of returns (the ratio of the rates is not being calculated here) that is smaller than the actual value. The equation used in this calculation is one that arose during the derivation of the equation reported above. It is

$$P_N = \frac{1}{3} + \frac{{}^2/_3 g_2 - {}^1/_6 - {}^1/_2 x}{g_2 - g_1} g_1 N + \frac{{}^1/_6 + {}^1/_2 x - {}^2/_3 g_1}{g_2 - g_1} g_2 N$$

where P_N = observed excess oxygen-18 in the benzoyl product normalized to a starting value of 1.0.

x = probability of attack at the labeled position here ${}^3/_4$.

$$g_1 = \frac{1 + \sqrt{1 - 3x + 3x^2}}{2} \qquad g_2 = \frac{1 - \sqrt{1 - 3x + 3x^2}}{2}$$

N = number of returns, with the limitations discussed above

Calculation of N for the reaction of the *p*-nitrobenzoic benzoic anhydride gives a value between four and five. This average value is low since the rate of formation of product has been ignored.

Effect of Solvent.—The reaction of the labeled anhydride with aniline in dimethylformamide, acetonitrile and ether have been investigated. In all of these cases the products were completely equilibrated. In going from ether to dimethylformamide and acetonitrile, the dielectric constant of the solvent has changed from 4.34 to 37.5. An increase in dielectric constant of the solvent should markedly increase k_1 and decrease k_{-1}. An increase in k_2 should also be observed if, as seems likely, the charges in II are separated farther apart than in I. If such is the case, one would expect k_2 to decrease. The effect of increased dielectric on k_4 should be a slight decrease since in the transition state leading from II to products, *i.e.*, the proton transfer, there will be a dispersal of positive charge. In Path B k_3 should increase and k_{-3} decrease if the charge separation in III is greater than in II. The effect on k_5 should be relatively slight. The predicted over-all effect of increased dielectric constant is less equilibration of the oxygen-18, since the large decrease in k_{-1} relative to the changes of the other constants should make return a slower process. Since in all of the non-basic solvents studied to date the products have been equilibrated, it is impossible to test this prediction. Future experiments using monolabeled *p*-nitrobenzoic benzoic anhydride should give a quantitative measure of the solvent effect in this reaction.

Effect of Nucleophile.—Cyclohexylamine in ether and methanol in acetonitrile were allowed to react with the labeled anhydride. In both of these cases the products contained completely equilibrated oxygen-18. These findings are not unexpected since the controlling factors for these reactions do not appear to involve the rate of formation of I which will be affected markedly by a change in the power of the nucleophile.

Acknowledgment.—We wish to thank the Esso Research Corporation for making available the mass spectrometer used in this work.

Experimental

Benzoic Anhydride (V).—A solution of 6.70 g. (0.048 mole) of benzoyl chloride-O^{18} (from III) in 30 ml. of chloroform was shaken intermittently over a 48-hr. period with a solution of 6.00 g. (0.050 mole) of benzoic acid and 2.00 g. (0.050 mole) of sodium hydroxide in 50 ml. of water. The chloroform solution was dried and concentrated *in vacuo* to afford material which after two crystallizations from petroleum ether had m.p. 41.5–42°; yield 5.80 g. (55%).

Benzoic Anhydride (VII).—To an ice-cold stirred suspension of 40.0 g. (0.175 mole) of silver benzoate and 25 g. of glass beads in 250 ml. of dry ether was added 24.0 g. (0.171 mole) of benzoyl chloride-O^{18} (from IV) in 25 ml. of ether. The mixture was stirred at 0° for 12 hr. The ether solution was evaporated to give 31.5 g. of crude anhydride which after crystallization from hexane afforded 26.4 g. (68%) of VII, m.p. 43–43.5°.

Benzoic Anhydride (VIII).—To a stirred solution of 43.8 g. (0.312 mole) of benzoyl chloride in 60 ml. of ether was added over 15 minutes a solution of 38.0 g. (0.312 mole) of benzoic acid-O^{18} (V) and 24.7 g. (0.312 mole) of pyridine in 100 ml. of ether. The solution was washed with water, 10% hydrochloric acid and 10% sodium bicarbonate solution. After drying the ether, it was evaporated to afford 67.0 g. of crude VIII. The crude material was crystallized from hexane–benzene to afford 61.0 g. (86%) of VIII, m.p. 41–42°.

Reactions and Reagents.—In general the solvents and reagents were purified by standard methods. The products in all cases were isolated easily in high yield with a minimum amount of effort. All of the products were purified before analysis. Table III contains the experimental data.

Cyclohexylamine-ND$_2$.—A solution of 5.0 g. of cyclohexylamine in 25 ml. of ether was shaken with 3 ml. of deuterium oxide followed by four 1-ml. washes. The ether layer was dried over magnesium sulfate and evaporated to yield the deuterated amine. The infrared spectrum of this material indicated the presence of deuterium in the molecule. The amine was used as such in the reaction with the anhydride.

***p*-Nitrobenzoic Benzoic Anhydride-*p*-nitrobenzoyl Carbonyl-O^{18} (IX).**—The labeled anhydride was prepared as described by Denney and Greenbaum.[9]

Reaction of VI in the Presence of Benzoic Acid-C^{14}.[10]—To a solution of 0.465 g. (0.005 mole) of aniline, 0.61 g. (0.005 mole) of benzoic acid-C^{14}, activity 4.07 mμc./mg. C and

[a] Unless otherwise specified the quantities of reactants used were 0.01 mole. [b] 0.0018 mole of VI used. [c] A large recovery of starting material indicated that this reaction was not completed.

0.61 g. (0.005 mole) of dimethylaniline in 50 ml. of anhydrous ether was added 1.13 g. (0.005 mole) of benzoic anhydride. After standing 1 hr., 10 ml. of 10% hydrochloric acid was added and the ether was evaporated. The heterogeneous mixture was treated with chloroform to dissolve the solid. The chloroform was washed with 10% sodium carbonate solution and water. The dried chloroform was evaporated to afford 1.01 g. of benzanilide which was recrystallized from methanol–water to afford 0.70 g. (71%) of material, m.p. 162.2–163.4°. The basic extracts were acidified to yield crude benzoic acid which was recrystallized from hexane to afford 0.90 g. (74%) of benzoic acid, m.p. 121–122°.

The recovered benzoic acid had an activity of 2.02 mμc./mg. C and the benzanilide showed 0.093 mμc./mg. C. These data indicate that 15% of the theoretical amount of C^{14} has been incorporated into the benzanilide.

When benzoic anhydride was allowed to stand under the same conditions but in the absence of aniline, the recovered benzoic anhydride had 0.63 mμc./mg. C which corresponds to 46% equilibration of the C^{14}.

Electronic Effects in Elimination Reactions. I. Pyrolysis of Acetates[1]

BY C. H. DEPUY AND R. E. LEARY

RECEIVED FEBRUARY 8, 1957

Pyrolytic eliminations of some acetates of substituted 1,3-diphenyl-2-propanols lead to the formation of that olefin which also predominates when the possible olefins are equilibrated and not to the olefin which would be formed by loss of the most acidic hydrogen. It is suggested that in the transition state for acetate pyrolysis reactions, a large amount of double bond character has been developed.

Although the Saytzeff and Hofmann rules—which allow the position of the double bond in unsymmetrical elimination reactions to be predicted—have been formulated for nearly a century, the underlying steric and electronic effects which determine this position still are not fully understood. The most generally accepted interpretation of the rules is that of Hughes and Ingold.[2] According to their view, in the Hofmann elimination (elimination from trialkylammonium or dialkylsulfonium salts with base) the most acidic hydrogen is removed and the direction of elimination is determined by this factor. In the Saytzeff elimination (elimination of halogen or other neutral anions), the stability of the resulting olefinic product is the more important factor and controls the direction of elimination. Hyperconjugative factors were postulated to be of primary importance. Recently Brown and co-workers[3] have demonstrated the importance of steric effects in directing eliminations.

A priori, an elimination of the type I might be imagined to have a whole spectrum of transition

$$H\text{–}C\text{–}C\text{–}X \longrightarrow H^+ C{=}C\ X^- \qquad (I)$$

states available to it, depending upon the nature of the group X, the particular mechanism of the elimination, the type of solvent and a host of other factors. As one extreme, a case might be imagined in which the carbon–hydrogen bond is completely broken before the C–X bond has even started to rupture, II. At the other extreme, both the C–H

$$H\cdots\overset{|}{C}\text{—}\overset{|}{C}\text{—}X \qquad (II)$$

and C–X bonds might be very much broken in the transition state, III. Other situations may be imagined. An understanding of the structural

$$H\cdots\overset{|}{C}\cdots\overset{|}{C}\cdots X \qquad (III)$$

factors that affect the transition state configuration could allow more control over the nature of the product to be expected in eliminations and the amount of olefin being formed in competing reac-

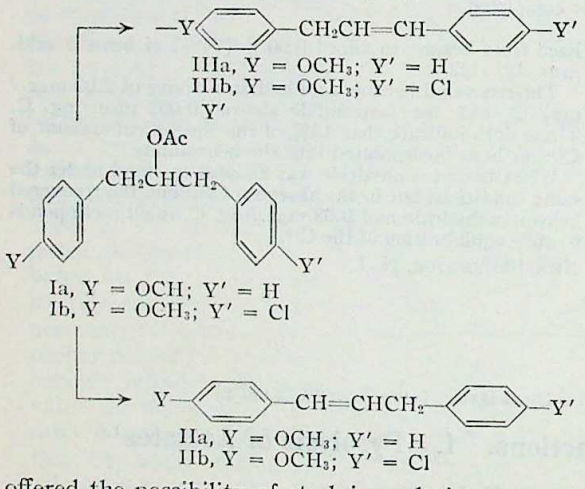
tions. To this end we have begun a general investigation of the effect of various electronic factors on the rate of several elimination reactions.

In studying elimination reactions, we wished to choose a system in which we could readily determine both the acidity of the hydrogens being removed and the relative stability of the olefins being formed. In addition, we desired a system in which base-catalyzed eliminations could be followed kinetically, and at the same time eliminations could be studied in which kinetic data would be either difficult to obtain (pyrolytic eliminations) or of no value (first-order eliminations). For this investigation we have chosen compounds of the type I. These 1,3-diphenyl-2-propyl compounds



offered the possibility of studying relative rates of eliminations where actual rate measurements were not possible. Thus, in a pyrolytic elimination of acetic acid the rate for a substituted benzene ring could be compared to the rate for an unsubstituted ring by analyzing the olefin mixture for the relative amounts of olefins II and III. Variations in the nature of the substituent would allow a Hammett σ–ρ treatment to be carried out. Concurrently a straight kinetic investigation of base-catalyzed eliminations in the simpler but analogous β-phenyl ethyl system was begun.

If the system I appeared satisfactory from the standpoint of kinetics, it also seemed attractive for the investigation of both the stabilities of the resultant olefins and the acidities of the hydrogens. Thus, Ingold and Shoppee[4] had shown that olefins of this type could be equilibrated in base and, of course, the proportion at equilibrium would reflect the relative thermodynamic stabilities of the two olefins. The relative hydrogen acidities could be estimated from the Hammett σ-values of the substituent groups and, if more precise data were deemed necessary, a study of the *rates* of the equilibration of the olefins would be indicative. Two other advantages of this system made its selection propitious. First the absence of selective steric effects served to simplify the interpretation of results, and secondly the ease of analysis of the mixture of products, as will be discussed below, offered the possibility of studying a number of different eliminations with the same system.

Synthesis.—For reasons that will become apparent in the discussion of the analytical method, it was felt desirable to have Y = OCH_3. In order to make the rate differences as large as possible, the presence of a *p*-chloro group seemed desirable. In base-induced eliminations where hydrogen acidity is important, the presence of a *p*-chloro group favors the elimination by a factor of nearly ten.[5] On the other hand, a *p*-methoxyl group conjugates well with a double bond[3] and would be expected to accelerate those reactions in which the relative stability of the olefin played a dominant role. For this reason Ia and Ib were synthesized. The synthesis of the requisite alcohols are summarized in Charts I and II. These paths had the advantage over other imaginable paths of providing the olefins for equilibration and analysis studies.

Analytical Method.—In the pyrolysis of the acetates the two possible olefins would be obtained together with varying amounts of unreacted acetate. Other contaminants were to be anticipated when these compounds were applied to the study of other elimination reactions. While spectral analysis would probably be possible in this system, it appeared to be extremely difficult to make general. In choosing these particular compounds for the study, we planned to make use of the well-known variation in the reactivity of substituted benzyl compounds.[6] The mixture of olefins was converted to a mixture of benzyl bromides with HBr in methylene chloride under conditions where the initial acetate was unreactive. These solutions were made up to a known volume with absolute acetone and, after the addition of a small amount of water, the bromides allowed to solvolyze. The *p*-methoxybenzyl bromides formed by addition of HBr to olefins IIa and IIb solvolyzed very rapidly as compared to either the unsubstituted (from IIb) or *p*-chloro bromides (from IIc), and titration of the liberated acid after about 40 minutes at 25° gave the amount of this bromide present. Solvolysis at higher temperatures with more water added, or reaction with silver nitrate solution, was used to get the total halide and from this the amount of unsubstituted or *p*-chlorobenzyl bromide. By this method known mixtures could be determined to within 3%. It should be pointed out that the large differences in solvolysis rate which were utilized in these experiments are not necessary for the analytical method to be useful. Differences of a factor of three or less are sufficient if more kinetic points are taken.

Results and Discussion

Acetate pyrolysis reactions have been extensively investigated by Bailey and co-workers[7] in an effort to determine the direction of elimination. In three aliphatic cases the Hofmann rule was obeyed exclusively, that is, the hydrogen was abstracted from a CH_3 group in preference to a CH_2 group and from a CH_2 group in preference to a C–H group. This preference for the methyl hydrogen

was observed again in the pyrolysis[8] of 1-methoxy-2-propyl acetate and in 1-dimethylamino-2-propyl acetate. However, in compounds containing a benzene ring, Hofmann control was less complete. In 1-phenyl-1-propyl acetate, 75% of the resultant olefin was conjugated to the benzene ring; and this rose to 100% in the case of 1,1-diphenyl-2-propyl acetate.[9] Compounds containing nitro[10] and ester[9] groups also have given products not in accordance with the Hofmann rule.[11] In these cases the olefin formed was found to be conjugated with the unsaturated group. Bailey has interpreted these results to mean that the acidity of the hydrogen being removed is primarily responsible for determining the direction of elimination. Since our system gave a means of checking this conclusion where the various electronic influences were determinable and since, in addition, steric factors were the same for the competing eliminations, we decided to investigate the electronic effects in acetate pyrolyses as the first case in our general study of elimination reactions.

From the standpoint of its electronic effects, a *p*-methoxyl group appeared to be a desirable substituent. From its σ-value (-0.268)[12] it could be predicted to have the effect of decreasing the acidity of the benzyl hydrogens and so of making eliminations slower which depended on this acidity.[5] Ingold and Shoppee[4] have measured the position of equilibrium of the olefins IIa and IIIa and had found that IIa, in which the olefin was conjugated to the methoxyl group, predominated at equilibrium by a factor of 2.3. As a consequence, olefin IIa is the more stable of the two and should predominate in the pyrolysis if olefin stability is the more important effect in the transition state.

The results of a number of pyrolyses of acetate Ia under different conditions are summarized in Table I. Under all conditions investigated, the more thermodynamically stable of the two possible olefins is formed in the elimination. In fact, the olefin proportion is the same, within experimental error, as that which would result from equilibration.

TABLE I

PYROLYSIS OF 1-PHENYL-3-*p*-METHOXYPHENYL-2-PROPYL ACETATE

Phase	Conversion, %	*p*-Methoxy (IIa), %	Hydrogen (IIIa), %
Liquid	47	70	30
Vapor	46	75	25
Vapor	20	73	27
Vapor	..	70	30
Liquid	11	75	25

We next investigated a compound in which the difference in hydrogen acidity would be even larger than was the case in Ia. Replacement of the *p*-hydrogen with a chlorine ($\sigma = +0.227$) gave Ib in which the benzyl hydrogen acidity was greatly enhanced. On the other hand, our equilibration experiments showed that at equilibrium the *p*-methoxyl olefin should still predominate. The results of these pyrolyses, summarized in Table II, again indicate that the stability of the olefin being formed is controlling the direction of the elimination.

Vapor	26	77	23
Vapor	46	87	13

Because of the fact that the pyrolysis products and the equilibrium products were the same, it had to be demonstrated that the actual products isolated were those arising directly from the elimination and not being formed by equilibration of an initially formed mixture of a different composition. To establish that the products are stable to the reaction conditions, we have carried out the following experiments. (1) Pure olefins were subjected to the conditions of the reactions and did not equilibrate. (2) Benzyl acetate XIIa on vapor phase pyrolysis gave only IIIa, uncontaminated with its isomer, despite the fact that the isomer formed is the least stable of the pair and that small quantities of the other isomer would be easily detectable by our analytical method. (3) Liquid phase eliminations of the four possible benzyl acetates in the synthetic procedures, followed by distillation, gave high yields (about 70%) of the corresponding olefins which were uncontaminated with the other isomer. We believe that these control experiments establish the absence of post-equilibration to a high degree of probability.

Our results demonstrate that the relative stabilities of the olefins being formed are instrumental in determining the rate of eliminations and that, at least in our system, relative hydrogen acidity is not of importance. In compounds with very acidic hydrogens, as in the nitro and carbethoxy cases, it may be that resonance stabilization of anions is important; but our data make it unlikely that hydrogen acidity is important in the simple aliphatic systems. It seems more probable that steric factors are playing an important role in determining the course of the reaction[13] in these cases and that only when steric factors are canceled out, or the electronic effects become overpowering, do non-Hofmann products arise.

A transition state whose structure is rather close to that of the olefin seems a reasonable one for the acetate pyrolysis. Both the leaving group (–OOCCH$_3$) and the base (O=C) are weak, and simultaneous breaking of both the C–H and C–O bonds would be expected. The elimination would be anticipated to be much less exothermic than the E$_2$ reaction of the corresponding halides, and hence the transition state would occur well along the reaction coördinates.[14] This would lead to appreciable double bond character in the carbon–carbon bond, and interactions between this developing double bond and the aromatic substituents would parallel the interaction found in the olefinic products.

An alternative mechanism for these pyrolytic eliminations appeared possible. In this mechanism the C–O bond-breaking would precede C–H bond-breaking, and the elimination would be in reality an E$_1$ type. Since E$_1$ eliminations have been assumed to give the most stable olefin as product, this would be in accord with the facts. To rule out this possibility, we ran liquid phase eliminations of the *p*-methoxybenzyl acetate VI and the unsubstituted benzyl acetate XIIa. If the elimination were E$_1$ in character, the *p*-methoxyl acetate would be expected to eliminate many times faster than the unsubstituted acetate. However, the actual differences in rate were small and consistent with the view that differences in stability of the olefins being formed in the two cases were responsible for the differences in rates.

It seems probable then that the transition state for ester pyrolysis reactions is well along toward products and that, in the absence of steric effects, the olefin stability, as reflected in the transition state, determines the direction which the elimination will take. Strongly acid-strengthening groups may affect the timing of the C–H and C–O bond-breaking steps enough to exert a specific control on the reaction.

Experimental[15]

Preparation of 1-(*p*-Anisyl)-3-phenylpropanol (V).—To a Grignard reagent prepared from 9 g. (0.375 mole) of Mg and 70 g. (0.375 mole) of *p*-bromoanisole in 250 ml. of ether was added slowly a solution of 44 g. (0.328 mole) of freshly distilled hydrocinnamaldehyde in ether. After the addition was complete, the mixture was heated at reflux for 0.5 hr. and decomposed by the addition of 450 ml. of a cold, saturated solution of ammonium chloride. After washing and drying, the ether was removed and the oily residue distilled. The product (56.5 g., 71% yield, b.p. 175–180° (0.5 mm.)) crystallized upon scratching. Recrystallization from hexane gave needles, m.p. 46–48°. Several times during distillations, spontaneous elimination occurred giving the olefin IIa directly.

Preparation of 1-(*p*-Anisyl)-3-phenylpropene (IIa).—The olefins could best be prepared in a pure form by liquid phase pyrolysis of the acetates. The alcohol V was acetylated with pyridine and acetic anhydride to give 1-(*p*-anisyl)-3-phenylpropyl acetate (VI), b.p. 170–175° (1 mm.), n^{18}D 1.5458. The acetate (10 g.) was placed in a small distilling flask equipped with a short column and a graduated centrifuge tube as a receiver. The liquid was heated with a soft bunsen flame until acetic acid began to distil. Heating was continued at such a rate that the acetic acid distilled rapidly and until the calculated amount had been collected. The residue was then cooled, taken up in methylene chloride and washed free of any excess acid. Distillation gave 5.5 g. (70% yield) of olefin, b.p. 160° (1 mm.).

Anal. Calcd. for C$_{16}$H$_{16}$O: C, 85.68; H, 7.19. Found: C, 85.80; H, 7.04.

Preparation of Hydroxybenzoate VII.—A cold mixture of the olefin IIa (45 g., 0.2 mole) and 24 g. (0.2 mole) of benzoic acid in 240 ml. of methylene chloride was added over 0.5 hr. to a cold solution of 30 g. (0.23 mole) of perbenzoic acid in methylene chloride. The solution was stirred and kept below 5° with an ice-bath during the addition. After the solution stood overnight at 4°, the excess acid was removed by extraction and the methylene chloride removed. The crystalline hydroxybenzoate which remained could be used in the next step without further purification. A sample crystallized from aqueous alcohol gave m.p. 98–99°.

Anal. Calcd. for C$_{23}$H$_{22}$O$_4$: C, 76.22; H, 6.12. Found: C, 75.94; H, 6.06.

Preparation of 1-(*p*-Anisyl)-3-phenylpropanol-2 (Ia).—A solution of 40 ml. of concd. H$_2$SO$_4$, 40 ml. of water and 250 ml. of alcohol was added to 40 g. of the hydroxybenzoate

and the mixture heated at reflux for 3.5 hr. After cooling the mixture, water (200 ml.) was added and the ketone extracted with three 150-ml. portions of ether. The extracts were washed with carbonate and water and the solution dried. Distillation gave the ketone (b.p. 160–170° (1 mm.)) which could not be induced to crystallize. The crude ketone was reduced with lithium aluminum hydride to give, after distillation at 175–180° (1.5 mm.), a colorless oil which soon crystallized. Recrystallization from pentane and then from alcohol gave Ia as long needles; yield 20 g., 71% (based on hydroxybenzoate), m.p. 48–48.5°. Admixtures with alcohols V and XIa showed large depressions in melting points.

Anal. Calcd. for $C_{16}H_{18}O_2$: C, 79.68; H, 7.49. Found: C, 79.50; H, 7.50.

The acetate, prepared in the usual manner, had b.p. 188–190° (0.5 mm.). *Anal.* Calcd. for $C_{18}H_{20}O_3$: C, 76.03; H, 7.09. Found: C, 76.10; H, 7.18.

Preparation of 1-Phenyl-3-(*p*-anisyl)-1-propene (IIIa).—*p*-Anisaldehyde and acetophenone were condensed and reduced catalytically according to the method of reference 16 to give 1-phenyl-3-(*p*-anisyl)-1-propanone (Xa), m.p. 65–66°. Lithium aluminum hydride reduction gave the alcohol XIa, m.p. 64–65°.

Anal. Calcd. for $C_{16}H_{18}O_2$: C. 79.68; H, 7.49. Found: C, 78.95; H, 7.20.

Acetylation gave the acetate, b.p. 166–170° (0.7 mm.).

Anal. Calcd. for $C_{18}H_{20}O_3$: C, 76.03; H, 7.09. Found: C, 76.20; H, 6.95.

Pyrolysis of the ester by heating 30 g. in a pear flask with a free flame until approximately the calculated amount of acetic acid distilled and distillation of the residue gave the olefin, b.p. 147–148° (0.3 mm.), $n^{24}D$ 1.5948.

Anal. Calcd. for $C_{16}H_{16}O$: C, 85.68; H, 7.19. Found: C, 85.90; H, 7.20.

Addition of HBr in methylene chloride to a sample of this olefin and subsequent solvolysis showed it to be uncontaminated with the other isomer.

Preparation of 1-(*p*-Anisyl)-3-(*p*-chlorophenyl)-1-propanol (XIc).—This alcohol, prepared by $LiAlH_4$ reduction of the corresponding ketone Xc,[15] was distilled at 196–200° (1 mm.). It could not be induced to crystallize.

Preparation of 1-(*p*-Anisyl)-3-(*p*-chlorophenyl)-2-propanol.—This alcohol was synthesized using the same procedure as above. In this series the hydroxybenzoate failed to crystallize, but the oily product was used directly to furnish crystalline ketone, m.p. 42–44°. Lithium aluminum hydride reduction of this ketone gave the alcohol, m.p. 69–69.5° after recrystallization first from hexane and then from alcohol–water.

Anal. Calcd. for $C_{16}H_{17}O_2Cl$: C, 69.43; H, 6.19; Cl, 12.85. Found: C, 69.60; H, 6.43; Cl, 12.70.

The acetate, prepared in the usual manner, had m.p. 64–65°. *Anal.* Calcd. for $C_{18}H_{19}O_3Cl$: C, 67.81; H, 6.01; Cl, 11.12. Found: C, 68.09; H, 6.09; Cl, 11.15.

Pyrolysis.—The pyrolyses were carried out by two different methods. In the liquid phase experiments the pure liquid acetates, together with a crystal of a polymerization inhibitor, were heated in a small flask until approximately 50% of the calculated amount of acetic acid was collected. The residue was taken up in ether or methylene chloride and washed free of acetic acid. The solvent was then removed and the residue analyzed. In the vapor phase experiments pure liquid acetate was added dropwise to the top of a vertical glass pyrolysis tube, electrically heated and equipped with a thermocouple. The tube was heated to 500°. Glass beads and glass helices gave identical results when used as packing for the tube. To minimize carbonization, eliminations were carried out to 20–50% conversion. The products were collected in a Dry Ice trap, an aliquot was removed and analyzed for acetic acid and the remainder was washed free of acid, dried and the solvent was removed. Samples of the residue were analyzed for the olefin proportions and other samples for unreacted acetate and total olefin.

Analytical Methods.—In a typical experiment 1.0746 g. of the pyrolysis mixture of Ia was dissolved in 5 ml. of purified CH_2Cl_2. The solution, in a centrifuge tube equipped with a gas inlet tube, was cooled to −10° and gaseous HBr, from a sample collected in Dry Ice, was passed in. When an excess had been added, fumes of HBr began to appear and the addition was stopped. After an additional minute to ensure completion of the reaction, N_2 gas was passed through the solution to remove as much of the excess HBr as possible. The solution was transferred to a 50-ml. volumetric flask and diluted to 50 ml. with anhydrous acetone. A 5-ml. aliquot was removed and the excess HBr was determined by titration with triethylamine in acetone. The sample required 0.09 ml. of 0.1 *N* base. Water (2 ml.) was added and the flask was placed in a constant temperature bath at 25°; 5-ml. samples were removed periodically and titrated. After 40 minutes, 1.80 ml. of amine was required, and this amount did not change after an additional 30 minutes at this temperature. This corresponds to 0.160 meq. of bromide conjugated to the *p*-anisyl group. Another 5-ml. sample of the solution was added to 5 ml. of standard aqueous silver nitrate solution, and the excess silver was determined by titration with standard thiocyanate. Silver (0.213 meq.) was used. Therefore, the olefin was 75% IIa and 25% IIIa. The sample contained 46% olefin. Titration of the acetic acid liberated in the pyrolysis had indicated that 47% reaction had taken place. A saponification equivalent on a sample of the pyrolysis product showed it to contain 51% unreacted acetate. Hence, 97–98% of the product was accounted for. At higher conversions the percentage of the product which could be accounted for by this method dropped off, presumably because of polymerization of the olefinic products, and olefin proportions from these runs are not reported.

Equilibration of Olefins.—The procedure was that of Ingold and Shoppee[4] except that the olefins were analyzed by the reaction with HBr described above. In the case of the IIa–IIIa equilibrium Ingold and Shoppee reported a 70–30 mixture and our results confirmed this. In the case of IIb–IIIb we found 85% IIb and 15% IIIb.

Control Experiments.—1-Phenyl-3-(*p*-anisyl)-1-propyl acetate (XIIa) was pyrolyzed over both glass beads and glass helices at 550°. The product was analyzed in the usual manner. In three runs with conversions up to 42% no easily solvolyzable bromide could be detected and the olefin was completely non-equilibrated. Samples of the pure olefins were passed through the pyrolysis tube and subsequently analyzed for olefin proportion. They were free of detectable amounts of the other isomer. Olefins prepared in the synthetic scheme by liquid phase pyrolysis were analyzed and shown to be uncontaminated with the isomers.

A sample of the pure 2-propylacetates Ia and Ib were subjected to the conditions of the analytical procedure. No detectable solvolyzable bromide was formed, nor was any silver bromide precipitated. In the cases of the benzyl acetates, XII, HBr was absorbed to form presumably the benzyl bromides.

Solvents and Reagents.—The acetone was purified by refluxing with potassium permanganate and drying with Drierite. It was then distilled through a 50-plate column. The triethylamine was refluxed over sodium for 0.5 hr. and then distilled through a 50-plate column; b.p. 88.0°. The indicator was a mixture of brom cresol green and methyl red.[5]

Competitive Pyrolyses of Benzyl Acetates.—Two grams of 1-(*p*-anisyl)-3-phenyl-1-propyl acetate (V), and 1-phenyl-3-(*p*-anisyl)-1-propyl acetate (XIIa), were placed in separate test-tubes and simultaneously placed in a Woods metal-bath at 320° for three minutes. The samples were removed at the same time and analyzed for olefin by reaction in methylene chloride solution with a standard solution of perbenzoic acid. Under these conditions V developed 74% olefin and XIIIa developed 20%.

Electronic Effects in Elimination Reactions. II. The E_2 Reaction[1a,b]

BY C. H. DEPUY AND D. H. FROEMSDORF

RECEIVED FEBRUARY 8, 1957

The base-promoted elimination reaction of substituted β-phenylethyl halides, tosylates and sulfonium salts has been studied as a function of substituents. Good fits to a Hammett $\sigma-\rho$ plot were obtained, indicating that the acidity of the hydrogen being removed is controlling the direction of elimination. In contrast to their reactivity in solvolysis and displacement reactions, tosylates are eliminated very slowly as compared to bromides and iodides.

In connection with a general study of electronic effects in elimination reactions,[1b] we were led to an investigation of the electronic effects in the E_2 reaction, both because of the interest in the reaction for its own sake[2] and because such a study would serve as a reference for our investigation in the similar 1,3-diphenylpropyl system. Surprisingly, no comprehensive investigation of substituent effects on E_2 eliminations has been reported[3] except for some polyhalo compounds[4] and for a few β-phenylethyl chlorides.[5] Quantitative data on E_2 tosylate eliminations are likewise unavailable.[6]

Our data for the elimination of β-phenylethyldimethylsulfonium iodide, β-phenylethyl bromide, iodide and tosylate are summarized in Tables I and II. For the sulfonium salts $\rho = 2.75 \pm 0.21$, the highest value of ρ for the series. For the bromides $\rho = 2.14 \pm 0.15$ and for the iodides $\rho = 2.07 \pm 0.09$. Omitting the point for the *p*-methoxy group, $\rho = 2.50 \pm 0.06$ for the tosylates. A high positive value for ρ implies that in the transition state of the reaction a large amount of negative charge has developed, and those groups which make a negative charge more stable speed up the reaction.[7]

It has been suggested that the Saytzeff rule is a consequence of a transition state in which the stability of the incipient double bond is the dominant characteristic.[2a,8] Our results indicate that when the hydrogen being removed is on a carbon adjacent to a benzene ring, the stability of the product being formed is not of importance,[9] for if it were the *p*-methoxystyrene should be formed most rapidly.[1b,10] The fact that the sulfonium salts, bromides and iodides, and to a major extent the tosylates,[9] all show a good correspondence of rate with a measure of hydrogen acidity is to be contrasted with our results with acetate pyrolysis reactions in which a good correlation with product stability was observed[1b] in an analogous system. In these two cases we have demonstrated the extremes of transition state structural variation, from one in which double bond development is too small to be significant (E_2) to one in which the stability of the double bond being formed determines the rate of elimination.

TABLE I

RATES OF THE ELIMINATION REACTION OF $XC_6H_4CH_2CH_2Y$ at 30.10°

X	Y	k	Olefin, %	k_{E2}
H	Br	4.10×10^{-4}	100	4.10×10^{-4}
p-Cl	Br	1.88×10^{-3}	100	1.88×10^{-3}
p-OCH_3	Br	1.73×10^{-4}	100	1.73×10^{-4}
m-Br	Br	3.71×10^{-3}	100	3.71×10^{-3}
H	I	2.66×10^{-3}	100	2.66×10^{-3}
p-Cl	I	1.05×10^{-2}	100	1.05×10^{-2}
p-OCH_3	I	9.56×10^{-4}	100	9.56×10^{-4}
m-Br	I	2.03×10^{-2}	100	2.03×10^{-2}
H	OTos	1.18×10^{-4}	33	3.92×10^{-5}
p-Cl	OTos	2.93×10^{-4}	47	1.38×10^{-4}
p-OCH_3	OTos	8.61×10^{-5}	20	1.69×10^{-5}
m-Br	OTos	5.53×10^{-4}	67	3.69×10^{-4}
H	$S(CH_3)_2I^-$	3.79×10^{-3}	100	3.79×10^{-3}
p-Cl	$S(CH_3)_2I^-$	2.18×10^{-2}	100	2.18×10^{-2}
p-CH_3	$S(CH_3)_2I^-$	9.13×10^{-4}	100	9.13×10^{-4}

TABLE II

	ρ (method of least squares)	log k_0 (calcd.) Intercept
Tosylates (omitting *p*-methoxy)	2.50 ± 0.06	−4.427
Tosylates (including *p*-methoxy)	2.04 ± .47	−4.280
Bromides	2.14 ± .15	−3.260
Iodides	2.07 ± .09	−2.497
Sulfonium salts	2.75 ± .21	−2.330

The fact that the ρ-value for the sulfonium salts is larger than that for the bromides and iodides implies that the transition state for Hofmann eliminations has significantly more carbanionic character than that for the elimination of iodides or bromides. Whether this difference would be enough to account for some of the differences in direction of halide and 'onium salt eliminations in strictly aliphatic systems[2] cannot yet be said with certainty.

Perhaps the most surprising result of this investigation is the very slow rate of elimination of the tosylates. For the unsubstituted cases, $k_I/k_{Tos} = 68$ and $k_{Br}/k_{Tos} = 10$. In the case of direct displacement reactions, sulfonic acid esters appear to be more reactive than either bromides or iodides,[11] although admittedly the data are meager. This slowness in the elimination reaction has a synthetic as well as a theoretical value. From Table I it can be seen that the percentage olefin in the product varies from 20 to 67% for the tosylate eliminations. In all other cases of leaving groups studied, the olefin yield was close to 100%. Hence, while the E_2 reaction is slow, apparently the S_N2 reaction remains fast. For this reason the tosylate can be useful in preparing the corresponding ethers or amines[12] when the iodides and bromides lead only to olefin. The meagerness of available data makes a firm theoretical conclusion hazardous, and we shall discuss in subsequent papers the results of a more detailed study of tosylate elimination. The *p*-methoxy tosylate eliminates significantly faster than would be predicted on the basis of the ρ-value of the reaction. This may imply that, in this relatively unactivated case, some effect of the olefin stability is being felt in the transition state.

Experimental

Preparation of 2-Arylethanols. 2-(*m*-Bromophenyl)-ethanol.—*m*-Bromoacetophenone was prepared by bromination of acetophenone in the presence of excess anhydrous aluminum chloride.[13] This was transformed into *m*-bromophenylacetic acid by heating under reflux for 16 hr. 103 g. of the ketone with 68 g. of morpholine and 25 g. of sulfur. The resulting thiomorpholide was hydrolyzed by boiling with 10% potassium hydroxide for 18 hr. and then acidifying. The precipitated *m*-bromophenylacetic acid weighed 78.7 g. (70.7% yield) and had m.p. 99–100° (lit.[14] m.p. 100°). Lithium aluminum hydride reduction of the ethyl ester gave the alcohol, b.p. 107–110° (1 mm.).

2-(*p*-Chlorophenyl)-ethanol was prepared by refluxing *p*-chlorobenzyl cyanide with 95% ethanol and concentrated sulfuric acid[15] to yield the ethyl ester of *p*-chlorophenylacetic acid. Reduction with lithium aluminum hydride gave the alcohol (75.5% yield), b.p. 98–100° (1 mm.) (lit.[16] b.p. 110° (0.5 mm.)).

2-(*p*-Methoxyphenyl)-ethanol was prepared from *p*-methoxyacetophenone by the same method[17] as the 2-(*m*-bromophenyl)-ethanol, b.p. 110–113° (1 mm.) (lit.[18] 148° (19 mm.)).

2-Phenylethanol was Eastman Kodak Co. White Label.

Preparation of Tosylates.—The tosylates were prepared from the corresponding alcohol by Tipson's procedure.[19]

2-(*m*-Bromophenyl)-ethyl-*p*-toluenesulfonate, m.p. 43–44°. *Anal.* Calcd. C, 50.75; H, 4.26; S, 9.02. Found: C, 51.05; H, 4.54; S, 9.44.

2-(*p*-Chlorophenyl)-ethyl *p*-toluenesulfonate, m.p. 79.3–80.3°. *Anal.* Calcd. C, 58.00; H, 4.87; S, 10.32. Found: C, 58.00; H, 4.76; S, 10.69.

2-(*p*-Methoxyphenyl)-ethyl *p*-toluenesulfonate, m.p. 58.6–59.6°. *Anal.* Calcd. C, 62.72; H, 5.92; S, 10.46. Found: C, 62.86; H, 5.82; S, 10.60.

2-Phenylethyl *p*-toluenesulfonate, m.p. 38.5–39°. *Anal.* Calcd. C, 65.20; H, 5.84; S, 11.60. Found: C, 65.45; H, 5.77; S, 11.25.

Preparation of 2-Arylethyl Bromide.—The bromides were prepared by addition of the appropriate tosylate to a solution of anhydrous lithium bromide in acetone[20] and careful fractionation of the resultant bromides: 2-(*m*-bromophenyl)-ethyl bromide, b.p. 98–100° (1 mm.); 2-(*p*-chlorophenyl)-ethyl bromide, b.p. 79° (0.5 mm.); 2-(*p*-methoxyphenyl)-ethyl bromide, b.p. 79° (0.5 mm.); 2-phenylethyl bromide was Eastman Kodak Co. White Label which was redistilled, b.p. 65° (2 mm.).

Preparation of 2-Arylethyl Iodides.—The iodides were prepared by addition of the appropriate tosylate to a solution of anhydrous sodium iodide in acetone[20] and fractionation: 2-(*m*-bromophenyl)-ethyl iodide, b.p. 105–110° (1 mm.); 2-(*p*-chlorophenyl)-ethyl iodide, b.p. 115–117° (1 mm.); 2-(*p*-methoxyphenyl)-ethyl iodide, b.p. 117–119° (1 mm.); 2-phenylethyl iodide was Eastman Kodak Co. White Label which was redistilled, b.p. 95° (3 mm.).

Preparation of Sulfonium Salts.—The sulfonium salts were prepared by treating the appropriate iodide with sodium methylmercaptide[8]; this gave the sulfide. The sulfide was then treated with methyl iodide[8] in acetonitrile which gave the dimethylsulfonium iodide: 2-(*p*-chlorophenyl)-ethyldimethylsulfonium iodide, m.p. 127–128°; 2-(*p*-methoxyphenyl)-ethyldimethylsulfonium iodide, m.p. 118–119°; 2-phenylethyldimethylsulfonium iodide, m.p. 124–125°.

Procedure for Kinetics.—The reactions were carried out in 100-ml. volumetric flasks. About 0.06 mole of the desired compound was placed in the volumetric flask and weighed accurately. Then 0.12 *N* sodium ethoxide in absolute ethanol, previously equilibrated thermally with the bath, was added to the calibration mark of the volumetric flask. After adequate agitation, the flask was placed in the bath and allowed to come to thermal equilibrium. Aliquots were then withdrawn periodically with a calibrated automatic pipet.

A modification of this method was necessary for the sulfonium salts because of their slow rate of dissolution. The weighed sulfonium salt was dissolved in 50 ml. of absolute ethanol and 0.24 *N* sodium ethoxide in absolute ethanol added so the total volume was 100 ml.

Olefin Determinations.—The reactions were allowed to go to completion, and 25-ml. aliquots were poured into water and extracted with carbon tetrachloride (3 × 10 ml.), the extract washed with water and the amount of olefin determined by bromination with standard bromide–bromate solution.[21] Duplicate runs agreed to within 1%.

In the bromination of the *p*-methoxystyrene it was necessary to modify the above method by adding the bromide–bromate solution in 1-ml. aliquots until a color remained to the solution. This was necessary to minimize substitution by avoiding an excess of bromine. In the case of sulfonium salts it was necessary to wash the carbon tetrachloride layer twice with saturated mercuric chloride solution to extract dimethyl sulfide.

Mechanisms of Elimination Reactions. II. Rates of Elimination from Some Substituted 2-Phenylethyl Bromides and 2-Phenylethyldimethylsulfonium Bromides[1]

BY WILLIAM H. SAUNDERS, JR., AND RICHARD A. WILLIAMS[2]

RECEIVED DECEMBER 10, 1956

A series of *p*-substituted 2-phenylethyl bromides and 2-phenylethyldimethylsulfonium bromides has been prepared. The rates of their reactions with sodium ethoxide in ethanol were determined over a range of temperatures and the enthalpies and entropies of activation calculated. All of the compounds studied gave quantitative yields of the corresponding styrenes. The data fit the Hammett equation satisfactorily, giving $\rho = +2.15$ for the bromides and $+2.64$ for the sulfonium salts when the substituents are *p*-methoxyl, *p*-methyl, hydrogen and *p*-chloro. The substituents *p*-acetyl and *p*-nitro require the use of σ-values derived from the reactions of phenols and anilines. Factors affecting the balance and timing of the bond-making and bond-breaking processes in E2 eliminations are discussed, and some applications of these ideas to previous results are made.

Recent studies of base-promoted elimination reactions have suggested the need for revision of some commonly accepted ideas. For instance, the usual marked preference for *trans* elimination may be greatly reduced when electron-withdrawing substituents are present on the β-carbon atom[3] or when the four centers involved (H–C–C–X) cannot achieve coplanarity.[4] Reactivities of diastereomeric 1,2-diphenyl-1-propyl derivatives show that the degree of eclipsing in the transition state may be greatly modified by changes in the leaving group, the solvent and the base.[5] The absence of an appreciable sulfur isotope effect in eliminations from 2-phenylethyldimethylsulfonium bromide has been taken as indicating a transition state possessing considerable carbanion character.[1]

These and other results provide evidence that many E2 eliminations may depart rather widely from the conventional picture of a synchronous *trans* process. Recent evidence that steric[6] as well as electronic factors may be important in elimination reactions also calls for a reconsideration of former concepts. We felt that a systematic study of electronic influences on rates of eliminations might shed further light on these problems. Consequently, the preparation of a series of *p*-substituted 2-phenylethyl bromides and 2-phenylethyldimethylsulfonium bromides was undertaken and the rates of their reactions with sodium ethoxide in absolute ethanol were determined. It was anticipated that the direction and magnitude of substituent effects would lead to information on the electron distribution in the transition state.

Syntheses of the desired compounds were accomplished by conventional procedures. The reactions employed in most cases are summarized in Fig. 1. A considerable number of the intermediates and products were unknown prior to this investigation. Details on these and other aspects of the synthetic approach are given under Experimental. Some departures from the general scheme were necessary. Direct acetylation[7] of IIIa and IVa yielded IIIe and IVe, respectively. Nitration[7] of IIIa gave IIIf. Attempts to prepare Vf were unsuccessful and were abandoned when it became apparent that the reaction of Vf with base would be too fast to measure.

The compounds examined in the kinetic studies were IIIa-f in the bromide series and Va-d in the sulfonium bromide series. The corresponding styrenes (VI) were, for the most part, obtained by treatment of the sulfonium salts with aqueous sodium hydroxide, followed by isolation and careful distillation of the styrenes. The ultraviolet absorption spectra of the styrenes were determined in absolute ethanol. Extinction coefficients at the maxima used for analysis are recorded in Table I. These values were used in the calculation of olefin yields in the kinetic experiments.

TABLE I

ULTRAVIOLET ABSORPTION OF *p*-SUBSTITUTED STYRENES IN 95% ETHANOL

Cpd.[a]	λ_{max}, mμ	Molar extinction $\times 10^{-4}$
VIa	248	1.38[b]
VIb	252	1.69
VIc	258	1.92
VId	253	1.97
VIe	280	2.07[c]
VIf	300	1.37[d]

[a] See Fig. 1 for numbering of compounds. [b] Lit.[1] 1.35 $\times 10^4$. [c] G. Baddeley, E. Wrench and R. Williamson, *J. Chem. Soc.*, 2110 (1953), give 2.15×10^4. [d] M. J. Kamlet and D. J. Glover, THIS JOURNAL, 77, 5696 (1955), give 1.39×10^4.

The rates of the reactions of III and V with sodium ethoxide in absolute ethanol were followed acidimetrically. Olefin yields were calculated from the ultraviolet absorption of the reaction mixtures at the appropriate maxima. Rate constants and olefin yields are collected in Table II. The olefin yields are obviously within experimental error of 100% and thus the rate constants are attributable entirely to elimination.[8] The reactions were all

[a] See Fig. 1 for numbering of compounds. [b] Extrapolated from the Arrhenius plot of data at other temperatures. [c] Deviations listed are average deviations.

Inspection of the rate constants shows that the elimination reaction in both series is strongly accelerated by electron-withdrawing substituents. Activation enthalpies for the sulfonium salts run 3–5 kcal. higher than for the bromides, but the reactions of the sulfonium salts are actually faster because of a compensating difference in entropies of activation. The much larger entropies of activation for the sulfonium salts probably can be ascribed mainly to entropies of solvation. Since the reaction is between oppositely charged ions, solvent molecules should be released on going to the transition state. The variation in entropy of activation among the bromides (except IIIf) appears to be within experimental error. The difference for IIIf may have mechanistic significance, but we cannot exclude the possibility of systematic errors in the rate constants aggravated by the high speed of the reaction. Entropies of activation for the sulfonium salts are spread over a wider range (*ca.* 5 e.u.), and there is a tendency for high $\Delta S^{\ddagger}$ to be associated with high $\Delta H^{\ddagger}$.[9]

TABLE III

ENTROPIES AND ENTHALPIES OF ACTIVATION FOR ELIMINATIONS FROM 2-ARYLETHYL BROMIDES AND 2-ARYLETHYLDIMETHYLSULFONIUM BROMIDES

Vd	20	22.2	7.2

[a] Mid-point of the temperature range of the data. [b] Calculated from the slope (method of least squares) of a log k *vs.* $1/T$ plot and the equation $\Delta H^{\ddagger} = E_a - RT$. [c] Calculated from the intercept (method of least squares) of a log k *vs.* $1/T$ plot. [d] lit.[8] reports E_a = 23.9 kcal., which is equivalent to $\Delta H^{\ddagger}$ = 23.3 kcal.

Rate constants at 30° (some extrapolated from data at other temperatures) for the *p*-substituents methoxyl, methyl, hydrogen and chlorine in each series were fitted to the Hammett equation[10] by the method of least squares, using the σ-values tabulated by Jaffé.[10b] Table IV records the results of these calculations. Reaction constants for the entire series of bromides IIIa to IIIf are also tabulated. It is evident that the calculations employ-

(9) J. E. Leffler, *J. Org. Chem.*, **20**, 1202 (1955), discusses such relationships and quotes many examples.

Va-d	2.639 ± .157	.059	.996	2.365

[a] Calculations by the least squares procedure as outlined in ref. 10b. [b] Using σ^*-values for *p*-nitro and *p*-acetyl. [c] Using ordinary σ-values for *p*-nitro and *p*-acetyl. All σ-values are from ref. 9b. [d] Standard deviation of ρ. [e] Standard deviation of experimental points from the least squares line. [f] Correlation coefficient. [g] Calculated value of the intercept.

ing σ^*-values[10b] (those derived from the reactions of phenols and anilines) give a far better fit with the *p*-acetyl and *p*-nitro groups. Figure 2 shows that the use of ordinary σ-values for these two substituents produces marked curvature.[11]

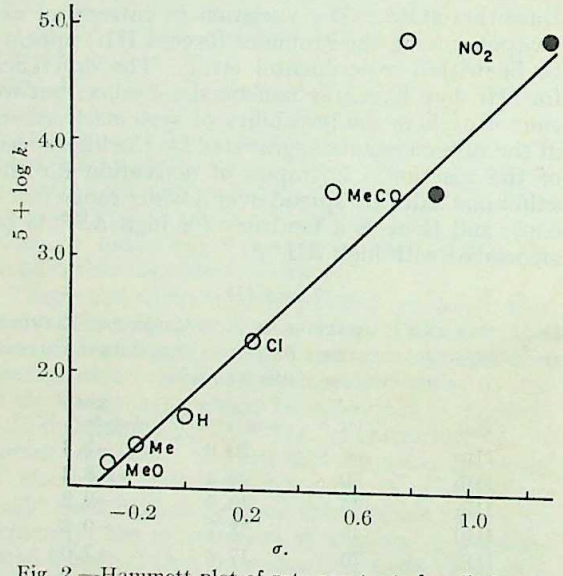

Fig. 2.—Hammett plot of rate constants for eliminations from *p*-substituted 2-phenylethyl bromides. The straight line is constructed from data given in line 2, Table IV. Open circles, ordinary σ-values; solid circles, σ^*-values.

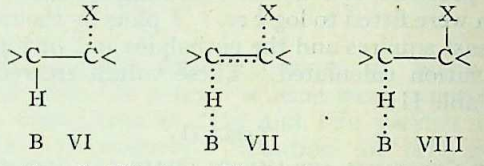
The results of the Hammett correlation clearly show that eliminations from the sulfonium salts are more sensitive to electronic effects than are eliminations from the bromides. The rather large positive values of ρ suggest that the carbon atom adjacent to the ring (the β-carbon) acquires considerable negative charge in the transition state[12] and that this increase in charge density is greater for the sulfonium salts than for the bromides. Further support for this view is found in the necessity of using σ^*-values for *p*-nitro and *p*-acetyl, since these are derived from cases where strong resonance interaction of a negative charge or an unshared pair with the substituent is possible.[13] Since the two systems under discussion have leaving groups of different charge types, the objection might be raised that this factor in itself influences the value of ρ. What ρ measures, however, is a *difference* in electron density at the β-carbon between the ground state and the transition state. The effect of charge type should therefore cancel, particularly in view of independent evidence[1] that the C–S bond is little disturbed on going to the transition state.

The nature of the transition state in E2 eliminations can be discussed best in terms of the structures VI–VIII.[5] In this representation VII is the



conventional E2 transition state. Appropriate changes in reaction variables could, however, shift the mechanism either toward the E1 (VI) or the E1cb (VIII) end of the scale. The manner in which the solvent, the base and the nature of the group "X" affect the transition state already has been discussed by Cram.[5]

The larger ρ-value for the sulfonium salts than for the bromides is in harmony with the greater ease of heterolysis of a C–Br bond than a C–$\overset{+}{S}R_2$ bond.[14] The positive charge on sulfur would also increase the ease of heterolysis of the C–H bond *via* an electrostatic effect. Both of these factors would increase the contribution of VIII. Our evidence leads to the somewhat surprising conclusion that even with the bromides the transition state is closer to VIII than to VII. If simple alkyl halides are assumed to react *via* a transition state similar to VII, this means that a β-phenyl group shifts the mechanism toward the E1cb end of the scale. Comparison of our results with those of Cram[5] suggests that an α-phenyl group has the opposite effect.[15] It should be remembered, however, that the *p*-substituents themselves probably affect the nature of the transition state. The calculated ρ thus represents an average over the range of compounds studied and is not necessarily a good measure of electron distribution in the unsubstituted case. The systems studied by Weinstock, Pearson and Bordwell[3] probably react *via* a carbanion-like transition state because of the strongly electron-withdrawing β-sulfone grouping. The low preference for *trans* over *cis* elimination supports this view, since a transition state with a large contribution from VIII and only a small contribution from VII would not be very dependent on a *trans–anti* arrangement of the β-hydrogen and the leaving group. Another example of an electron-withdrawing group reducing the preference for *trans* elimination has been given by Cristol and Norris.[16]

(11) The compound Ve was also examined kinetically at 0 and 10°. The extrapolated rate constant appeared to fit the σ^*-value better, but the measured constants were very imprecise due to the high speed of reaction. Discussion will therefore be reserved until contemplated studies in aqueous solution are completed.

(12) See C. G. Swain and W. P. Langsdorf, Jr., THIS JOURNAL, **73**, 2813 (1951), for an excellent discussion of the reasoning in this interpretation of reaction constants.

(13) The σ^*-values also apply to activated nucleophilic aromatic substitution. Here, too, ability to delocalize a negative charge should be important. See J. F. Bunnett, F. Draper, Jr., P. R. Ryason, P. Noble, Jr., R. G. Tonkyn and R. E. Zahler, *ibid.*, **75**, 642 (1953).

There are only a few examples in the literature of other applications of the Hammett equation to elimination reactions.[17] Eliminations from IX and X have been studied with sodium hydroxide in

Ar_2CHCCl_3 $Ar_2CHCHCl_2$

IX X

92.6% ethanol.[18] Recalculation of these data at our temperature (30°) and using only our substituents (*p*-methoxyl, *p*-methyl, hydrogen and *p*-chloro) gives $\rho = 2.43$ for IX and 2.26 for X. These ρ-values are larger than for the phenylethyl bromides. The result is not unexpected, since both the additional β-aryl group and the substitution of chlorine for bromine as the leaving group should increase the carbanion character of the transition state. Comparison of our results with the data of Simonetta and Favini[19] on the 2-arylethyl chlorides is more difficult because they used different temperatures (60 and 70°), different substituents (*p*-methoxyl, *m*-methoxyl and hydrogen) and a much more aqueous solvent (2:1 ethanol–water). Since variations in the kind and number of substituents alone may change ρ considerably (*cf.* Table IV), conclusions would be unwise.

Finally, the present results provide additional support for the Hughes–Ingold explanations of the empirical rules of orientation in elimination reactions. In their interpretation the Hofmann rule is a consequence of electrostatic influences on the acidity of the β-hydrogen,[20] while the Saytzeff rule is a consequence of hyperconjugative stabilization of the partial double bond in the transition state.[21] An increased contribution to the transition state from VIII would result in an increased sensitivity to electrostatic effects. Since there should be a concomitant decrease in the contribution of VII, a decreased sensitivity to hyperconjugative effects is also expected. Our evidence shows that sulfonium salts, which follow the Hofmann rule, are more sensitive to electrostatic effects than bromides, which follow the Saytzeff rule.

No mention of steric effects has been made in this discussion, because our results provide neither positive nor negative information on their possible importance. Undoubtedly there are many situations where such effects are important. It should be noted, however, that Brown's[6] arguments are based on VII as a model for the transition state and may therefore require some modification.

Experimental[22]

Preparation of 2-Arylethanols.—The appropriate arylmagnesium bromide was treated with ethylene oxide according to the general procedure of Houston and Agett,[23] using a 10% molar excess of ethylene oxide. Compounds prepared by this procedure are listed below.

2-(*p*-Tolyl)-ethanol: 65% yield, b.p. 110–111° (10 mm.), $n^{24}D$ 1.5279 (lit.[24] b.p. 105° (4 mm.), $n^{21}D$ 1.5275).

2-(*p*-Anisyl)-ethanol: 76% yield, b.p. 142–145° (15 mm.), $n^{25}D$ 1.5397 (lit.[25] b.p. 148° (19 mm.)).

2-(*p*-Chlorophenyl)ethanol: 50% yield, b.p. 77–78° (0.5 mm.), $n^{25}D$ 1.5482 (lit.[26] b.p. 110° (0.5 mm.)).

Preparation of 2-Arylethyl Bromides.—The arylethanol was treated with phosphorus tribromide, using a procedure similar to that of Rupe.[27] The bromides obtained by this and other procedures are as follows.

2-(*p*-Tolyl)-ethyl bromide: 81% yield, b.p. 43.5° (0.3 mm.), $n^{22}D$ 1.5490 (lit.[28] b.p. 103.5–105° (11 mm.)).

2-(*p*-Anisyl)-ethyl bromide: 50% yield, b.p. 63° (0.15 mm.), $n^{21}D$ 1.5595 (lit.[29] b.p. 147–149° (22 mm.)).

2-(*p*-Chlorophenyl)-ethyl bromide: 61% yield, b.p. 86.5° (1.6 mm.), $n^{25}D$ 1.5697.

Anal. Calcd. for C_8H_8BrCl: C, 43.76; H, 3.67. Found: C, 43.82; H, 3.75.

2-Phenylethyl bromide was redistilled commercial material of b.p. 66° (2 mm.), $n^{26}D$ 1.5542 (lit.[30] $n^{24}D$ 1.5549).

2-(*p*-Acetylphenyl)-ethyl bromide was obtained by the acetylation of 2-phenylethyl bromide with acetyl chloride in the presence of aluminum chloride.[8] The product, obtained in 71% yield, had b.p. 111–112° (0.3 mm.), $n^{24}D$ 1.5722 (lit.[7] b.p. 117–118° (0.1 mm.), $n^{25}D$ 1.5724).

2-(*p*-Nitrophenyl)-ethyl Bromide.—The nitration of 2-phenylethyl bromide with nitric acid in acetic anhydride[7] gave 33% of a product of m.p. 69–69.5° (lit.[7] 69–70°).

Preparation of Methyl 2-Arylethyl Sulfides.—The 2-arylethyl bromides were converted to methyl 2-arylethyl sulfides by treatment with a solution of methyl mercaptan in ethanolic sodium hydroxide according to a procedure given by Fehnel and Carmack[31] for ethyl 2-phenylethyl sulfide. The sulfides prepared are described below.

Methyl 2-phenylethyl sulfide: 95% yield, b.p. 70–71° (11 mm.), $n^{24.5}D$ 1.5494 (lit.[32] b.p. 111° (12 mm.)).

Methyl 2-(*p*-tolyl)-ethyl sulfide: 93% yield, b.p. 49–50° (0.3 mm.), $n^{21}D$ 1.5450. *Anal.* Calcd. for $C_{10}H_{14}S$: C, 72.23; H, 8.49. Found: C, 72.24; H, 8.54.

Methyl 2-(*p*-anisyl)-ethyl sulfide: 83% yield, b.p. 102–103° (2 mm.), $n^{25}D$ 1.5522. *Anal.* Calcd. for $C_{10}H_{14}OS$: C, 65.89; H, 7.74. Found: C, 65.70; H, 7.84.

Methyl 2-(*p*-chlorophenyl)-ethyl sulfide: 87% yield, b.p. 83–85° (0.6 mm.), $n^{25}D$ 1.5630. *Anal.* Calcd. for $C_9H_{11}SCl$: C, 57.90; H, 5.97. Found: C, 57.82; H, 6.12.

Methyl 2-(*p*-Acetylphenyl)-ethyl Sulfide.—Methyl 2-phenylethyl sulfide was acetylated by the procedure of Foreman and McElvain,[7] using 2 moles of aluminum chloride per mole of sulfide. The product (88% yield) had b.p. 131–132° (1.0 mm.), $n^{24}D$ 1.5670.

Anal. Calcd. for $C_{11}H_{14}OS$: C, 67.99; H, 7.26. Found: C, 67.69; H, 7.23.

Preparation of 2-Arylethyldimethylsulfonium Bromides.—The sulfide was treated with methyl bromide in nitromethane solution[8b] and the product recrystallized from ethanol–ether.

2-Phenylethyldimethylsulfonium bromide: 70% yield, m.p. 135–135.5° dec. (cor.) (lit.[1] m.p. 135.5°).

2-(*p*-Tolyl)-ethyldimethylsulfonium bromide: 65% yield, m.p. 106.5–107° dec. (cor.). *Anal.* Calcd. for $C_{11}H_{17}SBr$: C, 50.57; H, 6.56. Found: C, 50.80; H, 6.66.

2-(*p*-Anisyl)-ethyldimethylsulfonium bromide: 50% yield, m.p. 133–133.5° dec. (cor.). *Anal.* Calcd. for $C_{11}H_{17}OSBr$: C, 47.65; H, 6.18. Found: C, 47.81; H, 6.34.

2-(*p*-Chlorophenyl)-ethyldimethylsulfonium bromide: 63% yield, m.p. 126–126.5° dec. (cor.). *Anal.* Calcd.

for $C_{10}H_{14}SClBr$: C, 42.64; H, 5.01. Found: C, 42.74; H, 5.27.

2-(*p*-Acetylphenyl)-ethyldimethylsulfonium bromide: 74% yield, m.p. 121–121.5 dec. (cor.). *Anal.* Calcd. for $C_{12}H_{17}OSBr$: C, 49.82; H, 5.92. Found: C, 49.53; H, 5.82.

Preparation of Styrenes.—The sulfonium bromide was dissolved in water, treated with 10% sodium hydroxide solution and the mixture warmed gently on the steam-bath. The cessation of methyl sulfide evolution indicated completion of the reaction. The styrene was decanted, dried over Drierite and fractionated in the presence of a small amount of *p-t*-butylpyrocatechol.

Styrene: 87% yield, b.p. 38° (15 mm.), $n^{25}D$ 1.5433 (lit.[33] $n^{25}D$ 1.5433).

***p*-Methylstyrene**: 87% yield, b.p. 50° (13 mm.), $n^{26}D$ 1.5395 (lit.[34] $n^{25}D$ 1.5402).

***p*-Methoxystyrene**: 92% yield, b.p. 85° (14 mm.), $n^{23}D$ 1.5595 (lit.[35] $n^{20}D$ 1.5608).

***p*-Chlorostyrene**: 93% yield, b.p. 38° (2.2 mm.), $n^{20}D$ 1.5650 (lit.[36] $n^{20}D$ 1.5648).

***p*-Acetylstyrene**: 88% yield, m.p. 33–33.5° (lit.[37] m.p. 33°).

***p*-Nitrostyrene** was obtained by treating 2-(*p*-nitrophenyl)-ethyl bromide with warm alcoholic sodium hydroxide for 15 min. The mixture was poured into a saturated salt solution and the organic layer taken up in ether and dried. Removal of the ether left a solid which was recrystallized from petroleum ether. There was obtained 70% of *p*-nitrostyrene, m.p. 29° (lit.[38] m.p. 28°).

Styrene Analysis.—Ultraviolet absorption spectra of the freshly distilled styrenes in 95% ethanol solution were determined on a Cary recording spectrophotometer. The optical densities at the maxima used for analysis (around 250 mμ) were then carefully determined on a Beckman DU spectrophotometer. Molar extinction coefficients at these maxima are listed in Table I. Beer's law was obeyed over the concentration ranges used, and the solutions underwent no changes in concentration over a period of at least 48 hr.

Samples of the reaction mixtures at "time infinity" were appropriately diluted and optical densities determined, from which the olefin concentrations were calculated. In some of the slower reactions there appeared to be a slow depletion of the styrene, so the determinations were made on aliquots taken after one or two half-lives. Under the conditions of the measurements the styrene precursors (bromides or sulfonium bromides), sodium ethoxide, sodium bromide and methyl sulfide did not contribute appreciably to the observed ultraviolet absorption. Olefin yields in Table II are averages of two or three analyses with indicated average deviations.

Kinetic Measurements.—Reactions were carried out in a 100-ml. volumetric flask to which was attached, above the calibration mark, a side-arm bearing a 10-ml. bulb sealed with a rubber ampoule-stopper. This could be covered with a ground-glass cap so that the entire vessel could be immersed in the constant-temperature bath. Runs were carried out in a thermostat with temperature control to ±0.05°. Runs at 0° were performed in a well-stirred ice–water slurry.

For the bromides (mostly liquids), 50.0 ml. of *ca.* 0.2 *M* sodium ethoxide in absolute ethanol (at bath temperature) was diluted to 99.0 ml. with thermally equilibrated absolute ethanol. To this was added a weighed portion of the bromide (0.005 mole, *ca.* 1 ml.). The reactor was agitated in the bath for two minutes following the addition. Aliquots were withdrawn periodically with a calibrated 5-ml. hypodermic syringe and delivered into excess aqueous hydrochloric acid. The quenched sample was diluted fivefold with water and titrated to the phenolphthalein end-point with standard sodium hydroxide. The sodium ethoxide solution was sampled at bath temperature and standardized before each run.

A weighed quantity of a sulfonium salt (*ca.* 0.005 mole) was dissolved in slightly less than 50 ml. of absolute ethanol and the solution allowed to equilibrate thermally. To this solution was added by pipet 50.0 ml. of thermally equilibrated ethoxide solution, the volume adjusted to 100 ml. and the vessel agitated for 1 minute. Sampling and analysis were carried out as with the bromides.

Compounds used had the physical constants indicated under their preparation. Absolute ethanol was obtained by the procedure of Smith as modified by Manske.[39] All solutions were frequently restandardized to ensure that rate constants would be comparable. Each run consisted of at least 10 points and the rate constants from the integrated second-order equation were arithmetically averaged. Values recorded in Table II are the averages of two or more runs with average deviations. Whenever there was a departure from the usual concentrations, ionic strength was maintained with added sodium bromide. Most runs covered two or three half-lives and no serious drifts were noted.

The Chemical Consequences of the $N^{14}(n,p)C^{14}$ Reaction in the Acetamide System and the Implications of Nuclear Recoil as a Tool for Synthesis[1]

BY ALFRED P. WOLF, CAROL S. REDVANLY AND R. CHRISTIAN ANDERSON

RECEIVED FEBRUARY 18, 1957

Acetic acid-1,2-C_1^{14} and propionic acid-1,2,3-C_1^{14} have been prepared from acetamide irradiated in a nuclear reactor. The distribution of activity in acetic acid averages 62% in the carbonyl carbon and 38% in the methyl carbon. For propionic acid obtained by basic hydrolysis of the amide we found 24% in the carbonyl carbon, 24% in the methylene carbon and 52% in the methyl carbon. These results are interpreted in terms of chemical mechanisms being the determining factors in the labeling process. The formation of acetone-1,2-C_1^{14} with 80% of the activity in the methyl groups and 20% of the activity in the carbonyl group is also reported. Acetonitrile as a product of the radiation chemistry of the system is mentioned. The implication of this work with regard to using nuclear recoil as a tool for the synthesis of labeled compounds is discussed.

The consequences of nuclear recoil in organic nitrogen-containing systems irradiated with neutrons have been the subject of an increasing number of studies.[2] The carbon-14 as it is born receives a recoil energy of about 40,000 e.v. This kinetic energy imparted to the carbon atom causes it to break its chemical bonds and to move into its surroundings. Energy loss occurs by coulomb scattering, collision with other atoms and other processes. When the carbon-14 has been slowed sufficiently to be able to react with its environment, it finds itself a considerable distance from its birthplace,[3-5] the estimates varying from 10 to 3000 Å. The fragmentation and recombination process caused by the recoil atom results in a complex mixture of products. While only one labeled product can result from each event, the amount of energy available for chemical reaction at the site of entrapment of the carbon-14 allows a large variety of compounds to be formed. This is reflected in the diversity of products obtained in an irradiation.

Numerous approaches to this problem are possible. A complete product analysis may conceivably be done. Investigation of specific products and the degree of labeling found in them can be carried out. Compounds with structural features of interest can be investigated in terms of what changes can be made to occur on exposures to carbon recoils. External influences on the products, such as temperature and pressure, might yield useful information. The effect of phase on product distribution is also of interest.

Our studies have been directed toward the elucidation of the mechanism of this process, which in turn should provide the necessary information for the intelligent use of the recoil method in labeling organic compounds. A consideration of the factors enumerated should yield this end.

Constancy of specific activity is the basic criterion for the purity of any product obtained by the recoil method. While chemical purity usually is achieved readily, radiochemical purity, in most cases, is obtained with inordinate difficulty. It became increasingly evident from our work on this and other systems that this difficulty was possibly due to *synthesis*[6] products. It must be kept in mind that these *synthesis* products are formed in microgram amounts or less (with one carbon-14 per molecule), distributed in tens of grams of irradiated material. The presence of these compounds, whose chemical behavior is sufficiently similar to the parent compound to make their separation quite difficult, makes purification a challenging task. Their detection and removal from the parent compound can be effected by carrier methods. Substitution of nitrogen or carbon in the parent compound by carbon-14 results in a *re-entry*[7] product. This product is also removed by carrier methods where applicable.

Results

Acetamide was irradiated in the Brookhaven reactor. Our approach has been to center attention on *re-entry* and *synthesis* products and further to center attention on activity distribution in the compounds themselves. Thus, the *re-entry* product, acetamide-1,2-C_1,[14] and the *synthesis* product, propionamide-1,2,3-C_1,[14] were investigated, and the extent of incorporation of carbon-14 in each position was determined. Both propionic acid and propionamide were added as carriers on the assumption that the synthesized, excited three carbon fragment might in some cases collapse to give propionic acid. The reactions are given in equations 1 and 2.

The hydrolysis was carried out both in acid and in base to investigate possible differences in state of the irradiated material. The hydrolysis in base was carried out on two independently irradiated samples. The results of these runs are listed in Tables I and II. Hydrolysis in acid yielded the results listed in Table III.

While it is clear from these results that synthesis does take place, it becomes evident that the reaction to give "propionamide" involves processes other than a simple replacement of hydrogen.

Discussion

A number of hypotheses have been suggested to account for the results of reactions activated by the n,γ-process. Notable among these are the "billiard ball collision–epithermal collision" hypothesis of Libby[8] and the "random fragmentation–brush heap" hypothesis of Willard.[9]

Yankwich[5] has published a stimulating article on the $N^{14}(n,p)C^{14}$ system in particular. He has provided a rationale for ionic crystal work based mainly on the Seitz and Koehler[10] description of the displacement of atoms during irradiation.

We have considered the formation of labeled species in terms of three steps, each of which may affect product distribution. *The first of these is the slowing down of the carbon-14 and its localization in a reactive site by elastic and inelastic processes. The second step involves the imposition of chemical considerations leading to a variety of intermediate chemical species depending on the structural features of the site and on the energy available for chemical reaction at the entrapment site. The third step involves the collapse of the intermediates to stable compounds or the collapse of reactive fragments, which lead to stable compounds, during the chemical operations carried out on the material subsequent to the irradiation.* Each step involves several factors. The first step is thought of as involving: (1) the energy of the recoil fragment just prior to entrapment in a site, where its motion becomes essentially diffusive in character; (2) the structural features of the fragment during this period and just prior to reaction; (3) the probability of interaction with a particular bond, atom or molecule. The second step is concerned with the chemical considerations which affect the nature of the final product. Involved are: (1) the probability of formation of any of a number of intermediates; (2) the probability that such an intermediate will lead to a stable product; (3) the effect of the surroundings on product distribution. Step three involves essentially three considerations: (1) the probability that a given intermediate will collapse to a compound stable in its surroundings; (2) whether or not the compound will be isolable under the reac-

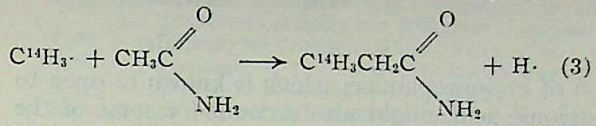
tion conditions; (3) the influence of the isolation method on product distribution.

In theory, a rigorous evaluation of these various factors should allow accurate prediction of product distribution in any given system. The complexity of product distribution from the $N^{14}(n,p)C^{14}$ reaction carried out in relatively simple systems such as ionic crystals has been demonstrated by Yankwich.[11] The greatly increased complexity resulting in an organic system, in which the $Br^{81}(n,\gamma)Br^{82}$ reaction was carried out and in which attention necessarily was centered on the organically bound bromine only, was elegantly investigated by Evans and Willard.[12] These results imply an almost staggering complexity for the product distribution in a system where a recoiling carbon comes to rest in an organic matrix. The complexity of product distribution is certainly evidenced by the work of Schrodt and Libby.[2m]

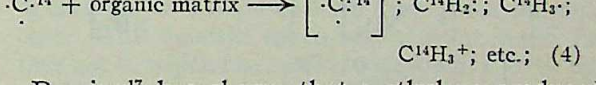
By centering attention on *re-entry* and *synthesis* products and, further, by centering attention on activity distribution in the compounds themselves, it becomes abundantly clear that chemical forces do indeed play a role in both *re-entry* and *synthesis*. Random distribution is not observed in the *re-entry* product, acetamide-1,2-C_1^{14}, and exclusive hydrogen substitution is not observed in the *synthesis* product, propionamide-1,2,3-C_1^{14}. This is a primary consideration with regard to using the recoil method as a means for preparing labeled compounds. The specificity observed in acetamide probably reflects the effects of factors 1 and 2 in step 2. The higher activity yield of labeled acetic acid from the acid hydrolysis of irradiated material may again reflect these same factors and in addition be a function of factors 1 and 3 of step 3. It may be suggested that the reactive fragment containing carbon-14 will react with its surroundings to give labeled malonic acid. The acid hydrolysis isolation procedure would augment the activity finally assayed as acetic acid since the malonic acid would readily decarboxylate to give acetic acid. It cannot be overemphasized that the nature of the product isolated reflects the structure of the active moiety in the organic matrix only insofar as there is an allowable chemical pathway from the moiety in the matrix to the compound finally isolated. It is not a necessary condition that the active fragment be isolable as a stable chemical entity, nor is it necessary that the final product observed is the result of sequential chemical steps identified with *one* starting moiety.[13]

A number of mechanisms can be suggested to account for the distribution of the activity in the propionamide. It is noteworthy that there is *synthesis* and that there is specificity for replacement of a methyl hydrogen. It is, however equally significant that in addition to the 3-position, the 1- and 2-positions are also labeled.

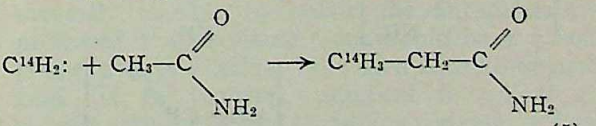
It seems reasonable to assume that the energy associated with the terminal "hot spot" where the recoiling carbon-14 is finally trapped will be of the order of 25–50 e.v.[15,10,14] Clearly then,[15] sufficient energy will be available to allow reaction 3 to occur even though the reaction indicated by equation



3 is endothermic in the ordinary sense. This "inversion" reaction is different from that of Hornig, Levey and Willard[16] in that the assemblage after collision need not have sufficient energy to cause bond rupture in the subsequent steps necessary to reduce it to thermal energies. It does not seem likely that such a reaction can take place in the high energy region, since, although the collisions can be between atoms of almost equal mass, the residual energy left, on the average, in such a hot spot will be so high as to allow complete rupture of many bonds, thus resulting in the destruction of any chemical coherence in the center of the spot.[10] The recoiling carbon-14 is an extremely active radical and can react with its surroundings, particularly when its motion becomes essentially diffusive, to give a variety of molecular species such as are indicated in equation 4.



Doering[17] has shown that methylene produced by the photolysis of diazomethane reacts indiscriminately with the carbon–hydrogen bonds in its surroundings. The reaction given by equation 5 is analogous to Doering's cases, particularly in that a methylene produced from a recoiling carbon can



(5)

certainly have an energy equal to or in considerable excess of the energy of a photolytically produced methylene. Although Doering observed no reaction with carbon–carbon bonds, such a reaction may be possible with a more energetic methylene. Propionamide might therefore be formed by the insinuation of methylene between the two carbons

(15) The maximum energy transmittable for a collision between two entities is given by

$$E_M = \frac{4M_1M_2}{(M_1 + M_2)^2} E_I$$

where E_I is energy of the incident particle of mass M_1. M_2 is the mass of the struck entity. On the average, the energy transmitted equals $\frac{1}{2}E_M$. The maximum fraction of the kinetic energy of the struck entity which is then available as internal energy is given by

$$E_{Int} = \frac{M_2}{M_1 + M_2} E_T$$

where E_T is the energy transmitted.

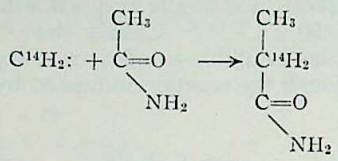
Digitized by Arya Samaj Foundation Chennai and eGangotri

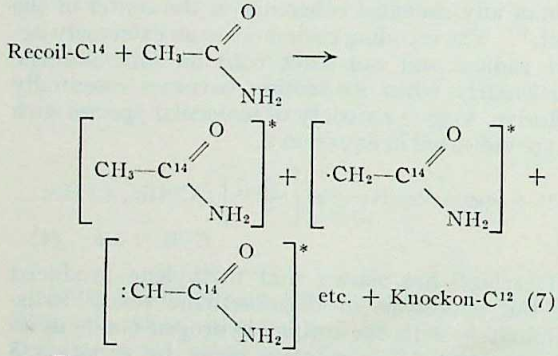
of acetamide as given in equation 6. The formation of cyclopropanone, which is known to open to propionic acid, might also account for some of the labeled acid.



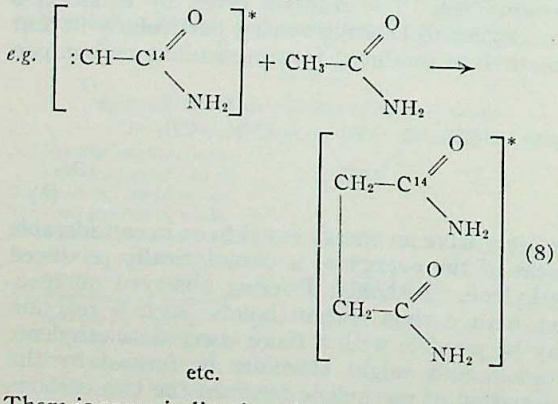
(6)

Activity in the carbonyl group might be the result of the formation of an intermediate which can then undergo skeletal rearrangement and shifting of the oxygen. An intermediate which becomes stripped of oxygen and is then reoxidized is also a possibility.

Here as with acetamide, the formation of an intermediate which subsequent chemistry can transform to propionic acid is a possibility. The case of carbonyl labeling is indicated by equations 7 and 8.



(7)

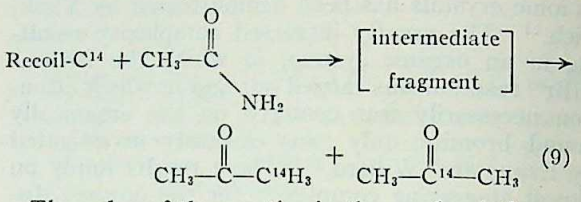


etc.

There is some indication that succinic acid may decarboxylate to give small amounts of propionic acid when in the presence of base and traces of heavy metal salts. Alternatively the excited succinamide might break a methylene to carboxamide bond to give a radical which would then abstract a hydrogen from its surroundings.

Experiments which will distinguish between these various mechanisms are in progress at the present time.

Acetone-1,2-$C_1{}^{14}$.—In our work on the acridine–anthracene[2] system it was shown that the ratio of activity as acridine to activity as anthracene averaged 18/1. A completely random *re-entry* would result in a ratio of 13/1. Muxart[18] has obtained an average ratio of 19/1 in the 5,6-benzacridine–5,6-benzanthracene system where the statistical ratio is 17/1. The activity as acetone in the carrier material was found to be 0.13% of the total activity produced. A ratio of 49/1 was found, whereas the statistical ratio for acetone is 2/1. The reaction is given by equation 9.



(9)

The value of these ratios in the mechanistic sense probably has real meaning when the molecules formed by *re-entry* do not have fundamentally different chemical stabilities. We also need to assume that the excited *re-entered* molecules will behave similarly in their surroundings in the chemical sense. For example, the excited states of acridine and anthracene are sufficiently similar that we might expect the *re-entered* acridine and the active anthracene from nitrogen replacement to have roughly equal probabilities of being reduced intact to thermal energies. Acridine which might be lost by the formation of biacridine might be mirrored by bianthracene formation from anthracene. Once formed, the chemical stabilities and their stability to radiation damage are nearly equal in terms of total product destroyed. This parallel behavior then lends validity to the conclusions one can draw from the statistical nature of the replacement.

The applicability of these hypotheses is supported by the results with acetone. Here the intermediates leading to acetone and *re-entered* acetamide probably bear no relationship. Further the radiation stabilities of these two materials, once formed, are markedly different. The deviation from statistical behavior is then a reflection of the chemistry of the system after *re-entry* has occurred, emphasizing the fact that a purely physical picture of the chemical results from a system containing recoil fragments is not sufficient.

In addition, the degree of labeling by position in acetone, being 20% in the carbonyl carbon and 80% in the indistinguishable methyl carbons, is significant in that it necessitates a mechanism involving not only *re-entry* but also rearrangement of the species after *re-entry*.

Acetonitrile.—The rate of energy absorption by the system due to the recoiling carbons is about 2.7×10^{15} e.v./sec./gram of acetamide and is about 3.5×10^{16} e.v./sec./gram of acetamide for the ejected protons. A crude calculation based on the "Dosimetry of Reactor Radiations" work by Richardson, Allen and Boyle[19] indicates that about 1.2×10^{17} e.v./sec./gram of acetamide are being dissipated in the sample due to pile irradiation. Since only 1.7% of the energy absorbed by the sample can be attributed to the recoil fragment,[20]

it seems unlikely that acetonitrile formation is a specific effect caused by the knockons from carbon-14. It is, however, interesting to speculate whether or not acetonitrile is a specific product of knockons by fast neutrons, ejected protons, and by recoil fragments or whether it is formed by means of the gross radiation the sample receives.[21]

Use of Nuclear Recoil as a Method for Labeling Organic Compounds.—Several factors must be evaluated in using nuclear recoil as a labeling method. The level of activity desired in the compound, the degree of labeling by position and the ease with which the labeled compound may be prepared by conventional methods must be considered.

It is necessary first to decide on the source of the required nitrogen. In many of the cases reported, the compound serves as its own nitrogen source. If the compound to be labeled contains no nitrogen, it may be mixed with a nitrogen source which will form a homogeneous solution[22] with the compound. This source must provide a high nitrogen to carbon ratio, be radiation stable and be easily removable from the desired compound. Derivatization of the compound with nitrogen-containing compound is a third possibility.

The optimum irradiation time is based on minimization of radiation damage such that a sensible amount of chemically pure material can be recovered. This must be coupled with maximization of activity produced. A review by Collinson and Swallow[23] on the radiation chemistry of organic substances can serve as a guide for the qualitative evaluation of the expected radiation damage. For example, acridine,[2i] after 20 days of pile irradiation, is 76% recoverable, whereas L-alanine[24] is only 22% recoverable after a six-day irradiation.

Calculation of the total activity produced during the irradiation can be carried out easily.[2i] The fraction of the total activity found in the *re-entry* product depends strongly on the nature of the compound to be *re-entered*. We have observed a wide range of values: *e.g.*, 0.2% in alanine,[24] ~ 1% in ethylpyridine,[24] 1.5–2% in benzene[2j,k] (not corrected for dilution by the nitrogen source), 3.5% in acridine, to 8.0% in acetic acid from the acid hydrolysis of acetamide. These percentages are corrected for the material lost by radiation damage. Higher *re-entry* figures have been reported for some organic compounds, but they do not serve as a basis for calculation in the absence of rigorous proof of constancy of the specific activities observed.

The specific activity obtainable is then given by equation 10.

$$S.A._x = \frac{A_T \times P_T}{M_C \times 100} \qquad (10)$$

$S.A._x$ = estimated specific activity expected in compound x in activity per milligram of carbon
A_T[25] = total activity produced during irradiation
P_T[26] = percentage of the total activity produced expected to be found in compound x
M_C = milligrams of carbon in total sample of compound x

This calculation assumes no radiation damage in evaluating M_C and thereby gives a common basis for comparison between compounds. Clearly the specific activity is the same for any compound derived from the compound irradiated provided the derived compound has the same number of carbons per mole and provided no carbons were exchanged.

The actual chemical yield of *re-entry* product is dependent on the amount not destroyed by radiation damage. After the material is shown to be chemically and radiochemically pure, it can be diluted as desired, depending on the detection limits of the assay method used. With our present assay equipment the acetic acid produced from the acid hydrolysis of acetamide (1.24 mμc./mg. C) could have been diluted 500-fold without appreciably changing[27] the precision of assay.

It must be remebered that the degree of labeling in each position *is not* uniform throughout the molecule. This must be taken into account in any further use to which the labeled compound is to be put.

The *re-entry* product resulting from replacement of nitrogen in the original compound, provided it acts as its own nitrogen source, and all *synthesis* products present a different picture. In theory, compounds with extremely high specific activity could be produced in this way. If it were experimentally feasible to isolate the anthracene-C_1^{14} produced from acridine,[28] we would have a compound with one carbon-14 in each anthracene molecule. It is, however, practical to adjust the specific activity desired by adding a greater or lesser amount of carrier at the end of the irradiation. Again the percentage of the total activity to be expected in the N-replacement and *re-entry* and/or *synthesis* products is estimated and sufficient carrier added to give the desired specific activity. For example, the specific activity of the propionic acid in the experiments reported here could have been increased by a factor of ten in any series by a corresponding decrease in the amount of added carrier. By the choice of a proper system and a high N/C

(21) Production by knockons would necessarily proceed with very high efficiency since an estimate of the energy deposited by "knockons" (total) alone indicates it to be a borderline possibility at best. This question might be resolved by comparing acetonitrile production from pile irradiation (at maximum fast neutron flux) with acetonitrile production from irradiation in a cobalt-60 source under conditions of identical total energy deposition.

(22) In labeling benzene,[2k] a mixture of benzene and 2-methylpyrazine was used; *cf.* 2a,l,m. We have used liquid ammonia without notable success because of the difficulty in finding appropriately soluble materials. Heterogeneous mixtures are not suitable because of the comparatively short range of the recoiling carbon-14. The percentage of carbon recoils reaching organic material in a mixture such as finely ground ammonium nitrate and anthracene is too small to make the method feasible.

(23) E. Collinson and A. J. Swallow, *Chem. Revs.*, **56**, 471 (1956).

(24) A. P. Wolf and C. S. Redvanly, unpublished work.

(25) While this is the value calculated, it should be noted (*cf.* ref. 33) that the activity produced experimentally is usually higher than the calculated value. Thus the value obtained as SA is a minimum in most cases. In no case that we have observed has the experimental value been greater than $1.8A_T$. An average of our published and unpublished work is $1.3A_T$. This variation from theoretical may be due to the primitive technology involved in carrying out these irradiations. An accurate value for the slow neutron flux integrated over the whole irradiation is not as yet available.

(26) As indicated in the text the value for P_T varies rather widely. A judicious guess based on the published work[2i] is required in order to evaluate P_T. We assume a value of 3% in lieu of any other information.

(27) D. R. Christman and A. P. Wolf, *Anal. Chem.*, **27**, 1939 (1955).

(28) A twenty day irradiation of 24 grams of acridine at a flux of 3×10^{13} neutrons/cm.^{2} sec. produces about 0.6 microgram of anthracene-C_1^{14} dispersed in the acridine.

ratio, it may be possible to obtain a *synthesis* or N-replacement product carrier free.

As with the *re-entry* product, it must be remembered that the labeling is not specific. In the cases observed to date, the majority of the label is found in the expected position in the N-replacement product, and in the *synthesis* products: methyl group in acetone; methyl group in propionamide; methyl group in toluene.[2k] The percentage found in the expected position is not, however, the same in all compounds. Again the application to which the compound is to be put is the determining factor.

The quantities of materials that can be produced are subject to the geometry of the facility available. The water-cooled facility with maximum available flux in the Brookhaven reactor can accommodate about 80 grams (assumed density = 1) of a liquid sample per irradiation. About 100 grams of tightly packed solid can be irradiated in the same facility. Radiation times range from 4 to 30 days.

It is hoped that this outline based on work to date will aid in deciding whether or not the method is applicable to the compound in question. The complexity of the purification is usually the deciding factor. With the advent of vapor phase chromatography, however, labeled liquid alkanes, aromatics, alcohols, acids, etc., can be prepared easily and quickly. Carrier-free materials may also be within reach.[29] It is clear that adequate fractionation techniques hold the key to the application of nuclear recoil as a labeling method.

The elucidation of the mechanisms involved in these reactions is the continuing interest of the authors. The investigation of the effect of structure and phase on *re-entry* and *synthesis* is being pursued.

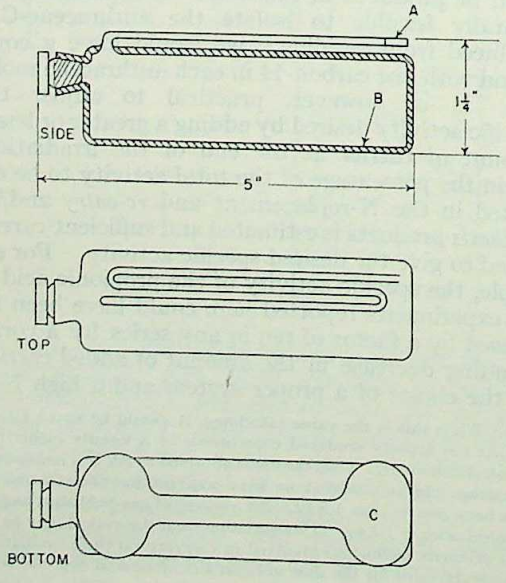

Fig. 1.—A, 0.5 mm. i.d. quartz capillary; B, 25 mm o.d. quartz tubing; C, ends blown flat and then ground for stability in boat.

Experimental[30]

Irradiation.—The samples were irradiated in the Brookhaven reactor at an approximate flux of 4×10^{12} neutrons/cm.^{2} sec. The fast neutron flux was $\geqq 10^{12}$ neutrons/cm.^{2} sec. The gamma exposure was $\geqq 2 \times 10^6$ r./hr. In order to correct approximately for fluctuations in neutron density during irradiation, an integrated value for the total irradiation is reported in megawatt hr.[31] All irradiations were carried out in a facility operating at 30°. After irradiation, at least ten days were allowed for the decay of short lived activities in the quartz containers.

Packaging.—The type of container used is pictured in Fig. 1. The plug is held in place with Kronig cement. The capillary aids in reducing the amount of air in continuous contact with the sample, while still allowing the gases formed during the irradiation to escape. Appreciable gas pressures build up on irradiation of many aliphatic compounds. Closed systems are contra-indicated for pile irradiation of these samples. Safe irradiation of samples evolving gases can be accomplished in closed systems if necessary.[32]

Fisher Certified Reagent acetamide, m.p. 80–81°, was used for all irradiations.

Anal. Calcd. for C_2H_5ON: C, 40.7; H, 8.5. Found: C, 41.1; H, 8.4.

Processing of Acetamide-C_1^{14}. Addition of Carriers. A Series.—Two samples of acetamide (1, 21.077 g.; 2, 23.662 g.) received an irradiation of 4965 megawatt hours; acetamide survival 74 ± 4% (average both samples).

Sample 1.—*Anal.* Calcd. for C_2H_5ON: C, 40.7; H, 8.5. Found: C, 39.0 ± 0.9; H, 8.2; 12.06 ± 0.93 mμc./mg. C.[33]

Sample 2.—*Anal.* Found: C, 40.1 ± 1.2; H, 8.4; 10.27 ± 0.51 mμc./mg. C.[33]

Samples one and two were combined before carrier material was added. A weighted average for the carbon value and the carbon-14 activity is given; C, 39.6 ± 1.5; 11.11 ± 1.06 mμc./mg. C. The total activity for the irradiated sample was based on the carbon value before irradiation multiplied by the specific activity value obtained by assay. The total activity produced was 0.202 mc.

Transfer of 35.999 g. of the mixture to a bulb which could be connected to a vacuum line was carried out. Carriers were added to the bulb as follows: (1) 5.117 g. of propionamide, (2) 5.13 g. of acetone, (3) 4.806 g. of propionic acid. The vacuum bulb was capped and raised to a temperature of 70°. Copious gas evolution occurred during the melting and dissolution process. The liquid was resolidified in an ice-bath.

Acetone-1,2-C_1^{14}.—The vacuum bulb containing the resolidified homogenate was evacuated through two liquid N_2 traps connected to a high vacuum system. A vacuum

(30) Microanalyses on inactive samples were performed by F. Schwarzkopf, Woodside 77, N. Y. Radioassays were performed by P. R. Hansell and D. R. Christman of this Laboratory. The method of D. R. Christman, N. E. Day, P. R. Hansell and R. C. Anderson, *Anal. Chem.*, **27**, 1935 (1955), was used. A minimum of two assays were performed on each compound. The standard deviation for any given assay is 1–2% ($\sigma = \sqrt{\text{total counts}} \times 100/\text{total counts}$). The root mean square error encompassing all errors inherent in the analysis is not greater than 5%.

(31) Reference 2i explains the method of calculation used.

(32) A. P. Wolf and A. Oltmann, Brookhaven National Laboratory Report No. 2811.

(33) The deviations given here are average deviations calcd. from the experimental data. Data was based on 9 determinations for sample 1 and 7 determinations for sample 2. It has been our observation on all but the most radiation-stable compounds that precise C, H data and precise radioassays are difficult to obtain on the unprocessed pile material. Various factors such as inhomogeneity of the sample and the presence of other radioactive species have been investigated as possible causes for these effects. Negative results have been obtained. In particular the CO_2 from combustions has been purified both by cycling through $BaCO_3$ and by passing the CO_2 through a Vapor Phase Chromatographic (V.P.C.) column. No significant improvement in statistics was noted. The disparity between samples 1 and 2 is due to their location in the pile during the irradiation, the former having been close to the position of maximum flux. It should be noted that the megawatt hour reading serves mainly as an approximate irradiation value.

transfer of the added acetone and other volatile constituents was effected. A negligible amount of the propionic acid was transferred. An 8.21-g. sample was obtained. The sample was separated into four fractions by distillation. Fractionation in an 8-inch glass helix packed column served to further purify the acetone fraction. Material boiling at 56° was converted to the semicarbazone. The semicarbazone was recrystallized twice from H_2O, m.p. 186°.

Anal. Found: 0.0674 mμc./mg. C., cor. for inactive carbon. The bisulfite addition product was prepared. *Anal.* Found: 0.069 mμc./mg. C.

Iodoform was prepared from the acetone using the procedure described by Meinwald.[34] *Anal.* Found: 0.082 mμc./mg. C.

Acetic Acid-C_1^{14}.—After vacuum transfer of the volatile constituents of the vacuum bulb had been effected, the residue, 40.0 g., was transferred to a r.b. flask. The mixture was hydrolyzed with 50 g. of sodium hydroxide in 200 cc. of H_2O. The solution was taken to *p*H 2 with sulfuric acid. The precipitate formed on neutralization was removed and washed with water. The combined aqueous solutions were continuously extracted with ether. The ether was removed through a Vigreux column. An acid fraction, 35.2 g., obtained on continued heating was used to charge the pot of a 12 mm. i.d. by 380 mm. long, $^3/_{32}$'' glass helix packed column. Mesitylene was used as a chaser.

A center cut of acetic acid was used for all derivative preparations. The cut was contaminated with a trace of mesitylene. *Anal.* Found: 0.721 mμc./mg. C.; b.p. 117–118.5°.

The *p*-toluidide of acetic acid was prepared, m.p. 145.5–146°. *Anal.* Calcd. for $C_9H_{11}ON$: C, 72.5; H, 7.4. Found: C, 72.8; H, 7.6; 5th recrys., 0.155 mμc./mg. C.; 7th recrys, 0.157 mμc./mg. C.; 0.702 mμc./mg. C., cor. for inactive carbon.

Acetic acid was converted to the thallous salt[35] for purification. Carbon dioxide free solutions of thallous hydroxide were prepared from thallous hydroxide obtained from Varlacoid.[36] The acid was carefully titrated to a phenolphthalein end-point. Care had to be taken to eliminate any excess of thallous hydroxide by back titration with an inorganic acid. A slight excess of thallous hydroxide makes subsequent purification more troublesome. After vacuum evaporation of the aqueous solution, the residue was triturated with absolute ethanol. The alcohol solution usually was treated with Darco and again taken to dryness. Thallous acetate can be recrystallized readily from absolute ethanol. It comes out of solution in shining platelets, m.p. 126.5–127.5°. The ease of preparation and purification coupled with the non-hygroscopic nature of this salt makes it ideal as a derivative and as a source of acetic acid in degradation procedures.

Anal. Calcd. for $TlC_2H_3O_2$: C, 9.1; H, 1.2. Found: C, 9.2; H, 1.2; 3rd recrys., 0.723 mμc./mg.C.

Propionic-C_1^{14} Acid.—The carrier propionic acid–propionamide was isolated as propionic acid during the fractionation described under acetic-C_1^{14} acid. The propionic acid fraction contained considerable mesitylene. The *p*-toluidide of propionic acid was prepared, m.p. 123.5–125°.

Anal. Calcd. for $C_{10}H_{13}ON$: C, 73.6; H, 8.0. Found: C, 73.5; H, 8.1; 3rd recrys., 0.675 mμc./mg. C.; 5th recrys., 0.654 mμc./mg. C.; 2.21 mμc./mg. C., cor. for inactive carbon.

Thallous propionate was prepared, m.p. 190–190.5°.[37] *Anal.* Calcd. for $TlC_3H_5O_2$: C, 13.0; H, 1.8. Found: C, 13.1; H, 1.8; 2.20 mμc./mg. C.

A further fractionation of 6 g. of this material was carried out in a 50-plate concentric tube column. Propionic acid boiling at 141.2° was used for analysis and degradation. A small trace of mesitylene still contaminated the sample.

Anal. Found: 2.13 mμc./mg. C. (cor. for trace of mesitylene).

Degradation of Acetic Acid-1,2-C_1^{14}.—The method used was an adaptation of the method of Phares[38] based on the Schmidt reaction. *Anal.* Found: CO_2, 0.840 mμc./mg. C. (2 runs).

The methylamine produced was converted to N-phenyl-N′-methylthiourea, m.p. 113–113.5°. *Anal.* Calcd. for $C_8H_{10}N_2S$: C, 57.8; H, 6.1. Found: C, 57.8; H, 6.1; 0.536 mμc./mg. C., cor. for inactive carbon.

Degradation of Propionic Acid-1,2,3-C_1^{14}.[39]—*Anal.* Found: CO_2, 1.49 mμc./mg. C. (4 runs).

The ethylamine produced from one of the runs was converted to N-phenyl-N′-ethylthiourea. *Anal.* Calcd. for $C_9H_{12}N_2S$: C, 60.0; H, 6.7. Found: C, 60.2; H, 6.7; 2.39 mμc./mg. C., cor. for inactive carbon (1 run).

The ethylamine was also converted to acetic acid by the method of Phares and degraded further. *Anal.* Found: CO_2, 1.44 mμc./mg. C. (2 runs).

The methylamine produced was converted to N-phenyl-N′-methylthiourea. *Anal.* Found: 3.30 mμc./mg. C. corr. for inactive carbon (3 runs).

Acetonitrile.—A higher boiling fraction obtained from the fractionation of the carrier acetone sample was shown to be infrared spectroscopically identical with authentic acetonitrile.

Processing of Acetamide-C_1^{14}; Addition of Carriers. C Series.—A sample of acetamide (32.745 g.) received an irradiation of 6254 megawatt hours. Acetamide survival 46% (estimated). *Anal.* Found: 15.27 ± 0.25 mμc./mg. C.[40] Total activity produced, 0.203 mc. The carriers (9.928 g. of propionamide, 9.663 g. of propionic acid) were added directly to the quartz irradiation vessel containing the remaining acetamide (31.825 g.). The contents of the vessel were homogenized by melting.

Acetic Acid-C_1^{14}.—The contents of the quartz vessel were transferred (48.768 g.) to a round-bottom flask containing 200 g. of sulfuric acid and 200 cc. of water. After boiling for 16 hr. the solution was distilled. The distillate was treated with 0.88 g. of potassium permanganate to remove the sulfite ion present. The solution was continuously extracted with ether for 24 hr. Removal of the ether left 59.53 g. of an acid–water mixture. A center cut, b.p. 118–118.5°, obtained by fractionation as previously described under Acetic acid-1,2-C_1^{14}, A series (no mesitylene chaser was used), was used for all derivative preparations. *Anal.* Found: 1.22 mμc./mg. C.

The *p*-bromophenacylacetate was prepared, m.p. 83–84.5°. *Anal.* Found: 1.26 mμc./mg. C., cor. for inactive carbon.

Thallous acetate was prepared as previously described. *Anal.* Found: 5th recrys., 1.23 mμc./mg. C., 7th recrys., 1.23 mμc./mg. C.

Acetic acid from this cut was purified by vapor phase chromatography (V.P.C.) on a 1.2 cm. × 250 cm. column containing crushed firebrick, Johns–Manville C-22, 80–100 mesh; 50% by weight of 90% Dow Corning (D.C.) 710 plus 10% stearic acid constituted the liquid phase. The column temperature was 120°. The heart cut of the acetic acid fraction was converted to the thallous salt. The dissolved salt was treated with Darco and subsequently recrystallized. *Anal.* Found: 1.24 mμc./mg. C.

Propionic Acid-C_1^{14}.—Propionic acid from the fractionation described under acetic acid-C_1^{14} was analyzed. *Anal.* Found: 1.02 mμc./mg. C.

Thallous propionate was prepared as previously described. *Anal.* Found: 1.00 mμc./mg. C.

Propionic acid was converted to methyl propionate by treatment with diazomethane. The ester was purified by V.P.C. on a column such as described under acetic acid-C_1^{14}. The liquid phase was Dow–Corning 710. After hydrolysis of the ester fraction with base, the solution was acidified and then extracted with ether. The thallous salt was prepared from the ether solution. Analysis of the salt followed its treatment with Darco and subsequent recrystallization. *Anal.* Found: 0.982 mμc./mg. C.

Degradation of Acetic Acid-1,2-C_1^{14}.[38]—*Anal.* Found: CO_2, 1.52 mμc./mg. C. (3 runs).

The methylamine produced was assayed as N-phenyl-

N′-methylthiourea. *Anal.* 0.888 mμc./mg. C., cor. for inactive carbon (3 runs).

Degradation of Propionic Acid-1,2,3-C_1^{14}.[39]—*Anal.* Found: CO_2, 0.583 mμc./mg. C. (4 runs).

The ethylamine produced from one of the runs was converted to N-phenyl-N′-ethylthiourea. *Anal.* Found: 1.10 mμc./mg. C., cor. for inactive carbon.

Acetic acid made from the ethylamine was degraded. *Anal.* Found: CO_2, 0.764 mμc./mg. C.

The methylamine produced was assayed as N-phenyl-N′-methylthiourea. *Anal.* Found: 1.46 mμc./mg. C., cor. for inactive carbon.

Processing of Acetamide-C_1^{14}; Addition of Carrier D Series.—A sample of acetamide (37.150 g.) received an irradiation of 5174 megawatt hours; acetamide survival, 65 ± 3%. *Anal.* Found: 11.86 mμc./mg. C. Total activity produced, 0.179 mc. The carriers (9.0128 g. of propionamide, 9.0413 g. of propionic acid) were added to 26.428 g. of irradiated acetamide. The mixture was homogenized by liquefaction.

Acetic Acid-C_1^{14}.—Hydrolysis of the mixture with base, isolation of the acids and fractionation of the acids was carried out as previously described under Acetic acid-C_1^{14}, A series (no mesitylene chaser was used).

Acetic acid, b.p. 118.5–119.5°, was further purified by V.P.C. The column previously described was used. The liquid phase was 90% D.C. 710 plus 10% stearic acid. A heart cut of the acetic acid was taken. This material was converted to thallous acetate and subsequently purified. *Anal.* Found: 0.811 mμc./mg. C.

Propionic Acid-C_1^{14}.—Propionic acid, b.p. 140.5–141.1°, from the fractionation of the acid fraction was purified by V.P.C. as described under acetic acid-1,2-C_1^{14}. The heart cut of this material was converted to thallous propionate and subsequently purified. *Anal.* Found: 0.886 mμc./mg. C.

Degradation of Acetic Acid-1,2-C_1^{14}.—The thallous salt was degraded. *Anal.* Found: CO_2, 0.991 mμc./mg. C.

The methylamine was assayed as N-phenyl-N′-methylthiourea. *Anal.* Found: 0.608 mμc./mg. C., cor. for inactive carbon.

Degradation of Propionic Acid-1,2,3-C_1^{14}.—The thallous salt was degraded. *Anal.* Found: CO_2, 0.644 mμc./mg. C.

The ethylamine was assayed as N-phenyl-N′-ethylthiourea. *Anal.* Found: 0.959 mμc./mg. C., cor. for inactive carbon.

Acetic acid made from the ethylamine was degraded. *Anal.* Found: CO_2, 0.646 mμc./mg. C.

The methylamine produced was assayed as N-phenyl-N′-methylthiourea. *Anal.* Found: 1.32 mμc./mg. C., cor. for inactive carbon.

The Rate of Hydration of Methylenecyclobutane and the Effect of Structure on Thermodynamic Properties for the Hydration of Small Ring Olefins[1]

BY PETER RIESZ, ROBERT W. TAFT, JR., AND ROBERT H. BOYD

RECEIVED FEBRUARY 4, 1957

The effects of small ring structure on the position of equilibrium in hydration of olefins to *t*-carbinols have been found to be of substantial magnitude and in the directions predicted by Brown's I-strain rules. The relatively small effects of ring size on the rates of hydration which are found indicate that there is no appreciable covalent bonding of a water molecule to carbon in the reaction transition state. It is concluded from the observed effects of structure on the rate of hydration that the π-complex provides a more suitable model for the molecular structure (nuclear arrangement) of the transition state than does the classical carbonium ion. The transition state exhibits the property of possessing carbonium ion character with respect to electronic, but not molecular, structure. This property is attributed to more sluggish nuclear than electronic rearrangements in attaining the transition state.

The rates of hydration of gaseous methylenecyclobutane and 1-methyl-1-cyclobutene to 1-methylcyclobutanol in aqueous nitric acid solution have been determined by measuring the rate of drop in the saturated vapor pressure of olefin over the solution in which the reaction occurs.[2]

Demjanow and Dojarenko have shown that methylenecyclobutane is converted to 1-methylcyclobutanol by treatment with 66% H_2SO_4.[3] We find no evidence that rearranged products are formed during the hydration.

Rates and equilibria in the hydration of the small ring olefins have been investigated in order to provide critical evidence concerning the reaction mechanism. Taft has proposed that the rate-determining step in the aqueous acid-catalyzed aliphatic olefin–*t*-carbinol interconversion involves the isomerization of π-complex and carbonium ion intermediates.[4] Several criteria of mechanism indicate that the same mechanism is involved for the small ring as for the open chain olefins.[4,5]

By combining the results of the present research with those of previous investigations, we have obtained data on the effect of structure on the thermodynamic equilibrium and rate properties for the hydration of small ring olefins relative to that for corresponding open chain olefins. This information provides new evidence in support of Taft's mechanism.

Experimental

Methylenecyclobutane.—The zinc reduction of pentaerythrityl tetrabromide[6] was carried out in a manner similar to that described by Roberts and Sauer.[7] In order to separate the olefins in the crude product from spiropentane, the reaction product was extracted several times with almost saturated aqueous silver nitrate solution and the olefin was regenerated by warming the solution.[8] The crude olefin product was fractionated through a 40-inch column packed

with glass helices. The material used for the kinetic work had a b.p. 40.8–41.0° (737 mm.), n^{20}D 1.4206. Literature values[9] for these constants are b.p. 41.4° (750 mm.), n^{20}D 1.4210. The infrared spectrum of the gaseous olefin sample was taken in a 10-cm. gas cell at a pressure of 5 cm. and corresponded closely to that reported by Cleveland, Murray and Galloway.[10]

1-Methyl-1-cyclobutene.—A mixture of this olefin and methylenecyclobutane was prepared following a procedure of Shand, Schomaker and Fischer.[9] Methylenecyclobutane was treated with HI and the resulting 1-methyl-1-cyclobutyl iodide was dehydrohalogenated with alcoholic KOH. The earlier workers obtained a sample containing 1-methyl-1-cyclobutene in a ratio of 2 to 1 to its exo isomer.[9] Our sample contained more nearly equivalent amounts of the two olefins (*cf.* Kinetic Procedure). The infrared spectrum of the gaseous mixture showed only the peaks reported for the two olefins.[10]

1-Methyl-1-cyclobutanol.—This carbinol was prepared in over 80% yield by the hydration of methylenecyclobutane with a 1:1 (by volume) mixture of aqueous sulfuric acid.[11] The crude product was dried over calcium hydride and fractionated through a 10-inch Vigreux column, b.p. 115–116° (uncor.) at 730 mm., n^{20}D 1.4343. Literature values[9,16b] for these constants are b.p. 115–118° (at 747 mm.), n^{24}D 1.4333. There was no evidence of the formation of other products such as cyclobutanemethanol (b.p. 142–143.5°, n^{20}D 1.4450; H. Pines, H. G. Rodenberg and V. N. Ipatieff, This Journal, **75**, 6065 (1953)) or 1-methylcyclopropane methanol (b.p. 128° at 750 mm., n^{20}D 1.4308; S. Siegel and C. G. Bergstrom, This Journal, **72**, 3815 (1950)—*cf.* further comment on reaction product from kinetic experiments).

Kinetic Procedure for Methylenecyclobutane.—The apparatus and the hydration procedures are those described in the study of the hydration of 1-methyl-1-cyclopentene.[12] The rate of hydration, k_p, of gaseous methylenecyclobutane at unit pressure in the gas phase by an aqueous nitric acid is given by the expression[2]

$$k_p = \left(\frac{r}{RT} + h\right)(s - k_{-1})$$

where

$$s = \frac{-\mathrm{d} \ln (P - P^e)}{\mathrm{d}t}$$

P = partial pressure of gaseous olefin at any time t
P^e = partial pressure of olefin when reaction has reached equilibrium
k_{-1} = rate of dehydration of aqueous alcohol at unit concentration (negligible in the present case)
r = ratio of volume of gas phase to volume of acid solution
h = distribution constant of olefin between liquid and gas phase

Since the distribution constant, h, was determined by separate experiments, it was possible to determine a k_p value from a single kinetic run. In general, four kinetic runs were made with values of r/RT ranging from 0.05 to 0.150 and the average k_p calculated. The probable errors given in Table III are based upon deviations from the mean. Distribution constants in acid solutions were estimated[13] from the value obtained in water, h_0, by using the Setschenow equation

$$\log (h_0/h) = KC$$

The value of the Setschenow parameter, K, at 25.17° was obtained from the value of h_0 (Table IV) and the value of h obtained indirectly in 3 M nitric acid. Nine hydration experiments in 3 M acid at varying values of r/RT were made (results are listed in Table I). Use was then made of the relationship[2]

$$\frac{RT}{rs} = \frac{1}{k_p} + \frac{hRT}{k_p r}$$

From the least squares calculation a value of $h = 22.6 \pm 2.0 \times 10^{-3}$ mole-l.$^{-1}$ atm.$^{-1}$ is obtained. Accordingly, $K = -0.056 \pm 0.013$.

Table I

Hydration of Methylenecyclobutane in 2.995 M Nitric Acid at 25.17°

$r/RT \times 10^3$	33.71	46.38	49.94	60.23	79.51
$s \times 10^2$	7.68	6.52	6.60	5.60	4.39
$r/RT \times 10^3$	142.0	151.7	152.2	158.9	
$s \times 10^2$	2.70	2.45	2.60	2.50	

The equilibrium pressures obtained in the hydration of methylenecyclobutane were not equal to the solvent pressures but slightly larger. This difference was independent of a variation of r/RT from 0.05 to 0.150 and independent of temperature, both of which would have a large effect if the residual pressure were due to reversibility. In all experiments this residual corresponded to about 3% of the amount of original olefin introduced. No drift was noted in the equilibrium pressures after 10 half-lives and no systematic deviation from linearity could be detected in any of the rate plots which were followed to as much as 95% of complete reaction. It was therefore concluded that 3% of an inert impurity was present in the methylenecyclobutane. It has been shown previously that the presence of a small amount of inert gas (air) does not affect the measurements when the hydration is irreversible.[2] The infrared spectrum of a gas sample enriched in this impurity was obtained by "hydrating out" methylenecyclobutane. The spectrum shows large absorption peaks at 10.07 and 12.57 μ which were barely noticeable in the original sample. The enrichment factor of both peaks was comparable. The absorption peak at 10.07 μ is identical in position and appearance with that from a spiropentane sample.[10]

Kinetic Procedure for 1-Methyl-1-cyclobutene.—The rates of hydration of gaseous 1-methyl-1-cyclobutene and methylenecyclobutane were determined simultaneously in 2.52 M nitric acid solution at 25.0°. The procedure used is that given previously,[12] and the olefin mixture used was that obtained from the dehydrohalogenation of 1-methyl-1-cyclobutyl iodide. The methylenecyclobutane reacts so much faster (about seven times) than its endo isomer that no difficulty was encountered in precisely resolving a plot (Fig. 1 is a typical example) of log P *vs.* t into the two first-

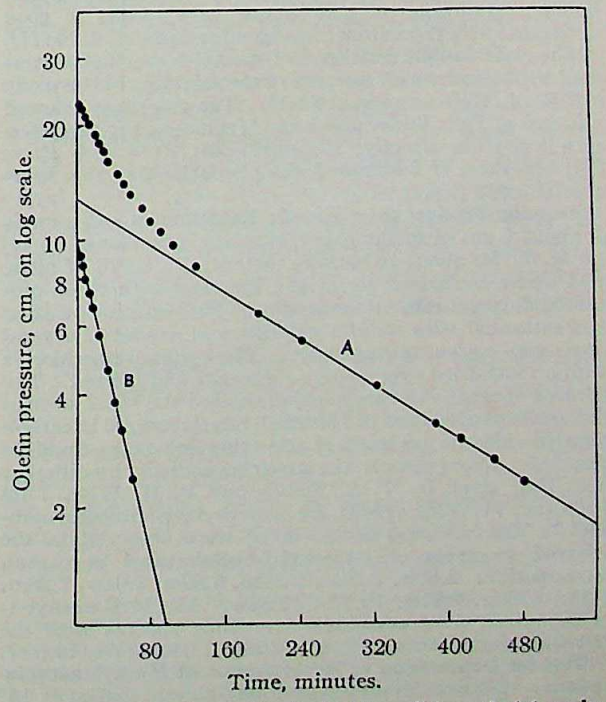

Fig. 1.—Parallel first-order hydration of 1-methyl-1-cyclobutene (A) and methylenecyclobutane (B).

order components using conventional procedure.[14] The plot becomes precisely linear after about 75% of the original olefin has reacted, and the resulting slope, $s/2.303$, used in the equation, $k_p = (r/RT + h)(s)$, provides a value of k_p for the slower reacting olefin. Typically the k_p value is based upon the pressure drop from about 6 to 2 cm. with an initial pressure of 20 to 25 cm. The partial pressure due to the slower reacting olefin was calculated from the first-order rate law and subtracted from the observed pressure to obtain the partial pressure of the faster reacting isomer. These pressures followed precisely a first-order rate law (*cf.* Fig. 1) from which, in turn, the k_p value for the faster reacting olefin was obtained. Intercepts in the log P *vs.* t plots indicate that the composition of the olefin sample is approximately 45% in the latter olefin. Table II lists results obtained in several experiments.

TABLE II

SIMULTANEOUS HYDRATION OF 1-METHYL-1-CYCLOBUTENE AND METHYLENECYCLOBUTANE IN 2.523 *M* NITRIC ACID AT 25.0°

r/RT	k_p, 10^4 moles-l.$^{-1}$-atm.$^{-1}$-min.$^{-1}$ 1-Methyl-1-cyclobutene	Methylene-cyclobutane	Intercept ratio
0.1078	4.77	33.0	1.3
.1165	4.62	32.6	1.3
.1167[a]	4.60		4.3
.1325[b]	4.70	32.1	1.3
.1498	4.76	30.3	1.2
Mean value	4.64	32.0	

[a] Experiment with enriched 1-methyl-1-cyclobutene sample. [b] Concentration of acid 2.55 *M*.

The mean value of k_p identifies the faster reacting olefin as methylenecyclobutane. The rate of hydration of this olefin has not previously been determined in 2.52 *M* HNO_3 but has been shown to follow the equation log $k_p = (-1.29)H_0 - 3.53$ for the range 0.973 to 4.94 *M* HNO_3.[4b] The observed value agrees substantially with that calculated from this equation. Combined with the earlier data, the hydration rates for methylenecyclobutane are best fitted by the equation log $k_p = (-1.27)H_0 - 3.49$.

In order to check the above results, methylenecyclobutane was "hydrated out" of the original olefin sample, giving a sample which by kinetic analysis (ratio of intercepts) and by infrared analysis contained 80–85% of 1-methyl-1-cyclobutene. Hydration of this sample gave results in good agreement with those from the original sample (*cf.* Table II).

The olefin sample enriched in 1-methyl-1-cyclobutene was used to obtain a rough measure of the solubility of this olefin in 2.52 *M* HNO_3 solution at 25.0°. The procedure followed was that of Taft, Purlee and Riesz[13] (equation 1 of this reference is given incorrectly; it should read: $P^0 = P + \rho(t - t')$); the value of h obtained using equation 3 of this reference is 0.010 mole-l.$^{-1}$.

Reaction Product from Kinetic Experiments.—A sample of about 1 ml. of methylenecyclobutane was allowed to react at 45° for about 10 half-life periods with 0.973 *M* nitric acid under conditions essentially identical with those prevailing during a rate measurement. The resulting solution was saturated with sodium chloride and extracted several times with carbon tetrachloride. The carbon tetrachloride solution was dried over sodium carbonate and filtered. The infrared spectrum of this solution showed the same absorption peaks as a solution of 1-methyl-1-cyclobutanol in carbon tetrachloride and no trace of any other substance could be detected. (For example, the spectrum is distinctly different from that given by V. A. Slabey and P. H. Wise, THIS JOURNAL, 71, 3252 (1949), for α-methylcyclopropanemethanol.) The following peaks (in μ) were observed in the infrared spectrum of 1-methyl-1-cyclobutanol in carbon tetrachloride: 2.80w, 3.04w, 3.40m, 6.89m, 7.01w, 7.28m, 7.95s, 8.49m, 9.81w, 10.47s, 10.89w. Liquid 1-methyl-1-cyclobutanol gives essentially the same spectra with the following modifications: 2.80 missing, 3.04s, 8.49s, 14.00w.

Test for Deuteration or Isomerization of Methylenecyclobutane.—Gaseous methylenecyclobutane was shaken at 45° with 0.973 *M* nitric acid in 60% deuterated water under the conditions of a rate experiment until the pressure had fallen to half of the initial value. The residual olefin was then removed and its infrared absorption observed in the gaseous state with a path length of 10 cm. at a pressure of 5 cm. Comparison of this spectrum and that of the original olefin showed that no detectable deuteration or isomerization of the olefin occurs during the hydration reaction.

Dehydration of 1-Methylcyclobutanol.—The gaseous material obtained as indicated in the Results section gave the following infrared peaks (in μ) which were used to characterize isoprene (we are indebted to Professor J. D. Roberts for suggesting this assignment): 6.25m, 10.08m, 11.04s and 11.20s. Peaks at 5.96 (w), 7.00 (w) and 11.40 (s) characterize methylenecyclobutane. 1-Methyl-1-cyclobutene was identified by peaks appearing at 6.90 (m), 7.80 (w), 11.40 (s), 11.68 (s) and 3.68 (m). The quantitative analysis of the olefin mixture was based upon the following peaks: 1-methyl-1-cyclobutene, 13.68 μ; isoprene, 6.25, 10.08 and 11.04 μ; methylenecyclobutane, 5.96 and 11.40 μ. The analysis given has been rounded off to the nearest 5% and is estimated to be accurate within this limit.

Results

Rate Data.—Measurements of the rate of hydration of methylenecyclobutane in 0.972 *M* nitric acid have been made for the temperature range 25 to 45°. In this temperature range the hydration is, within the precision of measurement, completely irreversible. Table III lists the rate constants, k_p, obtained.

TABLE III

RATE CONSTANTS, k_p, FOR THE HYDRATION OF GASEOUS METHYLENECYCLOBUTANE IN 0.972 *M* NITRIC ACID IN 10^4 MOLES-L.$^{-1}$-ATM.$^{-1}$-MIN.$^{-1}$

Temp., °C.	25.17	34.58	45.15
k_p	3.97	9.47	22.75
Probable error	0.036	0.072	0.15

A plot of log k_p against $1/T$ is linear essentially within the precision of measurement. Thus the value of 10^4 k_p in 0.972 *M* nitric acid at 34.58° calculated on the basis of this linearity from the value at 25.17° is 9.31 ± 0.06, compared with the observed value 9.47 ± 0.07.

From equations 8 and 9 of reference 3, we calculate the best values of the enthalpy of activation, $\Delta H_p^{\ddagger}$, to be 15.83 ± 0.11 kcal. and the entropy of activation, $\Delta S_p^{\ddagger}$, to be −28.81 ± 0.34 cal./deg. These quantities represent the difference in enthalpy and entropy between the activated state in solution on the one hand and the gaseous olefin and aqueous acid on the other.

The rate constants, k_p, obtained for 1-methyl-1-cyclobutene and methylenecyclobutene in 2.52 *M* nitric acid at 25.0° are 4.69×10^{-4} and 3.20×10^{-3} mole-l.$^{-1}$-atm.$^{-1}$-min.$^{-1}$, respectively. The value of k_p for 1-methyl-1-cyclobutene in 0.973 *M* nitric acid at 25.0° may be estimated as 6.8×10^{-5} mole-l.$^{-1}$atm.$^{-1}$-min.$^{-1}$ by the relationship: log $(k^2/k^1) = (-1.25)(H^2_0 - H^1_0)$.[4b]

Solubility Measurement.—The distribution constant, h, for methylenecyclobutane between gas phase and water has been measured over a temperature range from 15 to 45°. The results are recorded in Table IV.

A plot of log h against $1/T$ is linear to a reasonable precision. Thus the value of 10^3h at 34.95° calculated on the basis of this linearity from the value at 25.17° is 11.04 ± 0.08; the observed value is 10.95 ± 0.14.

TABLE IV

DISTRIBUTION CONSTANT, h, FOR METHYLENECYCLOBUTANE BETWEEN GAS PHASE AND WATER AS A FUNCTION OF TEMPERATURE IN 10^3 MOLES-L.$^{-1}$-ATM.$^{-1}$

Temperature, °C.	16.02	19.95	25.17	30.11	34.95	45.13
h	21.56	18.99	15.49	12.63	10.85	8.01
Probable error	0.20	0.29	0.20	0.10	0.14	0.02

The heat and entropy of solution of methylenecyclobutane in water were calculated from the slope of the appropriate least squares lines. The value of the enthalpy of solution, ΔH_{sol}, is -6.43 ± 0.12 kcal. and that of the entropy of solution, ΔS_{sol} is -29.5 ± 0.4 cal./deg. The standard state is hypothetical one molal.

The rate constant for dissolved olefin at unit concentration, k_c (in units of min.$^{-1}$), is obtained from the relationship[2]: $k_c = k_{p/h}$. Using the value of h (0.010 mole-l.$^{-1}$-atm.$^{-1}$) obtained for 1-methyl-1-cyclobutene in 2.52 M nitric acid at 25.0° and the Setschenow equation with an estimated K value of 0.074,[4b] an h value for 0.973 M nitric may be estimated as 0.008 mole-l.$^{-1}$-atm.$^{-1}$. This value together with the estimated k_p value (6.8×10^{-5} mole-l.$^{-1}$-atm.$^{-1}$) gives $k_c = 9 \times 10^{-3}$ min.$^{-1}$. In a similar fashion from the data given above, the k_c value for methylenecyclobutane in 0.973 M nitric acid at 25.0° is calculated to be 2.3×10^{-2} min.$^{-1}$.

The relative enthalpies and entropies of activation, $\Delta\Delta H_c^{\ddagger}$ and $\Delta\Delta S_c^{\ddagger}$, respectively, for dissolved olefins at unit concentration (in 0.973 M HNO_3) can be obtained from the equations

$$\Delta\Delta H_c^{\ddagger} = \Delta\Delta H_p^{\ddagger} - \Delta\Delta H_{sol} \quad (1)$$

$$\Delta\Delta S_c^{\ddagger} = \Delta\Delta S_p^{\ddagger} - \Delta\Delta S_{sol} \quad (2)$$

The use of these equations in this manner involves the assumption that the relative enthalpies and entropies of solution, $\Delta\Delta H_{sol}$ and $\Delta\Delta S_{sol}$, respectively, are the same in one molar acid as in water. This assumption has been confirmed to a good approximation by direct measurements with isobutene and trimethylethylene.[15]

Hydration Equilibrium.—In the temperature range 25 to 45° the hydration of methylenecyclobutane was found to proceed to completion within the precision of pressure measurement. None of the olefins previously studied under comparable equilibrium conditions has been found to hydrate to this degree at 45°. It was therefore clear that the ring size of the olefin has an appreciable effect on the value of the equilibrium constant. The remarkable stability of 1-methyl-1-cyclobutanol toward dehydration has interested previous investigators.[16]

We have been able to estimate a maximum value for the equilibrium constant at 70° for the reaction

methylenecyclobutane (g) + H_2O(l) $\rightleftharpoons$ 1-methyl-1-cyclo-butanol(aq)

Using a one molar (nearly saturated) solution of the carbinol in 0.0973 M perchloric acid at 70°, a steady olefin pressure of about 0.7 cm. developed with long standing. Assuming, in accord with the experimental results given below, that not more than 20% of the generated olefin is methylenecyclobutane, an equilibrium constant, $K_p = C_a^e/p_0^e$, of greater than 500 moles-l.$^{-1}$-atm. is obtained.

A solution 0.9 M in 1-methyl-1-cyclobutanol and 0.3 M in $HClO_4$ was heated at reflux temperature for several hours, during which time a stream of nitrogen was swept through the system and the exit vapors were passed into a liquid nitrogen trap. The olefin sample collected was analyzed by infrared spectra in a 10-cm. gas cell at a pressure of 4.9 cm. The analysis indicated the decomposition product to be a mixture of approximately 45% 1-methyl-1-cyclobutene, 35% isoprene and 20% methylenecyclobutane. The formation of isoprene readily is pictured in the dehydration of 1-methyl-1-cyclobutanol in terms of a Whitmore β-cleavage of a C–C bond of the cyclobutane ring.

An estimate of the relative thermodynamic stability of the endo and exo isomers may be made from the present results. Assuming the composition of the dehydration product given above to provide a rough measure of the relative rates of formation of the two olefins from aqueous carbinol solution at 25°,[17] one may calculate from this and the relative hydration rates, k_p, that the free energy of formation of gaseous 1-methyl-1-cyclobutene is on the order of 1,5000 cal./mole more negative than that for methylenecyclobutane. Turner and Garner have recently reported results indicating that in 5- and 6-membered rings the 1-methyl-1-cycloalkene is also more stable than its methylenecycloalkane isomer.[18]

Discussion

By combining the data of the present research with that of previous investigations,[19] the effects of ring size on the rates, equilibria and thermodynamic properties given in Tables V and VI are obtained. The standard of comparison is isobutylene which apparently possesses properties reasonably typical of open-chain olefins leading to *t*-carbinols. Thus, the rates of hydration relative to isobutylene are: 2-methyl-2-butene, 0.67; 2-methyl-1-butene, 1.30; 2,3,3-trimethyl-1-butene, 1.20. The rates of dehydration relative to *t*-butyl alcohol are: *t*-amyl alcohol, 10 (to give 2-methyl-2-butene) and 2.0 (to give 2-methyl-1-butene); and dimethyl-*t*-butylcarbinol, 15. These relative rates and those given in Tables V and VI apply to dissolved reactants at unit concentration in one molar nitric acid solution at 30°.

The equilibrium data of Table V indicate that the formation of carbinol from olefin is favored ($K/K_0 >> 1$) by a very substantial factor when the carbon atom forming the C–O bond is in a 4-membered ring, but the reverse ($K/K_0 << 1$) is true for the 5-membered ring. A factor of greater than four powers of ten favors the hydration equilibrium constant for methylenecyclobutane compared to

(16) (a) Reference 10; (b) H. C. Brown and M. Borkowski, *ibid.*, **74**, 1894 (1952).

(17) If, as seems less likely, the composition of the dehydration product is equilibrium controlled, then the figure for the estimated difference in the free energy of formation of the two isomers should instead be about 500 cal./mole (favoring the endo compound). It is probable that the correct figure lies between 500 and 2000 cal./mole.

[a] Based on dehydration to methylenecyclobutane.

that for 1-methyl-1-cyclopentene. The results are in accord with the I-strain hypothesis of Brown.[20] According to this hypothesis increasing the coördination number of the carbon atom of the 4-membered ring from three to four (olefin to alcohol) is favorable because of the release of some ring strain. That is, constraint of the carbon valences to 90° involves less strain in the normally tetrahedral than in the trigonal state. Further, the unfavorable effect resulting from the increase from three to four of the coördination number of the carbon atom of the 5-ring system is explained on the basis of increased eclipsing of ring hydrogen atoms.

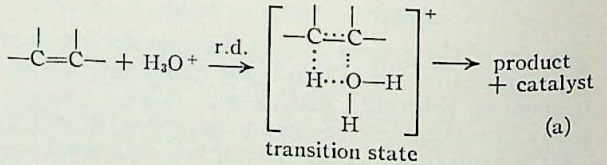
The rate of hydration (Table V) shows no such dependence on structure. In general there is relatively little effect of structure on the hydration rate. The maximum factor of one power of ten in the hydration rate involves exactly the opposite relationship to structure as that shown by the equilibria; namely, the 5-ring olefin, 1-methyl-1-cyclopentane, hydrates about ten times faster than the 4-ring olefin, 1-methyl-1-cyclobutene.

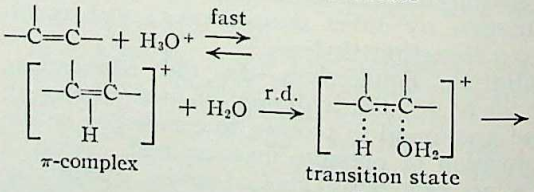
It is striking to note that in each case where temperature coefficients of rate or equilibrium have been determined (*cf.* Tables V and VI) the effects of structure on the relative free energy changes are accompanied by even larger effects in the same direction on the enthalpy changes.

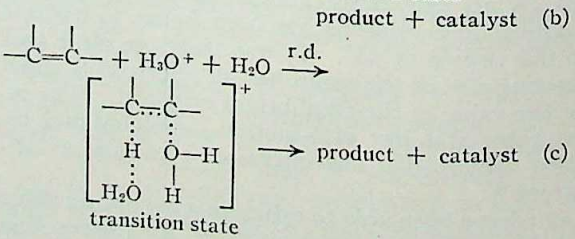
We conclude that there is no appreciable covalent bonding of a water molecule to carbon in the hydration transition state. The argument is based upon the proposition that if the transition state resembled the carbinol (with appreciable covalent C–O bond interaction), the effect of structure on the hydration rate and on the equilibrium would be in the same direction and of similar magnitude. That is, similar effects from increasing the coördination number of the ring carbon atom would result from the formation of either the transition state or the carbinol from the olefin. The relationships expected on this basis are not observed.

On the other hand, the formation of both the transition state and the olefin from the carbinol are similarly affected (in direction and in magnitude) by structure (compare corresponding values of K/K_0 and k/k_0 of Table VI). The direction of the observed effects are those expected according to the I-strain hypothesis for the decrease in coördination number of the ring carbon atom from four (carbinol) to three (olefin or transition state). In other words, the closely similar effects of structure on the rate and equilibrium of carbinol dehydration indicate that the water present in the conjugate acid of the carbinol is lost from carbon in the formation of either the olefin or the transition state. A similar conclusion has been reached earlier based upon the entropies of activation and reaction for olefin hydration and carbinol dehydration.[4]

The present results, therefore, exclude such mechanisms as the following (as well as those rigorously excluded by earlier results[5])







The results in Tables V and VI are consistent with, and lend further support to, the mechanism of Taft (given below) which pictures no appreciable covalent interaction between oxygen (of H_2O) and carbon (of olefin) in the proposed transition state.

Apparently the only alternate mechanism which is consistent with the present results is a rate-determining proton transfer from hydronium ion to olefin. This mechanism is considered to be of low probability on the basis of observed isotope effects on the hydration rate.[6]

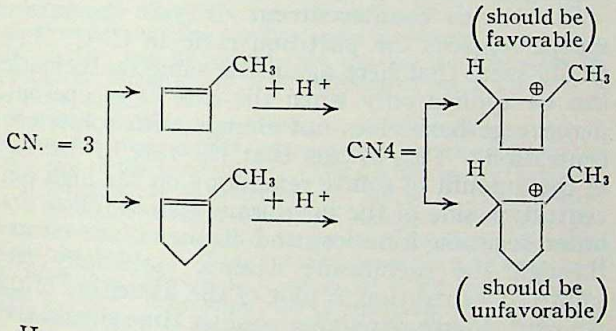
Application of the I-strain hypothesis to the relative rates of olefin hydration listed in Table V provides further evidence of importance concerning the structure of the transition state. If the positions occupied by the nuclei in the reaction transition state were those expected of a classical carbonium ion (in which the added H has formed a conventional C–H bond), then by arguments paralleling those used above, the rate of hydration of the cyclobutene should be favored and the cyclopentene retarded relative to the open chain olefins



However, as noted above, exactly the opposite order of rates is observed. We conclude therefore that the transition state does not possess the nuclear arrangement of a classical carbonium ion. On the other hand, the transition state is stabilized by those structural features which by electronic shifts (inductive or hyperconjugative electron-release) stabilize carbonium ions, as witnessed by the many powers of ten increase in rate in the series: ethylene << propylene << isobutylene.[21] The olefin hydration transition state may thus be ascribed the property of possessing carbonium ion character with respect to electronic but not with respect to molecular structure (nuclear arrangement). This property bears a striking similarity to the well-known Franck–Condon principle and, by analogy, leads to the proposal that the property results from more sluggish nuclear than electronic rearrangements in attaining the transition state.

It is a corollary of our conclusions that the transition state cannot be said (as frequently implied in discussions) to possess a fixed fractional character of the products and reactants of the rate-determining step, but this assessment, if it is to be generally useful, must be made with respect to both electronic and nuclear rearrangements.

Since the effects of structure on hydration rates shown in Table V are relatively small (compared to the effects on dehydration rates shown in Table VI), the π-complex appears to provide a suitable model for the molecular structure of the transition state. According to the structure proposed from the π-complex,[22] its formation from olefin should not require notable nuclear rearrangements.

(21) This is in contrast to the formation constants of the Ag^+ complexes of these olefins which show relatively little dependence on structure; *cf.* F. R. Hepner, K. N. Trueblood and H. J. Lucas, THIS JOURNAL, **74**, 1333 (1952).

Dialysis Studies. II. Some Experiments Dealing with the Problem of Selectivity

BY LYMAN C. CRAIG, TE PIAO KING AND ALFRED STRACHER[1]

RECEIVED FEBRUARY 6, 1957

A convenient cellophane dialysis cell for quantitatively studying dialysis rates is described. A series of proteins of increasing molecular weight up to 45,000 have been studied. The rate of dialysis for each protein has been shown to fall in the order of increasing molecular weight but the membrane becomes more selective as the solute size approaches the membrane pore size. The method may offer a simple means for detecting a change in shape or size during certain types of transformation and for studying homogeneity with respect to size.

In the first paper[2] of this series an experimental approach for fractional dialysis with cellophane was described which permitted multiple fractional separations to be made in a manner entirely analogous to that accomplished with a few stages of countercurrent distribution.[3] Evidence of unanticipated selectivity was encountered at that time which was sufficient to make the procedure as it was described of practical use for the preliminary fractionation of complex mixtures of solutes differing widely in size. It seemed likely that the overall selectivity of the method could be improved either by enhancing the inherent selectivity at each stage or by some mechanical systematization so that many stages could be applied with a minimum of labor as was done in countercurrent distribution.

This latter is made difficult by the fact that for each unit in a stage the dilute dialyzate must be concentrated in some way to one tenth or less of its volume before being transferred to the inside of the next unit in the series. Before attempting to

design a physical set up for accomplishing the larger number of stages it seemed wise to make a more thorough study of some of the factors which could contribute to the inherent and unexplained selectivity possible in each membrane. The present paper will describe certain experiments along this line.

The results already published and other experiments soon showed that the inherent membrane selectivity was a function of many different factors such as the type of membrane, the solvent, the nature of the solute, the temperature, etc. The proper evaluation of each of these factors is made difficult by the fact that they are all more or less interdependent.

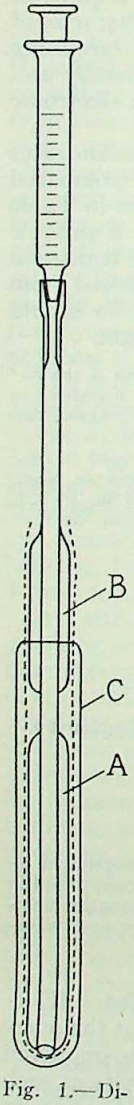

Fig. 1.—Dialysis cell.

In spite of such interdependence it was obvious from the data published[2] and from other preliminary data that the major factor governing selectivity, at least with cellophane membranes, and similar types of solutes, was primarily the size of the solute. Moreover, the effect of size appeared much greater than would be expected on the basis of difference in rates of diffusion in free solution. Apparently the membrane not only prevents mixing due to convection but in addition exerts a selective action of its own in inhibiting the diffusion of the larger molecules through it to a greater degree than the smaller ones. If this is true then it might be expected that relatively higher selectivity with a given membrane would be found for those molecules which due to their size are barely able to pass through the membrane.

Rather than search for a membrane which would slowly pass only small solutes or try to decrease the permeability of one already available it seemed more profitable first to study the passage of larger molecules through the commercial membranes already available to everyone.

In order to pursue this line of attack it seemed advisable first to consider some arrangement for shortening the time of passage of the more sluggish solutes through the membrane both in the interest of saving time and in minimizing the chance of transformation due to bacterial growth. The desired arrangement should not alter the inherent permeability of the membrane in any way such as stretching of the membrane by hydrostatic pressure. This point will be discussed later.

As might be expected, the net total rate of passage of solute caused solely by a concentration gradient of that solute across a membrane is directly proportional to the effective area of the membrane. When the rate is considered in terms of per cent. of the total solute included in the membrane at the beginning, as would always be the case in fractionation studies, it is apparent that in order to accomplish the above stated objective, the smallest volume possible of solution inside the sac should be in contact with the largest area of membrane while only the solvent with essentially no solute in it should be present on the other side of the membrane.[4]

These requirements were easily met in the very simple apparatus shown schematically in Fig. 1. The data given in the present paper were all obtained with a dialysis cell of this type.

Rather early in the development of the method of countercurrent distribution,[5] it was realized that the simple calculations of the binomial theorem could be applied only when the partition isotherms of the solutes were essentially linear, *i.e.*, the partition ratios for a given system did not shift with a change in solute concentration. This ideality proved to be best also from the standpoint of overall separation although non-linear isotherms often permitted better resolution of one component at the expense of the purity of the others.

Since with countercurrent dialysis the rate of escape replaces the partition ratio in C. C. D., it would seem that here again the same mathematics can be applied only when the rate of escape on a percentage basis does not change with solute concentration. This means that the rate of decrease of the amount of solute remaining on the high concentration side of the membrane should follow first order reaction kinetics, and if the solute escapes through the membrane against essentially zero solute concentration, a plot of the logarithm of the per cent. solute remaining against time should give a straight line. In countercurrent dialysis such a straight line behavior is analogous to a linear partition isotherm in C. C. D. Departure from linearity in the dialysis process would be expected to have an effect similar to that already so familiar in C. C. D.

Experimental

The simple apparatus shown in Fig. 1 is constructed easily by an amateur glass blower. A Pyrex glass tube of outside diameter slightly smaller than the diameter of the extended cellophane tubing is chosen and a 6 mm. tube sealed inside it is shown with the lower end of the smaller tube left open. The smaller tube passes through a ring seal at the upper end of the larger tube, A, and at distance of about one cm. from this ring seal into a second section, B, of the larger tubing. This second section of the larger tubing is approximately 0.5 mm. larger in diameter than the lower section, A, and approximates 4 cm. in length. After passing through the upper ring seal of the upper section, the 6 mm. tube is joined to the appropriate part of a standard Becton–Dickinson adapter so that a 2-ml. syringe can be fitted to it.

The dialysis casing to be used is soaked for a few moments in water and one end is tied off with a single knot exerting care not to stretch in any way the part of the membrane above the knot which will later serve as the dialysis membrane. The knot can be tightened adequately by holding the initial loosely formed knot with two fingers while it is pulled tight with the short piece extending below the knot. The extension is then cut off with scissors. The tubing is cut to form a sac of such length that most of section B will be covered when it is pulled over A. This can be done by slowly rotating the wet glass part while the wet membrane

is gently pulled over it. That part of the membrane covering A is kept immersed in water but that over B is permitted to dry. The latter almost immediately contracts in air sufficiently to fix the membrane in place.

Even though kept wet the membrane around A contracts slightly and a small allowance must be made for this in fixing the membrane to B. Likewise, allowance for this contraction must be made in the initial choice of the tube to give the correct outside diameter of A.

C is the part of the cell to contain the solvent into which the solute dialyzes. It is of such size that a volume of solvent 10–20 times that initially used inside the sac will provide a level as high as the upper part of A. The rim of C is heated above the melting temperature and permitted to collapse sufficiently so that A and B will barely pass through. This contracted opening later rests against B and serves to center the upper part of A in the cell C. When in use the unit is supported by a clamp gripping it just below the ground joint but C rests on the table. The lower end of A can then be centered in C by a small shift of the latter on the table. A small spout is made in the rim of C to facilitate pouring.

Before the solution to be dialyzed is inserted, a small hole is punched with a needle through the membrane at a point well above the top of A and just below the bottom of B. This is to avoid pressure when the solution is forced into the sac. The membrane is washed several times with portions of the solvent both inside and out. For the inside wash, the solvent is added through the ground joint. Depression of the plunger of the syringe attached to the top forces the liquid out around the annular space inside the membrane. The solution can be moved into the inside tube again by raising the plunger and then withdrawn by a pipet or a second syringe.

A second small syringe fitted to a plastic tube is most convenient for placing and withdrawing solutions from the lower end of the inside tube. The flexible plastic tube can be of polyethylene or better yet of "Kel F." It is attached to a standard Becton–Dickinson adapter with the end drawn out to a size slightly larger than the inside diameter of the plastic tube. If the tubing is forced over the prepared tip while it is kept hot in a steam jet it will remain firmly fixed in place. The other end of the glass adapter carries the ground joint for attachment to the syringe.

After withdrawing all the wash solution from the inside, the solution to be dialyzed is inserted and gently forced out into the annular space with the syringe. The solution must be of such volume that when the upper level in the annular space inside the membrane reaches the top of A none of it will remain in the glass tube inside A but all will be essentially in intimate contact with the membrane. In the case of the 20/32 and 18/32 membranes the volume inside was 0.6 ml. In these cells the outside diameter of A was 14.8 mm.

Since the annular space between the glass and the membrane only provides for a thin film of solution it is important that the distribution be uniform. This can be ensured by gentle manipulation of the membrane with freshly washed finger tips and by drawing the solution back and forth into the glass tube inside A with the plunger of the syringe.

After satisfactory adjustment the unit is hung in the solvent in C to a height so that the levels of liquid inside the membrane and outside are equal. The time is then recorded.

After an arbitrary interval the outside solution is changed and the first solution set aside for analysis. At each change of outside solution the solution inside the membrane is drawn back into the glass tube by moving the plunger of the syringe and redistributed over the membrane.

At the end of the dialysis experiment each change of solution is analyzed as well as the solution remaining inside the sac so that the rate of escape can be calculated on the basis of total recovery of the solute. The recovery may be slightly greater or less than the material taken, but too great a divergence serves to indicate analytical errors.

At the beginning of a dialysis run when the concentration of solute is highest inside the sac, water will tend to flow into the sac due to osmotic pressure. This dilution will become progressively less as the solute moves out. The effect of the dilution is included in the escape rates indicated by the plot of the decrease of solute against time. No attempt to correct for this effect has been made. The increase in volume inside the sac is usually not more than 20 to 50% but with certain proteins may be much greater. When the latter is the case the escape rate is seldom linear and may indicate strong association.

The cellophane tubing used thus far has steadily given off a small amount of solute absorbing in the range of 280 mμ in spite of the preliminary washing treatment. This absorption has amounted to about 0.010 to 0.015 density unit in the 1-cm. cell at the beginning. That it was not due to an analytical error was confirmed in a 10-cm. cell but has not been of sufficient amount to give a weighable residue in the weight analysis procedure when 1.0 ml. was evaporated.

The bacitracin used in this study was the A fraction obtained by countercurrent distribution. The salmine came from the Nordisk insulin laboratories in Denmark and the "protamine" from GBI. Cytochrome C from horse heart was obtained from Sigma. Subtilin was obtained from the Western Regional laboratories. Ribonuclease and lysozyme were obtained from Armour. The pituitary lactogenic hormone was a sample considered pure by C. C. D. and obtained from Dr. R. D. Cole. We take this opportunity to thank him and Dr. C. H. Li for it. The insulin was a fraction obtained by C. C. D. of a sample of Boots beef insulin. The other proteins were obtained from Worthington.

Results and Discussion

If a single pure solute behaves ideally in that it does not associate to form larger molecules, or be adsorbed appreciably by the membrane, it should be possible to set up experimental conditions for dialysis so that the net rate of passage of solute per unit area of membrane would be proportional only to the concentration gradient across the membrane.[4] That this has been achieved can be shown best experimentally by frequent replacement of dialyzate with fresh solvent. A plot of the logarithm of the per cent. of the original solute remaining in the sac against time then should give a straight line.

Actual experiments with a number of pure solutes in distilled water or dilute acid in the dialysis cell described above have given experimental results which adhered to a straight line to a remarkable degree over a wide concentration range. The solutes studied have included glucose, sucrose, leucine, tryptophan, aspartic acid, bacitracin, subtilin and others. Curves of escape rates for aspartic acid and for bacitracin already have been published.[6] A representative experiment is that made with a good preparation of the polypeptide subtilin and shown in Fig. 2. The result for bacitracin with the same membrane is also shown. As mentioned in the introduction this represents "ideal" behavior as far as fractionation is concerned. However, not all preparations studied were found to give straight lines and it was soon concluded that deviation from a straight line could arise from causes other than impurity as discussed later.

The membranes most used in the studies reported in this paper were Visking 20/32 dialysis tubing selected for dialysis work and 18/32 Visking seamless cellulose tubing. In a cell of the type described the former was found to pass solutes dissolved in 0.01 *N* acetic acid even up to the size of ovalbumin, mol. wt. 45,000, at an appreciable rate. Table I gives the 50% escape time[2] for a number of readily available proteins differing in molecular weight from 5743 to 45,000, plus a few smaller solutes for comparison. The 20/32 membrane is not the most suited for the smaller solutes as ex-

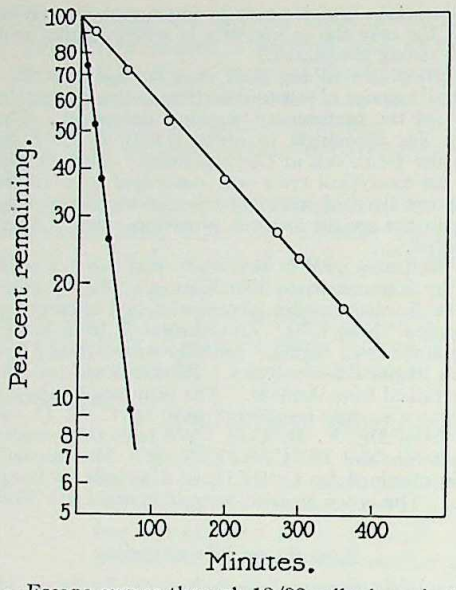

Fig. 2.—Escape curves through 18/32 cellophane in 0.01 *N* acetic acid: ●, bacitracin; ○, subtilin.

plained below. The cells used in gathering these data provided approximately 45 sq. cm. of dialyzing surface with a volume of solution inside the membrane of 0.6 ml. at the start of the dialysis. Each dialysis experiment required from 5 to 20 mg. of solute. A temperature of 25° was used throughout.

TABLE I

COMPARATIVE ESCAPE RATES OF A SERIES OF POLYPEPTIDES AND PROTEINS

Solute	Mol. wt.	50% escape time, min. 0.1 *N* HAc 20/32	0.01 *N* HAc 20/32	0.01 *N* HAc 18/32
Tryptophan	204	.....	4	6
Bacitracin	1,422	.....	15	21
Salmine	2000–8000	.....	40	150
Subtilin	3,300	.....	54	138
Insulin	5,733	1.5 hr.	..	Will not pass
Cytochrome C	12,000	.....	60	
Ribonuclease	13,600	3.5 hr.	2 hr.	
Lysozyme	14,000	3.5 hr.	2.3 hr.	
Trypsin	20,000	.....	4 hr.	
Trypsinogen	20,000	.....	6.5 hr.	
Chymotrypsin	24,500	.....	5 hr.	
Chymotrypsinogen	25,000	12 hr.	9 hr.	
Pit. lact. hormone	26,000	.....	13 hr.	
Gliadin	27,000	.....	29 hr.	
Ovomucoid	28,000	.....	35 hr.	
Pepsin	35,500	.....	80 hr.	
Ovalbumin	45,000	.....	More slowly than pepsin	

About half the solutes listed in Table I showed more or less of a tendency to deviate from straight line behavior—an indication of impurity, association or unexplained membrane effect of some kind. In these cases analysis of the escape rate by several different analytical methods as discussed below did not clearly reveal size inhomogeneity for the ones listed. However, the results from a number of preparations studied were thrown out on this basis and not listed.

In spite of the deviation it is worth comparing the 50% escape times with the latest accepted molecular weight values somewhat arbitrarily selected from the more recent literature. The values for most of the molecular weights of the proteins appear to be subject to a certain amount of revision (except for insulin and ribonuclease) and should not be considered as too exact. Certainly the 50% escape times should not be interpreted too strictly at this time. In spite of such uncertainties the correlation between molecular weight and escape rate is very striking. Only cytochrome C (granting its molecular weight range to be correct) would appear to be appreciably out of line. It is a strongly basic protein with a high isoelectric point (10.65) and contains many lysine residues. Earlier work[2] had indicated that strongly basic peptides with a high proportion of basic amino acids such as the polymyxins would show a higher escape rate in acetic acid solution than would otherwise be expected from their molecular size. The result given here could indicate that cytochrome C is a more tightly coiled molecule than has been suspected and thus of smaller molecular size than its molecular weight would indicate.

The proteins in Table I include ones with widely differing isoelectric points ranging from pepsin to lysozyme and cytochrome C. Yet they fall in the proper order according to size which indicates that charge does not play a very significant role in determining escape rate under the conditions chosen. It seems justifiable to conclude that molecular size is by far the most important factor in determining escape rate in a given cell, solution and membrane.

Tryptophan is one sixth the size of bacitracin but its 50% escape time approximates one fourth that of the latter. Ribonuclease is a little larger than one half the size of chymotrypsinogen yet its 50% escape time is also of the order of one fourth that of chymotrypsinogen.[7] The selectivity of the membrane obviously increases as the molecular size approaches the limit passed by the membrane. This is confirmed by comparison of the escape rates of bacitracin and subtilin in the 20/32 and 18/32 membranes.

It would now appear on the basis of these data, those in the previous paper, and other data still being accumulated in this Laboratory, that the relative molecular size of solutes up to molecular weights of 45,000 probably can be approximated by very simple, controlled dialysis experiments with considerable reliability. The reliability of the size derived for an unknown would of course depend on the assumption that the substance is reasonably globular in shape as are all proteins thus far studied. The deviation from spherical shape of the proteins listed in Table I as indicated by their published frictional ratios[8] is not sufficient to upset the relationship of molecular weight to 50% escape time.

Although considerable caution should be taken in interpreting the meaning of an escape rate until wider experience has been gained, there would appear to be no difficulty as far as the duplication of an experiment is concerned. The escape rates given in Table I for several of the proteins were checked by different workers at different times on more than one preparation and with membranes

(7) The value reported in (6) for chymotrypsinogen is a misprint.

prepared from rolls of cellophane purchased at different times. Apparently, within a given size the membrane is a remarkably uniform product as far as this type of test is concerned. The 50% escape times for check runs at different times have agreed to well within 10%.

It is of interest that trypsin gives a considerably smaller 50% escape time than trypsinogen. Although not shown to be significantly smaller by direct molecular weight determination heretofore, it is known that the activation of trypsinogen to trypsin involves a type of proteolytic splitting,[9] with loss of at least a hexapeptide.

Similarly chymotrypsin gives a significantly shorter 50% escape time than chymotrypsinogen. Again the former is formed from the latter by proteolysis[9,10] with loss of a peptide moiety.

In both pairs the enzyme is formed from the zymogen by loss of probably something less than 10% of its original weight. The difference in escape rate noted must therefore arise from a significant change in shape. That the transition from zymogen to active enzyme does involve a change in shape has been indicated strongly by the studies of Neurath, Rupley and Dreyer.[11] They found that the changes in optical rotation and viscosity produced by reversible urea denaturation were such as to indicate the active enzyme to be more tightly coiled or folded than the zymogen but capable of being unfolded to the same degree by urea.

Further information on the changes involved in the activation of trypsinogen and chymotrypsinogen is given by Neurath and Dreyer[12] who consider the molecular weights to be 23,800 and 23,000, respectively.

The foregoing and Table I have been presented to enable some rough over-all correlations to be drawn. Obviously, it is of equal importance to consider the finer details of the individual behavior of each substance or preparation.

For instance, a commercial protamine sample did not give a straight line. Its escape curve was characterized by two distinct breaks in the curve as shown in Fig. 3, curve 1. Since it has already been shown[6] by a curve of the escape rate of an artificial mixture of aspartic acid and bacitracin that a rather sharply breaking curve will be given by a mixture of two solutes provided their individual escape rates are sufficiently different, it is only natural to deduce from curve 1 that this sample of protamine is a mixture with at least three or more different molecular sizes present.

Further experience with the method, however, showed that such a conclusion could not be drawn unless the diffusion behavior of each pure solute with the same membrane under identical conditions was known already. Indeed, a few pure solutes have been found not to give a straight line with the 20/32 membrane. Thus tyrosine repeatedly gave a curve indicating two components. Histidine and threonine similarly did not give a straight line. Obviously a greater tendency to deviate from ideality is to be expected with these solutes, perhaps, due to some form of association between like molecules or with the membrane surface. These are the amino acids with substituents which would most likely permit some form of hydrogen bonding.

If a reversible association complex of dimers, trimers, etc., were formed, dilution would favor the monomeric form and it would be expected that the rate of escape would increase with dilution. This should lead to a deviation from a straight line as shown in the hypothetical case of the curve of Fig. 4. However, a striking deviation of this type has thus far not been observed and it seems most likely that the type noted in actual practice with the small solutes could be caused by a membrane effect of some sort. That it was not a concentration effect was established by beginning the dialysis with different amounts of solute. There is the unlikely possibility that those solutes with strong associating tendencies form dimers which pass through the membrane more rapidly than their monomers due to a different degree of adsorption on the membrane surface.

A further suggestion that the deviation stems from a particular membrane was obtained from the finding that the amino acids mentioned above gave a straight line when Visking 18/32 seamless cellulose tubing was substituted for the 20/32 membrane. The former gives a slower rate of escape and in fact will not permit any of the proteins thus far studied including insulin to pass in appreciable amount. It could be that the time interval was too short in this experimental set up for the small solutes to behave ideally in the 20/32 membrane.

Irrespective of the basic cause of such deviations it is not difficult to differentiate a divergence due to this phenomenon from that due to the presence of a mixture of molecular sizes. Thus the solute which has passed through until the time of the first break can be recovered and run again. If the original comprised a mixture of sizes, the escape rate of the re-run would then more nearly approximate a straight line, or at least show a faster escape rate than the original. Such a re-run of the first 20% of the sample of protamine gave curve 3 in Fig. 3.

In evaluating whether or not a mixture of sizes is present in a preparation it is helpful to analyze the different portions of the dialyzate with several analytical techniques. These could include weight analysis,[13] optical density, ninhydrin,[14] Folin–Ciocalteau,[15] acid or alkali titration, biological assay, etc.

If a single molecular size is present in the sample, the same curve will be obtained regardless of the analytical method used for determination of the escape curve. When it is possible to use direct weight analysis[13] this is the most reliable from the

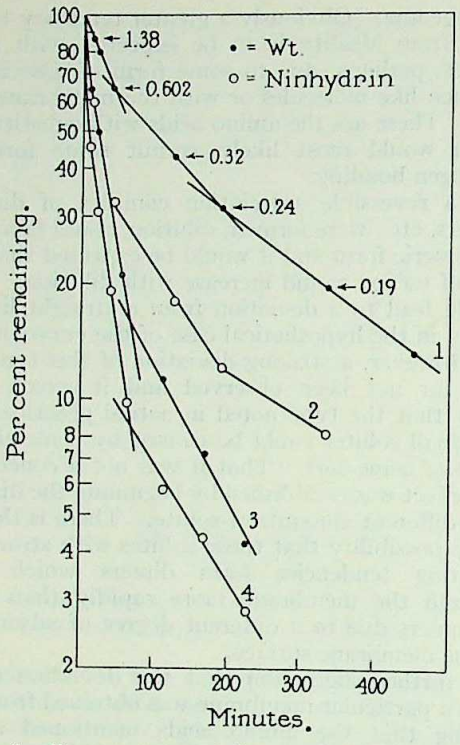

Fig. 3.—Escape curves of "protamine" through 18/32 cellophane in 0.01 *N* acetic acid: 1, weight curve of original; 2, ninhydrin curve of original; 3, weight curve of re-run; 4, ninhydrin curve of re-run.

standpoint of interpretation since it gives the per cent. escape rate based on total solute. The contrast of this with that based on one of the other selective methods then may be very enlightening as can be seen from curves 2 and 4 of Fig. 3 which are based on ninhydrin. As would be expected, the weight curve and ninhydrin curve more nearly agree on the re-run. Since the total solids in each dialyzate fraction is known, the change of ninhydrin color yield per mg. along the curve can be determined. The numbers given above curve 1 of Fig. 3 refer to leucine microequivalents of ninhydrin per mg. for the corresponding dialyzate. It is evident from these data that there is a steady partial resolution of molecular size since the smaller molecular sizes would be expected to give higher ninhydrin values per mg. of solute. It is also evident that further fractionation will be required.

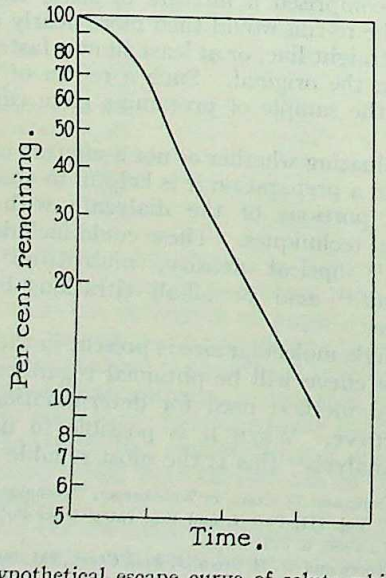

Fig. 4.—Hypothetical escape curve of solute which shows association–dissociation.

Figure 5 gives the comparative weight curves for the protamine mixture in the 20/32 and 18/32 membrane. The latter gives a much more distinct break in the curve indicating greater selectivity. It also shows a second break not revealed by the first. This again confirms the deduction from Table I that the selectivity becomes greater as the solutes approach the limit of size which will pass through the membrane.

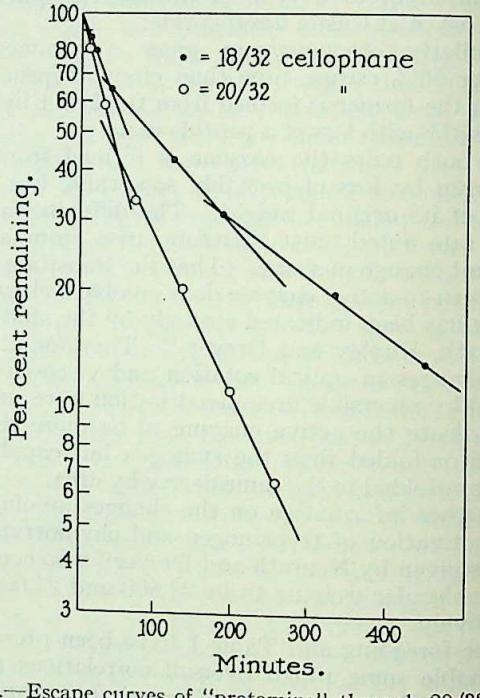

Fig. 5.—Escape curves of "protamine" through 20/32 and 18/32 cellophane in 0.01 *N* acetic acid.

The results in the case of insulin are interesting since more is known about the properties and structure of it than for any other protein. It is an unusually stable protein. These considerations make it a good model for basic studies.

A sample of beef insulin purified by extensive fractionation by countercurrent distribution[16] gave the lower curve in Fig. 6. The experiment was made with 12 mg. of insulin in 0.1 *N* acetic acid. Straight line adherence was observed until 85% of the solute had passed through the membrane. It should be pointed out that a result of this type is on a logarithm scale which has the effect of magnifying the relative importance of the last part of the solute to escape. Actually almost 99% of the insulin had passed through the membrane by 21 hours time.

This result contrasted sharply to that shown in the upper curve of Fig. 6, which was obtained with

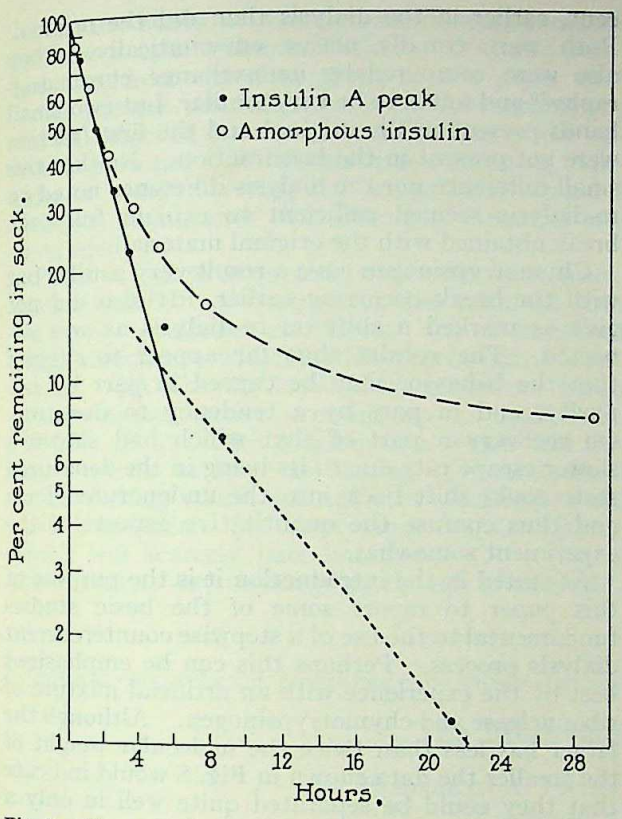

Fig. 6.—Escape curves of insulin through 20/32 cellophane in 0.1 *N* acetic acid.

an amorphous commercial sample. The latter was known by countercurrent distribution to be of the order of 70% pure.

Insulin is known to associate in the neutral *p*H range to a size with six or more sub-molecules in a particle. It also can form fibrils at acid *p*H ranges.[17] This tendency suggests that the deviation noted even in the lower curve could be due to associated molecules which do not return rapidly to the monomeric form.

Irrespective of the truth of this speculation it was found experimentally that a sample of insulin brought into solution in water with a minimum of dilute ammonia would not pass through the 20/32 membrane in appreciable amount after several hours in the standard cell when distilled water was used outside the membrane. During this time the original *p*H of the insulin solution had dropped from about 8 to 6. Ribonuclease (mol. wt. 13,600) readily passed under these same conditions.

In the first paper[2] of this series it was noted that the solvent had considerable influence on the rate of passage of smaller molecules through cellophane. Distilled water nearly always permitted the fastest rate. This appears to be even more true for the larger protein type molecules. All salt solutions thus far studied irrespective of the salt used have had a definite retarding effect as compared to distilled water when they were present in ionic strength greater than 0.01. The effect increased with increasing salt concentration to a certain salt concentration above which there was little effect.

(17) D. F. Waugh, in "Internal Secretions of the Pancreas," Ciba Foundation Symposia, Vol. IX, Little, Brown & Co., Boston, Mass., 1956, p. 122.

The *p*H also was found to have an effect but somewhat complicated by interrelationship with the salt effect. The data in Table I show that with several proteins studied 0.01 *N* acetic acid permitted a faster escape rate than 0.1 *N* acetic acid. The former permitted a rate not significantly different from distilled water.

With the larger molecules part of the experimental work has involved a search for conditions which would permit the most rapid dialysis without loss of selectivity. The use of distilled water or 0.01 *N* acetic acid as a solvent and with the 20/32 membrane has been uniformly the best thus far found. Fortunately, these conditions also have been those providing the nearest adherence to straight line escape rates. A straight line adherence until approximately 84% of the ribonuclease had escaped was noted, Fig. 7, if no salt was present in the solvent. Even somewhat better adherence was found when the solvent was distilled water alone. Here, although the main part of the curve coincided with that noted with 0.01 *N* acetic acid, a break in the curve was not observed until 93% of the solute had passed the membrane as shown by the dashed curve.

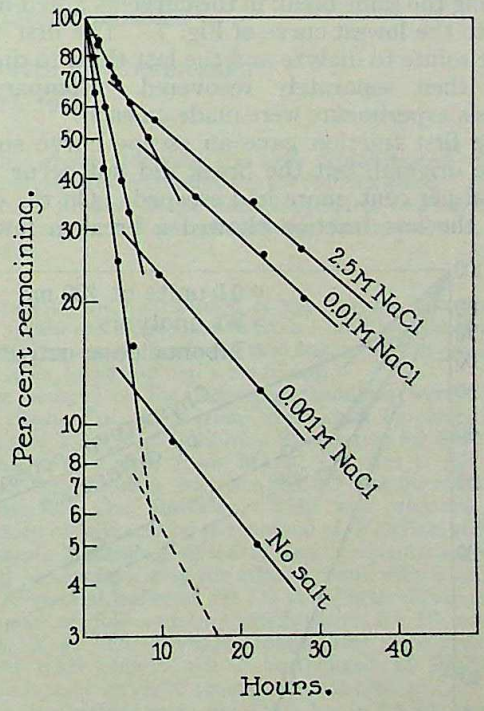

Fig. 7.—Escape curves of ribonuclease through 20/32 cellophane in 0.01 *N* acetic acid at various salt concentrations and in distilled water- - -.

The effect of various concentrations of sodium chloride in the 0.01 *N* acetic acid can be seen from Fig. 7. The salt effect is more pronounced up to 0.01 molar after which there is less increase in effect.

When the effect of *p*H was studied a marked influence other than that due to the salt effect of the buffer was not noted until a rather high *p*H was reached. The escape rate for 0.01 *N* ammonia was much less than for 0.01 *N* acetic acid.

The effect of urea also was studied. With insulin in 0.01 *N* acetic acid and six molar with re-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

spect to urea, the 50% escape time was increased from 1.5 to 5 hr. Straight line adherence was noted until about 70% of the solute had escaped but the remainder appeared to dialyze very slowly.

Similarly ribonuclease dialyzed very slowly through the 20/32 membrane in 6 molar urea, 0.01 *N* acetic acid. Here straight line behavior was not found, perhaps an indication of progressive denaturation or transformation of some sort.

Since conditions favoring denaturation appeared always to result in a much slower escape rate, it seemed likely that the deviations from straight line behavior even in 0.01 *N* acetic acid might be due to a tendency toward denaturation. However, before this could be considered the question of size inhomogeneity in the samples used should be considered.

With ribonuclease this question was studied in the following way. A standard run was made, but the escape rate was determined by weight determination, ninhydrin, optical density and quantitative enzymatic activity.[18] With the latter a reproducibility of the values of ±10% was found in several experiments. All of these gave a curve superimposable within the experimental error, but showing the same break in the curve as noted in the next to the lowest curve of Fig. 7. The first third of the solute to dialyze and the last third to dialyze were then separately recovered. Comparative dialysis experiments were made on each.

The first fraction gave an escape curve similar to the original, but the break did not occur until several per cent. more had escaped. On the other hand the last fraction showed a break a few per cent. earlier in the dialysis than did the original. Both were equally active enzymatically. They also were compared by ion-exchange chromatography[19] and found to be very similar, but two small bands present in the original and the first fraction were not present in the last fraction. Neither this small difference nor the dialysis difference noted on re-dialysis seemed sufficient to explain fully the break obtained with the original material.

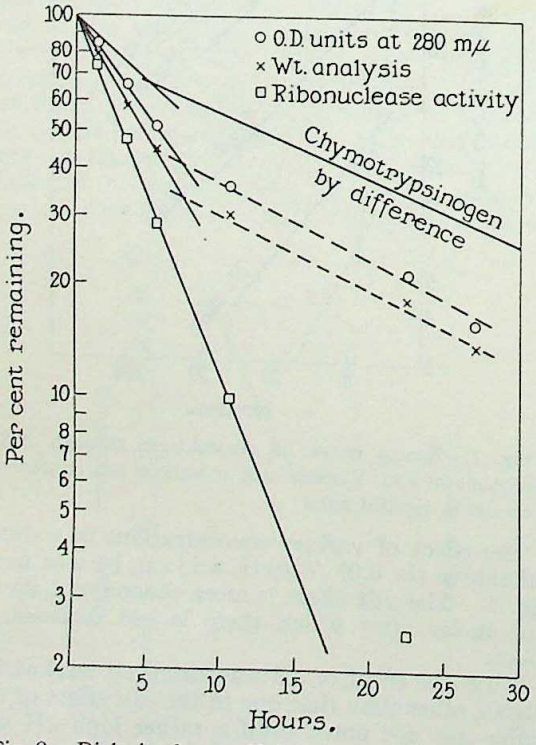

Fig. 8.—Dialysis of an artificial mixture of equal parts of ribonuclease and chymotrypsinogen through 20/32 cellophane in 0.01 *N* acetic acid.

Chymotrypsinogen gave a result very similar but with the break occurring earlier. It also did not give as marked a shift on re-dialysis as was expected. The results thus far appear to suggest that the behavior may be caused in part by impurity, and in part by a tendency to denature. On recovery a part of that which had shown a slower escape rate due to its being in the denatured state could shift back into the undenatured form and thus confuse the quantitative aspects of the experiment somewhat.

As stated in the introduction it is the purpose of this paper to report some of the basic studies fundamental to the use of a stepwise countercurrent dialysis process. Perhaps this can be emphasized best by the experience with an artificial mixture of ribonuclease and chymotrypsinogen. Although the larger has less than twice the molecular weight of the smaller the data shown in Fig. 8 would indicate that they could be separated quite well in only a few dialysis stages.[2] It so happens that these proteins are separated easily by other methods and Fig. 8 is of value only for an example.

Our studies thus far have shown that selectivity can be improved by choice of a membrane which will pass the solutes of interest only slowly under favorable conditions. For certain mixtures the selectivity can be improved by doubling the membrane.[6] It can be varied by choice of the solvent[2] and by substitution of the solutes, for instance, as by preparation of DNP derivatives of amino acids or peptides.[2]

A given roll of cellophane can be made considerably more porous by placing it under hydrostatic pressure. Thus 20/32 Visking will withstand a hydrostatic pressure of 200 mm. of Hg, but will stretch from a diameter of 15 to 24 mm. After release of the pressure the diameter will return to 21 mm. A cell made from this membrane will now pass larger proteins than the unstretched membrane. A brief treatment with sodium hydroxide also makes the membrane more porous.[4]

On the other hand acetylation of the membrane appears to make it less porous. A preliminary experiment with the 20/32 membrane has given a membrane which would not pass subtilin, but would permit bacitracin to pass slowly (50% escape time = 2.8 hr.). It readily passed tryptophan (50% escape time = 11 min.). Acetylation of 18/32 Visking gave an even less porous membrane which would scarcely permit bacitracin to pass although it gave a 50% escape time of 15 minutes for tryptophan. These findings with modified membranes are again in line with the thesis that size is the primary factor governing an escape rate for a given membrane and solution.

A closer study of modified membranes must be left for a later communication. It is apparent, however, from the data given in this paper that much greater over-all selectivity for separations can be achieved by use of a membrane of the optimum pore size. When mixtures containing molecules of widely differing size are to be separated a series of membranes with different porosities will be needed.

From our data at present with cellophane membranes and 0.01 *N* acetic acid five standard sizes are easily available as follows. (1) A stretched 20/32 membrane which readily passes native ovalbumin. (2) The 20/32 Visking cellophane which readily passes native proteins up to ovalbumin. (3) The 18/32 Visking cellophane which will not pass proteins as large as insulin. (4) Acetylated 20/32 Visking which will not pass subtilin but will pass bacitracin. (5) Acetylated 18/32 Visking which will scarcely pass bacitracin. A study of the optimum way to integrate the use of these different sizes with the countercurrent approach is in progress.

The porosity of the membrane does not correlate with the thickness as can be seen from the data in Table II, which gives five sizes of cellophane studied with insulin. The thickness given is that found with a micrometer on the dry membrane before use.

TABLE II

COMPARISON OF THICKNESS, SIZE AND POROSITY OF SEVERAL SIZES OF VISKING TUBING

Size	Thickness, mm.	Result with insulin
8/32	0.064	Slowly passes
18/32	.0175	Does not pass
20/32	.020	Rapidly passes
23/32	.0275	Does not pass
27/32	.025	Passes less rapidly than with 20/32

The Methylation of Deoxyuridine[1]

BY ELIZABETH A. PHEAR AND DAVID M. GREENBERG

RECEIVED JANUARY 15, 1957

The methylation of deoxyuridine, with formaldehyde as the methyl group precursor, has been demonstrated with cell-free preparations from various tissues. The most active of the extensively studied tissues was the thymus gland. Employing a Dowex-1-Cl^--treated, dialyzed rat thymus preparation, the primary product of the reaction appeared to be thymidylic acid, which was then partially converted to thymidine. Tetrahydrofolic acid, reduced phosphopyridine nucleotide, adenosine triphosphate and Mg^{++} were required as cofactors for the reaction.

Friedkin and Roberts[2] showed that deoxyuridine (UDR)[3] was incorporated into DNA-thymine and free TDR by suspensions of chick embryo and by rabbit and chick bone marrow. They concluded that the TDR was formed by a folic acid-dependent methylation. Reichard[4] also showed that deoxyuridine was incorporated into DNA-thymine. The observations of Friedkin and Wood[5] suggested that CDR also may be incorporated into DNA-thymine by the same or a similar reaction.

This paper describes studies of the methylation of UDR with $H_2C^{14}O$ in a cell-free preparation of rat thymus gland, and a survey of the distribution of this enzyme system in various other tissues.

Experimental

Materials.—Thymus glands from 1 month old Long-Evans rats were used for most of the work. In the determination of the distribution of the enzyme in various tissues, spleen and bone marrow from 1 month old rabbits, and marrow from pork, lamb and veal bones,[6] and thymus glands from steer, lamb and pig[7] were tested.

The sources of the following chemicals were: DPNH from Sigma Co., ATP from Nutritional Biochemical Co., UDR and TDR from California Foundation for Biochemical Research, folic acid from Mann, CF was a gift of the Lederle Laboratories, and the $H_2C^{14}O$ was purchased from the Bio-Rad Co., Berkeley. THF was prepared by the reduction of folic acid by the method of O'Dell, *et al.*[8]

Enzyme Methods.—Cell-free tissue preparations were obtained by homogenizing the minced tissue with 9 volumes of 0.05 *M* veronal buffer at *p*H 7.6 in a Potter–Elvehjem glass homogenizer, followed by centrifugation for 10 minutes at 20,000 × *g*. The thymus preparations were then batch-treated with Dowex-1-Cl^-,[9] centrifuged at 59,000 × *g*, and dialyzed overnight against veronal buffer.

The incubations were run for 2 hr. in 25-ml. beakers at 37° under nitrogen in a Dubnoff shaking metabolic incubator. Each vessel contained 2 ml. of enzyme (5–20 mg. protein) and substrates and cofactors at the following levels: $H_2C^{14}O$, 5 μmoles (98,400 c.p.m. per μmole); UDR, 10 μmoles; carrier TDR, 1.2 μmoles; ATP, 10 μmoles; DPNH, 2 μmoles; $MgSO_4$, 10 μmoles; THF 500 μg. The total volume was 2.7 ml. and when any of the above constituents was omitted the volume was made up with buffer; 0.05 *M* veronal buffer at *p*H 7.6 was used throughout unless otherwise indicated. Carrier thymidylic acid was added after incubation, since it inhibited the reaction, but the addition

of carrier TDR before incubation had no effect on the reaction, and counteracted breakdown of TDR.[10] The incubations were run in pairs, with UDR added to one member of the pair only. The TDR, TA and TCC formed from the UDR were deduced from the difference in activity of these compounds isolated from the two incubations.

The reaction was stopped by adding TCA to give a final concentration of 10%. The precipitate was washed with 5% TCA, and the supernatant and washings combined.

Analytical Methods. Total Thymine-containing Compounds (TTC).[11]—These were estimated in the incubation extract after removal of the TCA with ether. The liquid was dried and hydrolyzed for 15 min. with 0.2 ml. of 12% perchloric acid, and the latter removed with KCl. To eliminate amino acids and salts, the preparation was adjusted to *p*H 2.3 and eluted from a Dowex-50-H^+ column with water at *p*H 3. The eluate was neutralized with NH_4OH, dried and chromatographed on Whatman No. 1 paper with butanol–water (86:14) as solvent. After 18 hr. of diffusion, the thymine spots were located by ultraviolet light. These, together with paper blanks, were cut out, weighed and eluted with warm water at *p*H 3. The concentration and purity of the samples was estimated photometrically, by use of their absorption densities at 250, 260 and 280 mμ in acid solution.

Thymidine (TDR) was measured in the presence of 1.2 μmoles of carrier. Samples of the dried, TCA-free acid-soluble residues after incubation were streaked onto Whatman No. 1 paper and chromatographed for 18 hr. in butanol–water (86:14). The thymidine spots were eluted, dried and rechromatographed for 5 hr. in 0.1 *M* borate buffer at *p*H 9.3. The spots (located with ultraviolet light) together with paper blanks were cut out, weighed, and the concentration of thymidine estimated from its absorption density at 260 mμ.

"Thymidylic Acid" (TA).—The majority of counts were present in a substance which behaved similarly to, and moved together with thymidylic acid on chromatography in isopropyl alcohol–HCl (isopropyl alcohol 17 ml., concentrated HCl 41 ml., water 39 ml.), isobutyric acid–NH_3 (10 vol. isobutyric acid, 6 vol. 0.5 *N* NH_4OH), 0.1 *M* borate at *p*H 9.3, and butanol–water. However it was not possible to isolate and characterize this compound as thymidylic acid. It was estimated by chromatography in butanol–water in the presence of 5.6 μmoles of carrier thymidylic acid. The immobile area in this solvent was eluted, and rechromatographed in isopropyl alcohol–HCl. The TA spot was eluted, hydrolyzed, passed through a Dowex-50-H^+ column, eluted with water at *p*H 3, chromatographed on Whatman No. 1 paper in butanol–water, and estimated spectrophotometrically as thymine. The sum of the activity of *Thymidine and "Thymidylic acid"* (Table I) was obtained after chromatography of the TCA-free residue from incubations in isopropyl alcohol–HCl in the presence of carriers. The spot which contained both these compounds was eluted, hydrolyzed and estimated, after chromatography on Dowex-50-H^+, and on paper in butanol–water, as thymine. Radioactivity was measured in duplicate, on infinitely thin samples dried on polythene planchets, to 5% accuracy with a gas flow counter. $H_2C^{14}O$ activity was estimated after its conversion to the dimedon derivative.[12] Protein was estimated with the biuret reagent.[13]

It was shown that TTC formation was proportional to the protein concentration over the range 3–20 mg. protein per incubation, so results have been expressed as μmoles of TTC, TA and TDR formed per mg. protein.

The activity of the TTC formed in the absence of added UDR in Dowex-treated samples varied from 0–8% of that formed in its presence. Results using the paired incubation method for TTC estimation agree to within 10% of those obtained using 2-C^{14}-uridine prepared by the method of Friedkin and Roberts.[2]

Table I shows that of the total activity in TTC, most was present in the TA fraction, with about 10% in the TDR. As the work was concerned primarily with the methylation of UDR, TTC only was usually measured.

Results

A test for the incorporation of UDR and $H_2C^{14}O$ into the purine and pyrimidine bases of DNA and RNA was performed following an incubation by isolating the nucleic acids according to the method of Schmidt and Thannhauser.[14] After hydrolysis free bases were isolated by the method of Cohn.[15] In confirmation of the results of Friedkin and Wood,[5] only DNA-thymine contained significant activity. TTC was more active than the DNA-thymine, so further studies were confined to this fraction.

Substrate Specificity.—UDR was found to be a better substrate than CDR or deoxycytidylic acid for TTC formation, and thus was used throughout the work. In one experiment in which 10 μmoles of these bases were compared as substrates, a thymus preparation, formed 22.2×10^{-4} μmole of TTC per mg. protein from UDR and only 2.2×10^{-4} and 3.2×10^{-4} μmole from CDR and cytidylic acid, respectively.

TABLE I

DISTRIBUTION OF RADIOACTIVITY BETWEEN TTC, TA AND TDR

Thymine activity estimated as	μmoles formed per mg. protein $\times 10^4$
TTC	19.5
TDR	1.7
TA	16.8
TA and TDR	20.1

Occurrence of the Enzyme System.—Table II shows that cell-free preparations of spleen were more active enzymatically than bone marrow preparations from various sources. The comparative activity of other tissues was investigated in the rat, and the results are shown in Table III. An immature rat (100 g. wt.) was used in this experiment, since the tissues of young animals were found to be more active than those of older animals.

TABLE II

DISTRIBUTION OF METHYLATING ENZYME SYSTEM IN VARIOUS SPLEEN AND MARROW PREPARATIONS

Differences from standard incubation medium: 0.77 μmole $H_2C^{14}O$ per incubation, and 0.15 *M* KCl–$KHCO_3$ buffer, *p*H 7.4.

Preparations homogenized and centrifuged in 0.25 *M* sucrose exhibited less enzymic activity than those prepared in 0.05 *M* veronal buffer at *p*H 7.4. Acetone powders, and preparations frozen either before or after dialysis were completely inactive.

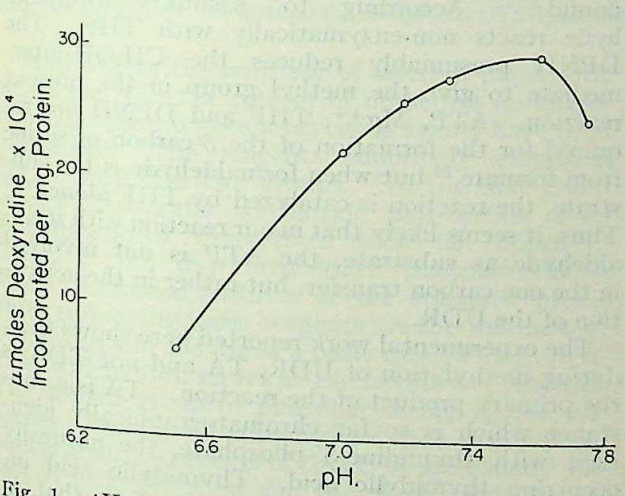

Fig. 1.—*p*H–activity curve for formation of acid-soluble thymine derivatives from deoxyuridine.

Attempts at fractionation of the enzyme system with $(NH_4)_2SO_4$ in 0.05 *M* veronal buffer at *p*H 7.4 were unsuccessful. If nucleic acids were first removed with protamine sulfate or $MnCl_2$,[16] and the $(NH_4)_2SO_4$ fractionation performed in 0.15 *M* KCl–$KHCO_3$ at *p*H 7.4, most of the enzyme activity was precipitated between 33 and 50% saturation. However, both the protamine sulfate and the $MnCl_2$ caused loss of activity. Moreover, recombination of the fraction containing most of the activity with that not precipitated at 60% $(NH_4)_2SO_4$ saturation, which alone had no activity, led to enhanced activity.

Dowex-1-Cl^- treatment and overnight dialysis caused no loss of activity, decreased the radioactivity of the TTC in the control vessel and facilitated the study of cofactor requirements. This is the only purification so far achieved with the enzyme system.

Cell-free preparations of rabbit bone marrow were more active in 0.05 *M* veronal than in 0.15 or 0.05 *M* tris-(hydroxymethyl)-aminomethane, glycylglycine or KCl–$KHCO_3$ buffers at *p*H 7.4. No enzyme activity was obtained in phosphate buffer. In veronal buffer the *p*H optimum was 7.4–7.7 (Fig. 1).

Conversion of Thymidylic Acid to Thymidine.—1.2 μmoles of TDR was added to a series of incubations of rat thymus preparation, containing 20 mg. protein per incubation. In these, the initial thymidylic acid carrier content varied from 0–5.6 μmole. The remainder, to give a total of 5.6 μmoles in each vessel, was added at the end of the experiment. Recovery of carrier thymidylic acid decreased serially from 2.9 μmoles in the incubation to which thymidylic acid had all been added after incubation, to 2.3 μmoles in the sample to which it had all been added initially. The TDR recovery varied inversely from 0.7–1.5 μmoles. This experiment shows qualitatively, since recoveries were low, that the TDR increases, and the thymidylic acid decreases in concentration during incubation. Some of the thymidylic acid may have been converted into acid-insoluble compounds, but some must have given rise to TDR. From the results obtained from studies of the relative activities of TA and TDR (*cf.* Table I and V), it seems that about 10% of the TA is converted to TDR during incubation under the present conditions in rat thymus preparations.

Cofactor Requirements.—The results obtained in a study of TA and TDR formation by a Dowex-1-treated, dialyzed rat thymus preparation are shown in Table V. Essentially similar results were obtained for TTC formation by rat thymus, rat spleen and rabbit bone marrow preparations. Table V shows that ATP, DPNH, THF and Mg^{++} are required for the formation of the methyl group of thymine compounds from UDR and formaldehyde.

THF was more effective than CF as the cofactor in this reaction, and other experiments (not given in the table) showed that folic acid at levels of 500 or 250 μg. was without effect.

In this table the need for DPNH in the presence of 500 μg. of THF was not clearly demonstrated. Paper chromatography of samples to which DPNH had not been added revealed the presence of DPN, which had presumably remained attached to the protein in the preparation. THF reduces DPN,[17] and the residual DPN is probably present in its oxidized form at the end of the manipulations prior to incubation. If the amount of THF is reduced to 166 μg., Table V shows that added DPNH definitely stimulated the reaction. Presumably at the higher level, the THF acts both as a reducing agent for the residual DPN in the preparation, and as cofactor, while at the lower level it functions mainly as a co-factor.

The requirement for DPNH also was shown in an experiment in which 6 ml. of rat thymus prepa-

ration was passed through a 6 × 1 cm. Dowex-1-Cl^- column at *p*H 7.2 before centrifugation, dialysis and incubation. 15.0 and 21.1 × 10^{-4} μmoles of TTC were then formed in the absence and presence of added DPNH, respectively, when 500 μg. of THF (which gave a maximum yield of TTC) was added. Presumably the column had been more effective in removing DPN than the usual batch treatment. Another possible explanation for the small effect of added DPNH could be that formaldehyde itself might reduce the THF-formaldehyde complex, and in so doing yield an equimolar quantity of HCOOH. To test this possibility, HCOOH was estimated by the method of Sakami.[18] It was found that it was formed in amounts comparable to the TTC, but that its formation was not dependent on the presence of UDR, so that it must have been produced by an independent reaction. Table V does not show clearly a requirement for DPN or TPNH, and shows that TPN is inhibitory. Table VI gives results of an experiment in which only TTC was measured. ATP, Mg and THF were present in all incubation flasks. This experiment shows that DPN is less effective than DPNH as a cofactor. TPN alone or in the presence of DPN was inhibitory. Addition of TPNH increased the yield of TTC only slightly. The requirement for TPNH has not been demonstrated clearly in any experiment, but experiments such as those described above do demonstrate clearly the need for DPNH has not been met with TPNH. Possibly, therefore, this is not a TPNH linked reaction, or possibly residual DPN in the preparation masks the effect of this added cofactor. Thus from the data a requirement for TPNH has not been demonstrated, but reduction can occur by a DPNH linked reaction.

TABLE V

COFACTOR REQUIREMENTS FOR METHYLATING ENZYME SYSTEM

Cofactors were added at the following levels: ATP, 10 μmoles; $MgSO_4$, 10 μmoles; DPNH, 2 μmoles; DPNH,[a] 0.67 μmole; TPNH, TPN and DPN, 0.67 μmole; CF, 500 μg.; THF 500 μg.; THF,[b] 166 μg., 1 μmole carrier thymidylic acid added initially and 4.6 μmoles after incubation.

Cofactors added	μmoles TA formed per mg. protein × 10^4	μmoles TDR formed per mg. protein × 10^6
Mg	0.0	0.0
Mg and DPNH	.1	.3
Mg and ATP	.0	.8
Mg and THF	.1	.0
Mg, THF and DPNH	.4	.8
Mg, THF and ATP	27.0	24.2
Mg, THF, ATP and DPNH	31.7	29.9
THF, ATP and DPNH	12.8	10.7
Mg, ATP and THF[b]	11.4	8.2
Mg, ATP, THF[b] and DPNH	21.5	21.6
Mg, ATP, THF and DPNH[a]	24.0	22.6
Mg, ATP, THF and DPN	21.5	20.7
Mg, ATP, THF, and TPNH	18.4	21.8
Mg, ATP, THF and TPN	0.8	0.7
Mg, ATP, DPNH and CF	3.9	17.6

Discussion

From the experimental work reported here it is concluded that the methylation of UDR with formaldehyde is dependent on the presence of THF, ATP, Mg^{++} and DPNH. These same cofactors serve in the biosynthesis of the methyl group of methionine in a system containing formaldehyde and homocysteine.[19]

TABLE VI

EFFECT OF PYRIDINE NUCLEOTIDES ON THE METHYLATING ENZYME SYSTEM

Pyridine nucleotide added 0.28 μmole	μmoles TTC formed per mg. protein 10^4
...	48.3
DPNH	75.2
TPNH	54.5
DPN	62.6
TPN	11.6
DPN and TPN	15.8

THF has been shown to be the most effective folic acid derivative in the transfer of one carbon units to form the β-carbon of serine.[20,21] It is evidently more closely related to the active cofactor than either CF[21,22] or folic acid.[19]

It has been proposed that "active formaldehyde" is N_{10}-CH_2OH·THF or a closely related compound.[22,23] According to Kisliuk[24] formaldehyde reacts non-enzymatically with THF. The DPNH presumably reduces the CH_2OH-intermediate to give the methyl group in the present reaction. ATP, Mg^{++}, THF and DPNH are required for the formation of the β-carbon of serine from formate,[22] but when formaldehyde is the substrate, the reaction is catalyzed by THF alone.[21,22] Thus, it seems likely that in our reaction with formaldehyde as substrate, the ATP is not involved in the one carbon transfer, but rather in the activation of the UDR.

The experimental work reported here shows that, during methylation of UDR, TA and not TDR is the primary product of the reaction. TA is a substance which is so far chromatographically identical with thymidine-5′-phosphate, the naturally occurring thymidylic acid. Thymidylic acid inhibits methylation of UDR, suggesting that it may be involved in the reaction, and in our system both TA (chromatographic material) and thymidylic acid are partially converted to TDR. Thus it seems probable that, since ATP is necessary for the reaction, a phosphorylated derivative and not UDR itself is the natural substrate for the reaction. In support of this, Friedkin and Kornberg[25]

have found that deoxyuridylic acid is converted to thymine nucleotides by bacteria. It has been suggested recently[27] and partially supported by experimental evidence[26] that the methylation of pyrimidine derivatives may involve first an aldol condensation of the CH_2OH-THF compound with the pyrimidine derivative and then formation of the 5-CH_2OH-dihydro-pyrimidine compound. This is followed by removal of water, yielding the methylene derivative, and finally there is a shift of the double bond. These steps also could possibly involve ATP.

ADDENDUM:—Friedkin and Kornberg[25] and Friedkin[28] have shown that deoxyuridine-5′-phosphate is the substrate for methylation. They postulate a direct condensation of $HOCH_2$·THF with the deoxyuridylic acid, with the splitting out of water, and subsequent cleavage to yield the methyl group. Presumably this would lead to an oxidation of THF to dihydrofolic acid. The function of the reduced phosphopyridine nucleotide might then be to reconvert the latter to THF.

Carbodiimides. VII.[1] Tetra-*p*-nitrophenyl Pyrophosphate, a New Phosphorylating Agent

BY J. G. MOFFATT AND H. G. KHORANA

RECEIVED JANUARY 12, 1957

Tetra-*p*-nitrophenyl pyrophosphate, prepared *in situ* by the reaction of di-*p*-nitrophenyl hydrogen phosphate with di-*p*-tolyl carbodiimide in anhydrous dioxane, has been found to phosphorylate alcohols at room temperature without basic catalysis and, therefore, constitutes a powerful phosphorylating agent. A number of tertiary di-*p*-nitrophenyl phosphate esters were thus prepared in excellent yields. The nitrophenyl groups may be removed by hydrogenolysis in the presence of platinum or by alkaline treatment. Very mild alkaline hydrolysis results in the quantitative formation of alkyl mono-*p*-nitrophenyl hydrogen phosphates. Some other interesting properties of the neutral di-*p*-nitrophenyl phosphate esters have been recorded. A method for the large scale preparation of di-*p*-nitrophenyl hydrogen phosphate is detailed.

Methods for the synthesis of esters of phosphoric acid have been the subject of numerous investigations and several phosphorylating agents have been introduced. The reagents commonly employed fall broadly into two groups. To the first group belong phosphorus oxychloride[2] and certain of its monofunctional derivatives such as diphenyl,[3] dibenzyl[4] and di-*p*-nitrobenzyl[5] phosphorochloridates. Common features of the standard procedures employing these reagents are the mildness of conditions and the use of a basic catalyst, *e.g.*, pyridine, which often serves as the medium of reaction. The second group of phosphorylating agents embraces a number of anhydrides[6,7] such as polyphosphoric acid. Reagents of this type are usually employed in large excess and the phosphorylation reactions, which are carried out in the absence of a base, proceed under relatively drastic conditions.[8] Although lacking in elegance, reagents of the second type offer advantages of ready accessibility and simplicity in operation and have proved useful in certain cases.[9]

While the successful application of the existing methods of phosphorylation to a variety of synthetic problems has been recorded, inert hydroxyl functions are sometimes encountered whose phosphorylation in a satisfactory yield presents difficulties. One specific example is that of 2′,3′-*O*-isopropylidene guanosine, the phosphorylation of which formed a part of our studies in the nucleotide field. In connection with this problem and our broader interest in developing new and improved methods for the synthesis of phosphate esters of biological interest it was considered desirable to devise a method of phosphorylation which would utilize a mono-functional, powerful and yet mild reagent and which would not require basic catalysis. The present communication describes a method which meets the above requirements and, therefore, combines the desirable features of the two aforementioned types of procedures. The application of this method to a satisfactory synthesis of guanosine 5′-phosphate is recorded in the following communication.[10]

A convenient and efficient method for the synthesis of the symmetrical esters of pyrophosphoric acid

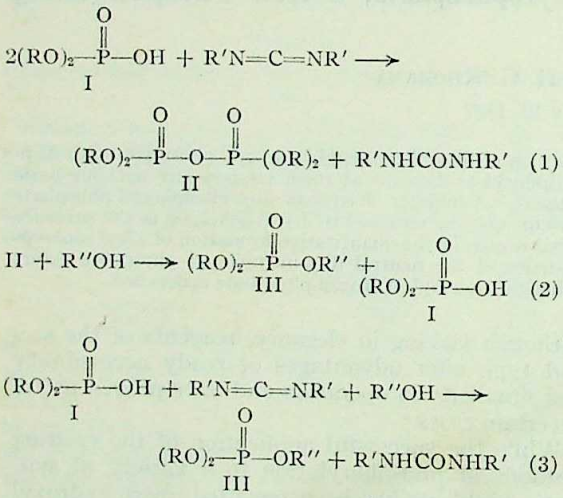
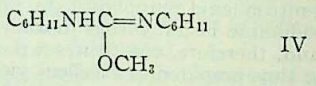
(II) is now available[11] (equation 1), and our first aim in the present work was to utilize a suitable compound of the type II for the phosphorylation of an alcohol according to equation 2. Since the liberated acid I would be expected to react again with the carbodiimide reagent to form II, the over-all reaction would be represented by equation 3. The fully protected pyrophosphate we chose to study as a phosphorylating agent was tetra-*p*-nitrophenyl pyrophosphate[11] (II, R = *p*-nitrophenyl). The choice of this ester was influenced by certain observations recorded by Todd and co-workers in their studies of the reactivity of the various fully protected pyrophosphates[12] and by a consideration of the ease of the subsequent removal of the protecting groups from the resulting esters of the type III



In the initial experiments, therefore, a mixture of di-*p*-nitrophenyl hydrogen phosphate (1 equiv.) and methyl alcohol (1.5 equiv.) was brought into reaction at room temperature in anhydrous dioxane with dicyclohexyl or di-*p*-tolyl carbodiimide (1 equiv.). In these experiments, varying amounts of the desired di-*p*-nitrophenyl methyl phosphate[13] were formed but side reaction(s) occurred. Thus when dicyclohexyl carbodiimide was used, a highly crystalline side product could be isolated, which from its elemental analysis was concluded to be the di-*p*-nitrophenyl phosphoric acid salt of N,N′-dicyclohexyl-*O*-methylisourea (IV). This conclusion was confirmed by the isolation and elemental analysis of the basic isourea (IV) itself from the salt. The latter could, subsequently, be prepared in quantitative yield by the addition of dicyclohexyl carbodiimide to an anhydrous methyl alcoholic solution of di-*p*-nitrophenyl hydrogen phosphate. A similar acid-catalyzed addition[14] of methyl alcohol to di-*p*-tolyl carbodiimide would be expected to occur, although the analogous compound was not isolated.

While the above experiments demonstrated the feasibility of the new approach, the side reaction observed precluded quantitative phosphorylation according to the scheme originally intended (equation 3) and it was therefore decided to add the alcohol to the preformed pyrophosphate, II (R = *p*-nitrophenyl), and to realize phosphorylation only according to equation 2 (the reaction mixture would thus contain no free carbodiimide). Because of the greater insolubility and consequent ease of removal of the resulting di-*p*-tolylurea, di-*p*-tolyl carbodiimide was preferred as the reagent.

Tetra-*p*-nitrophenyl pyrophosphate[15] was prepared *in situ* in anhydrous dioxane by the instantaneous reaction of di-*p*-tolyl carbodiimide with di-*p*-nitrophenyl hydrogen phosphate[11] and methyl alcohol was added. On working up (see Experimental) after a reaction period of some 15 hours, pure di-*p*-nitrophenyl methyl phosphate (III, R = *p*-nitrophenyl; R‴ = CH_3) was obtained in over 90% yield (based on equation 2). The generality of the



technique was established by the preparation of a number of simple alkyl di-*p*-nitrophenyl phosphate esters. By the same method, the primary hydroxyl groups in 2′,3′-*O*-isopropylidene uridine and 2′,3′-*O*-isopropylidene guanosine[10] were phosphorylated to give 90–95% yields of the corresponding di-*p*-nitrophenyl phosphate esters. (The phosphorylation of 1,2-*O*-isopropylidene D-xylofuranose by this reagent has been recorded elsewhere.[16])

An important consideration in the use of a method of phosphorylation, clearly, is the ease and selectivity with which one and/or both of the protecting groups may be removed from the initial products of phosphorylation. In this respect, obviously, the new reagent is akin to the well-established reagent diphenyl phosphorochloridate,[3] and, by analogy, the *p*-nitrophenyl groups may be removed by the platinum-catalyzed hydrogenolysis of the di-*p*-nitrophenyl phosphate esters. However, the presence of an acid (*e.g.*, hydrochloric acid) is necessary for removing both the protecting groups since otherwise hydrogenolysis does not proceed beyond the formation of the mono-*p*-aminophenyl esters of the type V. *p*-Aminophenyl methyl hydrogen phosphate (V, R = CH_3) was thus isolated as the crystalline free acid. Examples of the mono alkyl di-hydrogen phosphates prepared by the hydrogenolytic removal of the *p*-nitrophenyl groups are given in the Experimental section.

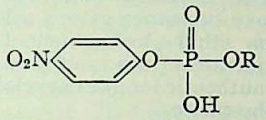
A characteristic and frequently useful feature of the neutral di-*p*-nitrophenyl phosphate esters of the type III (R = *p*-nitrophenyl) is the extreme ease with which one of the *p*-nitrophenyl groups may be removed under mildly alkaline conditions. This hydrolytic reaction, which may be followed conveniently by paper chromatography or by measuring spectrophotometrically the liberation of *p*-nitrophenol, occurs rapidly at room temperature in 0.01 to 0.1 *N* alkali and results in the quantitative formation of alkyl *p*-nitrophenyl hydrogen phosphates of the type VI. A number of diesters of this type were prepared in a crystalline state (see Experimental). Heating esters of the type VI at 100°



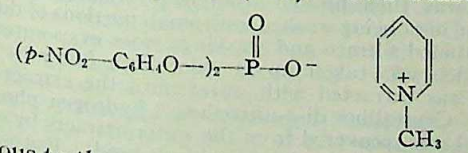
VI

in 1 *N* alkali for a few hours was necessary to remove the second *p*-nitrophenyl group. This alkaline hydrolysis[17] is useful as an alternative method for the removal of the protecting groups where platinum-catalyzed hydrogenolysis cannot be used (see for example the preparation of guanosine 5′-phosphate[10]).

Some other properties of the model substance di-*p*-nitrophenyl methyl phosphate may be briefly mentioned. As expected, in the presence of sodium benzoxide it underwent a rapid transesterification reaction to yield dibenzyl methyl phosphate. The latter substance was monodebenzylated with aqueous acetic acid[18] and the resulting benzyl methyl hydrogen phosphate was isolated as the crystalline cyclohexylammonium salt.

On heating di-*p*-nitrophenyl methyl phosphate in 50% acetic acid hydrolysis[19] occurred to give both di-*p*-nitrophenyl hydrogen phosphate and methyl *p*-nitrophenyl hydrogen phosphate; the proportions of the two products were, respectively, 77 and 23%. Hydrolysis in a mixture of 1 *N* hydrochloric acid and dioxane appeared to follow the same pattern.

An anhydrous pyridine solution of di-*p*-nitrophenyl methyl phosphate on standing for a few hours at room temperature deposited a highly crystalline material which from its elemental analysis, paper-chromatographic and paper-electrophoretic behavior was identified as N-methylpyridinium di-*p*-nitrophenyl phosphate (VII). This reaction is



VII

analogous to the quaternization reactions of neutral phosphate esters, especially, dibenzyl alkyl phosphates, which have been studied extensively by Todd and co-workers.[20] The great ease with which the reaction occurred in the present case, clearly, is a consequence of the strongly electron-withdrawing nitro groups since diphenyl *n*-propyl phosphate is apparently unaffected by refluxing in 4-methylmorpholine for three hours.[21]

Methods for the large scale preparation of di-*p*-nitrophenyl hydrogen phosphate have been examined in detail, since from the practical standpoint it was important that this starting material[22] in the described method of phosphorylation be readily available. The two step procedure involving (a) preparation of tri-*p*-nitrophenyl phosphate[23] from phosphorus oxychloride and (b) alkaline hydrolysis to the desired diester[24] (see Experimental) has given consistently an over-all yield of over 80% on a preparative scale. Initially, however, we prepared the diester by the reaction of phosphorus oxychloride with *p*-nitrophenol in pyridine according to Corby, Kenner and Todd.[12] The yields obtained in different runs varied and were rather unsatisfactory. Furthermore, in some runs the only crystalline product isolated was a low-melting (90–91°) substance. The nature of this interesting compound may be discussed in some detail. The substance, which was strongly acidic, was indistinguishable from authentic di-*p*-nitrophenyl hydrogen phosphate in its behavior on paper chromatograms developed in six solvent systems and, further, formed a crystalline cyclohexylammonium salt which was identical with that from di-*p*-nitrophenyl hydrogen phosphate (m.p., mixed m.p. and infrared spectrum). The possibility that the low-melting substance was a hydrate or an isomorphic form of di-*p*-nitrophenyl hydrogen phosphate was ruled out by the analytical data and the ultraviolet absorption spectrum. The latter, in fact, proved to be particularly informative; while it was practically identical with that of di-*p*-nitrophenyl hydrogen phosphate in the region 280–320 mμ, there was slightly increased absorption in the range 230–270 mμ. This evidence taken together with the observation that the low-melting substance was also encountered in the experiments in which aqueous pyridine was used for the hydrolysis of tri-*p*-nitrophenyl phosphate indicated that pyridine was present in the substance. Confirmatory evidence was provided by treating an aqueous solution of the 90–91° melting substance with an excess of Dowex-2-formate resin (removal of di-*p*-nitrophenyl phosphate ions) and determining the ultraviolet absorption spectrum of the clear supernatant. The "difference spectrum" was identical with that of pyridine. A quantitative determination of the pyridine content and of the neutralization equivalent, and the elemental analysis of the low-melting substance have led us to conclude that it represents a complex consisting of two molecules of di-*p*-nitrophenyl hydrogen phosphate and one molecule, each, of pyridine and water.

Finally, the preparation of the crystalline pyrophosphate VIII is recorded. This substance was prepared in order to test its use as a phosphorylat-

(17) The removal of phenyl groups from neutral phosphate esters by alkaline hydrolysis is well known. See *e.g.*, ref. 3c; and J. Baddiley and E. M. Thain, *J. Chem. Soc.*, 1610 (1953).

VIII

ing agent, in model experiments on the synthesis of unsymmetrical diesters of phosphoric acid. Preliminary experiments showed that basic catalysis was necessary for the phosphorylation of an alcohol by this pyrophosphate.

Experimental[25]

Paper chromatography was used extensively as an analytical tool. The two solvent systems which proved most useful were: *n*-butyl alcohol–acetic acid–water (4:1:5, v./v.)[26] (solvent A) and isopropyl alcohol–ammonia–water (7:1:2, v./v.)[27] (solvent B). In both solvent systems the R_f's of different types of esters followed the order: tertiary esters of phosphoric acid > diesters > monoesters. Some particularly relevant R_f's are mentioned in the text.

Sodium *p*-Nitrophenoxide.—Sodium hydroxide (110 ml. of 10 *N*) was added with stirring to a suspension of *p*-nitrophenol (150 g.) in boiling water (700 ml.). To the resulting clear solution was added a further volume (100 ml.) of 10 *N* alkali and the mixture rapidly cooled. The yellow sodium salt which separated was collected by filtration and washed three times with 50-ml. portions of ice-water. After drying thoroughly at 110° and pulverization the anhydrous salt was obtained as a red powder (165 g., 95%).

Tri-*p*-nitrophenyl Phosphate.—Rigorously dried, finely powdered sodium *p*-nitrophenoxide (112 g.) was added slowly to an anhydrous ethereal solution (400 ml.) of freshly distilled phosphorus oxychloride (16 ml.), with exclusion of moisture. The mixture was stirred mechanically at room temperature for 30 minutes and then refluxed for two hours. The resulting mixture of orange and white solids was collected by filtration and washed repeatedly with cold water (total volume, 1500 ml.) until the washings were colorless. The white crystalline residue of tri-*p*-nitrophenyl phosphate was dried *in vacuo* over phosphorus pentoxide. The yield was 76.6 g. (96%) and the m.p. 153–155° which was raised to 155–156° upon one recrystallization from ethyl acetate or acetone. The recrystallization was unnecessary for the next step.

Di-*p*-nitrophenyl Hydrogen Phosphate.—Tri-*p*-nitrophenyl phosphate (80 g.) was dissolved in warm dioxane (800 ml.) and the solution quickly cooled. To the solution were added 125 ml. of 4 *N* lithium hydroxide and sufficient water to give a homogeneous solution. The yellow solution was kept for 30 minutes and then neutralized by the portionwise addition of IR-120(H^+) resin. The resin was removed by filtration, washed with small portions of water and the combined filtrate evaporated to dryness under reduced pressure. The resulting sirup was dissolved in water (400 ml.) and the *p*H of the solution adjusted to 4 by the further addition of the acidic resin. The resin was removed and washed and the filtrate extracted repeatedly with ether until an extract produced no yellow color with aqueous alkali. The aqueous solution was then heated to 80° and strongly acidified by the slow addition (*ca.* 5 minutes) of concentrated hydrochloric acid.[28] The oil which initially separated solidified on cooling and scratching. The crystalline material was collected by filtration, dissolved in the minimum volume of boiling water and the solution kept at 0°. Di-*p*-nitrophenyl hydrogen phosphate (51 g.) separated as white needles and was collected by filtration. A further amount (2 g.) was recovered from the mother liquor by the addition of concentrated hydrochloric acid (2 ml.); total yield 53 g. (90%), m.p. after drying at 100° *in vacuo*, 175–175.5° (reported m.p. 176–178,°[12] 175°[29]).

Preparation of the Compound with M.P. 90–91°.—Tri-*p*-nitrophenyl phosphate (7 g.) was dissolved in dry, boiling pyridine (20 ml.) and an equal volume of water was added to the resulting colorless solution. The clear yellow solution now obtained was refluxed for 30 minutes. The solvent was then evaporated under reduced pressure and the oily residue taken up in water (100 ml.). The *p*H of the solution was adjusted to 5 with acetic acid and the resulting suspension was extracted with ether until an extract gave no yellow color with alkali. The clear aqueous solution was concentrated to 25 ml. and strongly acidified with concentrated hydrochloric acid. The light colored oil which separated, crystallized on trituration, was collected by filtration and recrystallized from ethyl acetate. The chunky crystals thus obtained (5.1 g.) had m.p. 90–91°, which remained unchanged upon further recrystallization. *Anal.* Calcd. for $C_{29}H_{23}N_5O_{16}P_2 \cdot H_2O$: C, 44.90; H, 3.24; N, 9.02; neut. equiv., 388. Found: C, 45.17; H, 3.27; N, 9.24; neut. equiv., 389.

Addition of excess cyclohexylamine to an acetonitrile solution of the above substance gave a salt which after recrystallization from ethyl alcohol melted at 188–188.5°. This material was identical (m.p., mixed m.p., and infrared spectrum) with an authentic sample of cyclohexylammonium di-*p*-nitrophenyl phosphate.

Forty grams of the substance with m.p. 90–91° was converted to the cyclohexylamine salt as described above and a hot suspension of the salt was treated with an excess of IR-120(H^+) ion-exchange resin. The strongly acidic solution was filtered from the resin and evaporated to give di-*p*-nitrophenyl hydrogen phosphate (35 g.) with m.p. 173–174° after crystallization from ethyl acetate.

Identification of Pyridine in the Compound with M.P. 90–91°.—The substance (5.81 mg.) with m.p. 90–91° and authentic di-*p*-nitrophenyl hydrogen phosphate (5.71 mg.) were each dissolved in 5-ml. portions of water and the solutions stirred with 1-ml. portions of freshly washed Dowex-2 (formate form) resin. The resin was removed and washed thoroughly with water until the optical density of the washings were zero. The two combined filtrates were diluted to 100 ml. with water and the ultraviolet absorption spectrum of the solution from the 91° melting substance was determined using the solution obtained from di-*p*-nitrophenyl phosphate as the blank. The spectrum was found to be identical with that of pyridine in 10^{-4} *M* formic acid solution. From the optical density of the above solution at 256 mμ and using a figure of 5400 as E_{max} for pyridine at this wave length, the pyridine content of the 91° melting substance could be calculated to be 10.07%. This corresponds to a monohydrate of a molecular compound of two moles of di-*p*-nitrophenyl phosphate and one mole of pyridine. This is in agreement with the elemental analysis recorded above.

Di-*p*-nitrophenyl Methyl Phosphate.—Di-*p*-nitrophenyl hydrogen phosphate (1 g., 2.94 mmoles) was dissolved in anhydrous dioxane (8 ml.) by warming with exclusion of moisture. The solution was cooled quickly to room temperature and di-*p*-tolyl carbodiimide (330 mg., 1.49 mmoles) was added. Di-*p*-tolylurea began to separate immediately and after ten minutes at room temperature anhydrous methyl alcohol (0.063 ml., 1.56 mmoles) was added. The stoppered flask was kept in a desiccator overnight and the solution was then filtered from di-*p*-tolylurea (335 mg., 94%), the urea being washed with small portions of dioxane. The combined filtrate and washings were evaporated to a sirup which was taken up in chloroform (10 ml.). The solution was extracted with water until the extracts were neutral. Crystalline di-*p*-nitrophenyl hydrogen phosphate (475 mg.) was recovered from the water extracts by acidification with concentrated hydrochloric acid. Evaporation of the chloroform solution gave a dry white residue which was crystallized from aqueous ethyl alcohol to give di-nitrophenyl methyl phosphate[13] (490 mg., 90%) as white needles, m.p. 142–143°, identical with that of a sample prepared according to Ketelaar and Gersmann.[13] (No depression in m.p. on admixture of the two samples.) *Anal.* Calcd. for $C_{13}H_{11}N_2O_8P$: C, 44.08; H, 3.13; N, 7.90. Found: C, 44.25; H, 3.07; N, 7.98.

Benzyl di-*p*-nitrophenyl phosphate was prepared in 96% yield by the phosphorylation of benzyl alcohol; m.p. 101–102° after crystallization from carbon tetrachloride. *Anal.* Calcd. for $C_{19}H_{15}N_2O_8P$: C, 53.00; H, 3.51; N, 6.51. Found: C, 53.17; H, 3.51; N, 6.36.

Cyclohexyl di-*p*-nitrophenyl phosphate was similarly pre-

(25) Melting points are uncorrected. Analyses recorded were performed by Mr. W. Manser, Zürich, Switzerland.

pared in 85% yield; m.p. 81–82° after crystallization from alcohol. *Anal.* Calcd. for $C_{18}H_{19}N_2O_8P$: C, 51.19; H, 4.54; N, 6.64. Found: C, 51.17; H, 4.70; N, 6.75.

2′,3′-*O*-isopropylidene Uridine 5′-Di-*p*-nitrophenyl Phosphate.—Di-*p*-nitrophenyl hydrogen phosphate (2.85 g.) was dissolved in anhydrous dioxane (15 ml.) by warming with exclusion of moisture. The solution was cooled to room temperature, di-*p*-tolyl carbodiimide (900 mg.) added and the mixture kept for ten minutes. Dry 2′,3′-*O*-isopropylidene uridine[30] (1.0 g.) was added and the sealed reaction mixture kept overnight at room temperature. Di-*p*-tolylurea (880 mg.) was removed by filtration and washed with small portions of dioxane. The combined filtrate was evaporated to dryness, the residue taken up in chloroform (25 ml.) and the solution extracted with water until an extract was neutral. Evaporation of chloroform gave 2′,3′-*O*-isopropylidene uridine 5′-di-*p*-nitrophenyl phosphate (1.916 g.) including the residual di-*p*-tolylurea (96 mg.). The material was used directly in the subsequent steps described later. A sample was crystallized from ethyl alcohol to give white needles with m.p. 118.5–120.5°. *Anal.* Calcd. for $C_{24}H_{23}N_4O_{13}P$: C, 47.53; H, 3.82; N, 9.24. Found: C, 47.34; H, 3.84; N, 9.03.

Methyl *p*-Nitrophenyl Hydrogen Phosphate.—To an acetonitrile (50 ml.) solution of di-*p*-nitrophenyl methyl phosphate (4.5 g.) was added 1 *N* aqueous lithium hydroxide solution (38 ml.) and the resulting yellow solution was kept for 30 minutes at room temperature. It was then partly evaporated to remove acetonitrile and the remaining aqueous solution adjusted to *p*H 5 with acetic acid. *p*-Nitrophenol was extracted with ether until an extract gave no yellow color with alkali. The residual solution was concentrated to 15 ml., and freed from lithium ions by passage through a 2.5 × 15 cm. column of IR-120(H^+) resin. The effluent and washings were evaporated to dryness under reduced pressure leaving free methyl *p*-nitrophenyl hydrogen phosphate as a colorless oil which crystallized on prolonged evacuation. The substance was recrystallized from a mixture of benzene and petroluem ether to give stout white needles (2.77 g., 94%) with m.p. 121–123°. One further recrystallization raised the m.p. to 123.5–124.5°. *Anal.* Calcd. for $C_7H_8NO_6P$: C, 36.09; H, 3.46; N, 6.01. Found: C, 36.27; H, 3.46; N, 5.91. The crystalline cyclohexylamine salt was prepared by adding an excess of cyclohexylamine to an acetonitrile–ether solution of the free acid. After recrystallization from benzene it melted at 150.5–151.0°. *Anal.* Calcd. for $C_{13}H_{21}N_2O_6P$: C, 47.00; H, 6.37; N, 8.44. Found: C, 47.18; H, 6.23; N, 8.44.

Other alkyl mono-*p*-nitrophenyl hydrogen phosphates prepared by the alkaline hydrolysis of the neutral esters are mentioned below.

Benzyl *p*-nitrophenyl hydrogen phosphate was prepared as the crystalline cyclohexylammonium salt in 90% yield; m.p. 168–169° after crystallization from benzene. *Anal.* Calcd. for $C_{19}H_{25}N_2O_6P$: C, 55.88; H, 6.17; N, 6.86. Found: C, 55.64; H, 6.17; N, 6.95.

Cyclohexyl *p*-nitrophenyl hydrogen phosphate was prepared as the cyclohexylammonium salt in 85% yield; m.p. 202–203° after crystallization from acetonitrile. *Anal.* Calcd. for $C_{18}H_{29}N_2O_6P$: C, 54.00; H, 7.30; N, 7.00. Found: C, 54.03; H, 7.50; N, 7.03.

***n*-Hexyl *p*-nitrophenyl hydrogen phosphate** also was prepared as the cyclohexylammonium salt in 85% yield; m.p. 109–110° after crystallization from acetonitrile. *Anal.* Calcd. for $C_{18}H_{31}N_2O_6P$: C, 53.90; H, 7.79; N, 6.97. Found: C, 54.08; H, 7.37; N, 7.00.

Uridine 5′-*p*-Nitrophenyl Hydrogen Phosphate.—To an acetonitrile (30 ml.) suspension of 2′,3′-*O*-isopropylidene uridine 5′-di-*p*-nitrophenyl phosphate (1.22 g.) was added lithium hydroxide solution (6.5 ml.) and water (15 ml.), and the yellow mixture shaken for 30 minutes. Paper chromatography at this stage showed that removal of one of the nitrophenyl groups was complete; R_f's of 2′,3′-*O*-isopropylidene uridine 5′-*p*-nitrophenyl hydrogen phosphate were: solvent A, 0.54; solvent B, 0.62. Most of the acetonitrile then was removed by evaporation under reduced pressure and the residual solution brought to *p*H 5 with acetic acid. The slight suspension of di-*p*-tolylurea was removed and the aqueous solution extracted with ether until an extract gave no yellow color with alkali. The *p*H of the solution was then adjusted to 2.7 by the addition of glacial acetic acid and the acidic solution heated in a boiling water-bath for 90 minutes. The solution was then evaporated to dryness, last traces of acetic acid being removed by co-evaporation with dioxane. The oily residue was dissolved in water and the solution passed slowly through a Dowex 50(H^+) column (10 cm. × 2 cm.), the column being washed thoroughly with water. The total acidic effluent was concentrated to about 5 ml. and the concentrate neutralized with aqueous barium hydroxide to *p*H 4.0. A trace of insoluble material was removed by centrifugation and the supernatant concentrated to an oil which solidified on trituration with ethyl alcohol. The amorphous barium salt (746 mg., 67%) was collected by centrifugation, washed with acetone and ether and dried under a vacuum at room temperature. Paper chromatography revealed a single strong spot; R_f's: solvent A, 0.25; solvent B, 0.45. *Anal.* Calcd. for $C_{15}H_{16}N_3O_{11}PBa^1/_2 \cdot 2H_2O$: C, 32.75; H, 3.66; N, 7.64. Found: C, 33.34; H, 3.75; N, 7.19.

A kinetic study of the degradation of this substance by snake venom diesterase has been carried out by Dr. C. A. Dekker and Miss M. L. Dirksen and will be reported by these authors elsewhere.

***p*-Aminophenyl Methyl Hydrogen Phosphate.**—A solution of di-*p*-nitrophenyl methyl phosphate (1 g.) in ethyl alcohol (200 ml.) was hydrogenated at room temperature in the presence of Adams platinum catalyst (200 mg.). After four hours, when hydrogen uptake (624 ml.) ceased, the catalyst was removed, washed with ethyl alcohol, and the combined filtrate evaporated to a colorless oil which was taken up in water (10 ml.). The aqueous solution was passed through a column (10 × 1 cm.) of IR-120(H^+) resin and the column washed until the effluent was neutral. The total effluent, which slowly turned brown in air, was evaporated to dryness under reduced pressure giving a brown solid (442 mg.), which was washed three times with ether. (Addition of cyclohexylamine to the ethereal extracts gave a small amount (27 mg.) of bis-cyclohexylammonium monomethyl phosphate). The ether-insoluble residue (m.p. 205–208°) was dissolved in hot aqueous ethyl alcohol, the solution decolorized with charcoal and allowed to cool. *p*-Aminophenyl methyl hydrogen phosphate (300 mg., 53%) was obtained as white needles of m.p. 212–213°. *Anal.* Calcd. for $C_7H_{10}NO_4P$: C, 41.62; H, 5.57; N, 6.90. Found: C, 41.62; H, 5.57; N, 6.93.

Benzyl Methyl Hydrogen Phosphate.—A freshly prepared solution of sodium benzoxide (from 200 mg. of sodium and 10 ml. of benzyl alcohol) was added to a benzyl alcohol (5 ml.) solution of di-*p*-nitrophenyl methyl phosphate (1 g.). The resulting orange solution was kept overnight, then filtered from some crystalline sodium *p*-nitrophenoxide which had separated, and evaporated under a high vacuum at 50°. The oily residue was dissolved in ether and the ethereal solution extracted repeatedly with 0.01 *N* alkali until the extracts were colorless. Evaporation of the ethereal solution gave an oil[31] which was treated with 35% acetic acid (30 ml.) at 100° for one hour. The acetic acid solution was then evaporated to dryness and the residue equilibrated with water (20 ml.) at *p*H 8. The aqueous solution was freed from the insoluble oil by extraction with ether. The clear aqueous solution was passed through a column (10 cm. × 1 cm.) of IR-120(H^+) resin, the column being washed with water until the effluent became neutral. The acidic solution was evaporated, the residual colorless oil (288 mg.) taken up in ether (5 ml.) and an excess of cyclohexylamine was added. On adding light petroleum and keeping the mixture at 0° cyclohexylammonium benzyl methyl phosphate (400 mg., 50%) crystallized; m.p. 99–101°, raised after one recrystallization from ether to 100–101.5°. *Anal.* Calcd. for $C_{14}H_{24}NO_4P \cdot 1H_2O$: C, 52.85; H, 8.21; N, 4.39. Found: C, 53.10; H, 8.14; N, 4.58.

Methyl Dihydrogen Phosphate from Di-*p*-nitrophenyl Methyl Phosphate: (1) By Alkaline Hydrolysis.—Aqueous lithium hydroxide (9 ml. of 1 *N*) was added to a dioxane (10 ml.) solution of di-*p*-nitrophenyl methyl phosphate (1 g.), and the yellow solution shaken for 30 minutes. The solution was neutralized with acetic acid and evaporated to a gum which was heated in 1 *N* lithium hydroxide (15 ml.) in a polyethylene tube at 100°. Paper chromatography in the solvent system butyl alcohol–acetic acid–water (4:1:5,

(30) P. A. Levene and R. S. Tipson, *J. Biol. Chem.*, 106, 113 (1934).

(31) The oil was very much in excess of the expected dibenzyl methyl phosphate and contained a large proportion of another substance, presumably dibenzyl ether.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

v./v.) showed that methyl *p*-nitrophenyl hydrogen phosphate (R_f, 0.55) had disappeared completely after three hours, only two spots corresponding to *p*-nitrophenol (R_f, 0.93) and methyl dihydrogen phosphate (R_f, 0.11) being present. The *p*H of the alkaline solution was then adjusted to 5 with acetic acid and the solution extracted with ether until an extract gave no yellow color with alkali. The colorless aqueous solution was then passed through a column (15 cm. × 1.5 cm.) of IR-120(H^+) resin and the acidic effluent and washings were evaporated to dryness, the last traces of acetic acid being removed by repeated evaporation in presence of dioxane. The oily residue was dissolved in water (5 ml.), the solution neutralized to *p*H 8.5 with cyclohexylamine and then evaporated. The white solid residue was crystallized from ethyl alcohol giving bis-cyclohexylammonium methyl phosphate (790 mg., 90%) as colorless needles, which on heating decomposed at 195–198°. The sample was dried *in vacuo* at room temperature.[32] *Anal.* Calcd. for $C_{13}H_{31}N_2O_4P \cdot 1H_2O$: C, 47.54; H, 10.13; N, 8.53. Found: C, 47.53; H, 10.13; N, 8.64.

(2) **By Catalytic Hydrogenation.**—Di-*p*-nitrophenyl methyl phosphate (500 mg.) was hydrogenated in ethyl alcohol (200 ml.) containing one ml. of concentrated hydrochloric acid in the presence of Adams platinum catalyst (100 mg.). After four hours, when hydrogen uptake ceased, the catalyst was removed by filtration and the alcoholic solution evaporated. The white solid was dissolved in water (5 ml.) and the solution passed through a column (10 cm. × 1 cm.) of IR-120(H^+) resin. The effluent was evaporated to dryness and converted to the bis-cyclohexylammonium salt as described above. The product (345 mg., 78%) was identical with that obtained above by alkaline hydrolyses.

Benzyl dihydrogen phosphate[33] was prepared in 94% yield from benzyl di-*p*-nitrophenyl phosphate by alkaline hydrolysis as described above; m.p. 94–96° after crystallization from ether–petroleum ether (reported[33] m.p., sharp but varying between 85 and 113°, depending upon rate of heating). *Anal.* Calcd. for $C_7H_9O_4P$: C, 44.70; H, 4.82. Found: C, 44.84; H, 4.87. The bis-cyclohexylammonium salt prepared by the addition of excess of cyclohexylamine to an ethereal solution of the acid had m.p. 232–234° (Chase, *et al.*,[33] quote 233–235°). *Anal.* Calcd. for $C_{19}H_{35}N_2O_4P$: C, 59.02; H, 9.12; N, 7.25. Found: C, 58.91; H, 8.91; N, 6.96.

***n*-Hexyl dihydrogen phosphate** was prepared in 91% yield from the corresponding di-*p*-nitrophenyl ester by hydrogenolysis in the presence of acid and was characterized as the bis-cyclohexylammonium salt. M.p. of the salt was 195–196° after crystallization from ethyl alcohol. *Anal.* Calcd. for $C_{18}H_{41}N_2O_4P$: C, 56.81; H, 10.86; N, 7.36. Found: C, 56.77; H, 11.01; N, 6.95.

Bis-cyclohexylammonium cyclohexyl phosphate also was prepared in 85% yield by hydrogenolysis of the corresponding ester; m.p. 218–219° after crystallization from a mixture of benzene and ethyl alcohol. *Anal.* Calcd. for $C_{18}H_{39}N_2O_4P$: C, 57.15; H, 10.38; N, 7.40. Found: C, 57.31; H, 10.38; N, 7.46.

N-Methylpyridinium Di-*p*-nitrophenyl Phosphate.—An anhydrous pyridine (5 ml.) solution of di-*p*-nitrophenyl methyl phosphate (1 g.) was kept at room temperature with exclusion of moisture. The highly crystalline N-methylpyridinium di-*p*-nitrophenyl phosphate which separated was collected by filtration after 18 hours; yield 1.06 g. Evaporation of the mother liquor afforded a further amount (100 mg.) of the same product; m.p. 134–135°, unchanged after recrystallization from ethyl acetate–ethyl alcohol. *Anal.* Calcd. for $C_{18}H_{16}N_3O_8P$: C, 49.89; H, 3.72; N, 9.70. Found: C, 49.87; H, 3.74; N, 9.72.

Paper chromatography and paper electrophoresis (*p*H 4) of the crystalline compound showed two ultraviolet absorbing spots; one, corresponding to di-*p*-nitrophenyl phosphate ion, and the second corresponding to N-methylpyridinium ion (identical in electrophoretic mobility and ultraviolet absorption spectrum to this ion prepared from dimethyl sulfate and pyridine in ether).

Acidic Hydrolysis of Di-*p*-nitrophenyl Methyl Phosphate.—To an acetic acid (2 ml.) solution of di-*p*-nitrophenyl methyl phosphate (40 mg.), maintained at 100°, slowly was added two ml. of water so as to maintain a homogeneous solution. Duplicate five microliter aliquots were removed at intervals and applied to Whatman No. 1 paper. Paper chromatography in solvent A showed the formation of spots corresponding to di-*p*-nitrophenyl hydrogen phosphate (R_f, 0.73) and methyl *p*-nitrophenyl hydrogen phosphate (R_f, 0.55). The percentages of the two products were ascertained by elution of the spots and determination of the optical density at 285 mμ. These were found to be: di-*p*-nitrophenyl hydrogen phosphate, about 77%; methyl *p*-nitrophenyl hydrogen phosphate, about 23%. The amounts of these products reached a maximum after three hours and then slowly decreased, with the concomitant formation of mono-*p*-nitrophenyl and monomethyl dihydrogen phosphates.

O-Methyl-N,N′-dicyclohexylisourea.[14]—Dicyclohexyl carbodiimide (310 mg.) was added to an anhydrous methyl alcoholic solution (5 ml.) of di-*p*-nitrophenyl hydrogen phosphate (500 mg.) and the solution kept at room temperature for four hours. The solvent was then evaporated and the residue crystallized from dioxane to give the di-*p*-nitrophenyl phosphate salt of *O*-methyl-N,N′-dicyclohexylisourea (IV) (710 mg., 84%) as colorless needles of m.p. 153–153.5°. *Anal.* Calcd. for $C_{26}H_{35}N_4O_9P$: C, 54.00; H, 6.10; N, 9.70. Found: C, 54.20; H, 6.30; N, 9.91.

A warm aqueous ethyl alcoholic solution of the salt (500 mg.) was well stirred with freshly washed IRA 400($O\bar{H}$) resin. The resin was removed by filtration, washed twice with ethyl alcohol and the total filtrate evaporated to dryness. The residual colorless oil was distilled in a short path apparatus to give O-methyl-N,N′-dicyclohexylisourea (185 mg., 90%) as a colorless mobile liquid; b.p. 90° (0.1 mm.). *Anal.* Calcd. for $C_{14}H_{26}N_2O$: C, 70.45; H, 11.00. Found: C, 70.10; H, 11.08.

P^1P^2-Di-*p*-nitrophenyl P^1P^2-Dimethyl Pyrophosphate (VIII).—To a solution of methyl *p*-nitrophenyl hydrogen phosphate (466 mg.) in anhydrous acetonitrile (5 ml.) was added di-*p*-tolyl carbodiimide (240 mg.) and the mixture, which deposited di-*p*-tolylurea immediately, was kept at room temperature for one hour. The urea was then removed by filtration in a dry box and the filtrate evaporated to an oil. It was suspended in ether (5 ml.) and acetonitrile gradually added until a clear solution resulted. On keeping at 0°, the solution deposited the pyrophosphate VIII as colorless stout crystals (350 mg., 78%); m.p. 81–83°, unchanged on recrystallization from the same solvents. *Anal.* Calcd. for $C_{14}H_{14}N_2O_{11}P_2$: C, 37.50; H, 3.15; N, 6.25. Found: C, 37.31; H, 3.21; N, 6.35.

Nucleoside Polyphosphates. IV.[1] A New Synthesis of Guanosine 5′-Phosphate

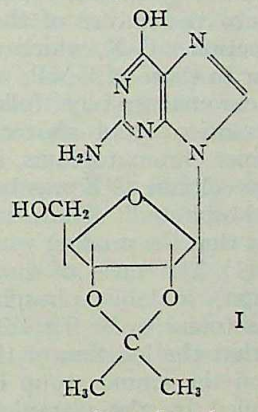
BY ROBERT WARNER CHAMBERS,[2] J. G. MOFFATT AND H. G. KHORANA

RECEIVED JANUARY 12, 1957

The previously recorded phosphorylation of 2′,3′-*O*-isopropylidene guanosine with phosphorus oxychloride in a mixture of pyridine and dimethylformamide has been re-examined. While some guanosine 5′-phosphate was produced, large amounts of the nucleoside always remained unreacted and phosphorus-containing side products, tentatively identified as guanosine 5′-di- and triphosphates, were formed. Guanosine 5′-phosphate was synthesized in a good (*ca.* 70%) yield by using tetra-*p*-nitrophenyl pyrophosphate as the phosphorylating agent. The steps were: 2′,3′-*O*-isopropylidene guanosine → 2′,3′-*O*-isopropylidene guanosine 5′-di-*p*-nitrophenyl phosphate $\xrightarrow{\bar{O}H}$ 2′,3′-*O*-isopropylidene guanosine 5′-mono-*p*-nitrophenyl phosphate $\xrightarrow[\text{snake venom or } \bar{O}H]{}$ 2′,3′-*O*-isopropylidene guanosine 5′-phosphate $\xrightarrow{H^+}$ guanosine 5′-phosphate. Some interesting properties of 2′,3′-*O*-isopropylidene guanosine 5′-di-*p*-nitrophenyl phosphate are recorded. An improved procedure for the preparation of 2′,3′-*O*-isopropylidene guanosine is described.

Nucleoside 5′-mono-, di- and triphosphates corresponding to all the four naturally occurring ribonucleosides were first demonstrated to be present in certain tissues by Potter and co-workers[3] and subsequent work reported from different laboratories has established the widespread occurrence[4] and biological importance[5] of these substances. In this Laboratory, attention has been devoted during the last several years to the development of methods for the chemical synthesis of nucleoside polyphosphates and related compounds. It was hoped that in addition to providing synthetic confirmation of structures, our studies might lead to new and improved procedures which would make some of the difficultly accessible members of this group readily available in a pure state. In continuing these studies,[6] we undertook the problems of the synthesis of guanosine 5′-mono-, di- and triphosphates. Chemical work in this series was anticipated to be particularly difficult, for the reasons which will become clear from the sequel,[7] and it was therefore considered that these problems would provide stringent tests for the synthetic methods which have been developed in this Laboratory. The present communication describes our work on the synthesis of guanosine 5′-phosphate (GMP) while the synthesis of the higher phosphates is reported in the following communication.[7] A brief account of a part of this work has already appeared.[8]

While highly satisfactory syntheses of a number of nucleoside 5′-phosphates[1,9,10c] have been recorded, previous attempts at the phosphorylation of guanosine derivatives[10] have met with only very limited success. In particular, the 5′-hydroxyl group in 2′,3′-*O*-isopropylidene guanosine (I) is



I

uniquely inert and resists phosphorylation[11] by the well-known phosphorylating agents, dibenzyl and diphenyl phosphorochloridates.[10] Michelson and Todd[10c] have, however, recorded the preparation of guanosine 5′-phosphate in 20% yield by using phosphorus oxychloride as the phosphorylating agent, and since at the time this work was undertaken this was the only applicable method,[12] we undertook a re-examination of this synthesis.

In the first experiments, Michelson and Todd's procedure was repeated exactly (addition of 1.1 equiv. of phosphorus oxychloride to a cold solution of 2′,3′-*O*-isopropylidene guanosine in a mixture of dimethylformamide and pyridine). Using paper chromatography, electrophoresis and ion-exchange analysis as analytical tools, two phosphorus-con-

(11) It should be pointed out that 2′,3′-*O*-isopropylidene guanosine is highly insoluble in pyridine. In the procedure reported by Michelson and Todd,[10c] a mixture of dimethylformamide and pyridine was used in order to obtain a homogeneous reaction mixture. The situation may be complicated by the reaction of phosphorylating agents with dimethylformamide. See, *e.g.*, H. K. Hall, Jr., THIS JOURNAL, **78**, 2717 (1956).

(12) The simple phosphorylating agent consisting of a mixture of phosphoric acid and phosphorus pentoxide which is satisfactory for the phosphorylation of the suitably protected pyrimidine nucleosides[1] was useless in the present case. 2′,3′-*O*-isopropylidene guanosine undergoes extensive degradation.

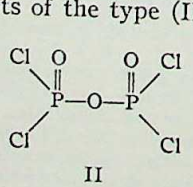
taining substances, in addition to guanosine 5′-phosphate, were detected as products. Further, about 50% of the starting material remained unreacted. The use of an approximately threefold excess of the phosphorylating agent caused no significant increase in the yield of the phosphorylated products. The results of the quantitative ion exchange analysis are recorded in the Experimental Section (Table II), the side products being designated as G-X and G-Y. As can be seen, GMP was formed in yields varying between 17 and 31%. However, the isolation of this desired substance was complicated by the presence of large amounts of inorganic phosphate and the yield of the pure product never exceeded 15% by this method of synthesis.

The phosphorus-containing side products (G-X and G-Y), both, had ultraviolet absorption spectra identical with that of guanosine 5′-phosphate and from their behavior on ion-exchange columns appeared to be polyphosphates. They were investigated more closely with the hope of obtaining some insight into the nature of the above phosphorylation reaction. G-X, which was present in amounts similar to those of GMP, was purified by ion-exchange chromatography followed by absorption and elution from charcoal. From its behavior on paper chromatograms, ionograms and an ion-exchange column, G-X was believed to be a "guanosine diphosphate." The evidence adduced below suggested that the product was guanosine 5′-diphosphate. (1) The ratio of guanosine (ultraviolet absorption) to labile phosphorus to total phosphorus was found to be 0.9:1.0:2.0. It may be mentioned that the location of the labile phosphoryl group on the amino group in the guanine ring was excluded by the ultraviolet absorption spectrum and the fact that the substance had survived the acidic treatment used to remove the isopropylidene group. (2) Crude snake venom degraded G-X to guanosine and inorganic phosphate. (3) The vicinal hydroxyl groups in the ribose moiety were intact as shown by the periodate–benzidine spray.

G-Y was only a very minor product and the availability of only a very small amount of the purified sample precluded a rigorous examination. However, experiments along the lines described above suggested that G-Y probably was guanosine 5′-triphosphate.

The formation of guanosine 5′-di- and triphosphates as side products suggests that linear phosphorylating agents of the type (II) are present in



II

the above reaction mixtures. (Inorganic pyro- and polyphosphates were also detected as reaction products.) These polyphosphorylating agents[13] could arise by the reaction of phosphorus oxychloride with traces of water present in the reaction mixture, although all possible precautions to exclude moisture were taken.[14]

The above experiments would appear to demonstrate conclusively the inertness of the 5′-hydroxyl group in I, since large amounts of the nucleoside always were recovered.[15] More recently, Hayes, Michelson and Todd[16] have also remarked on the inertness of the hydroxyl groups in 2′-deoxyguanosine derivatives. A possible explanation of this inertness is that the 5′-hydroxyl group is involved in hydrogen bonding with the 2-amino group in the guanine ring, a situation unique to this nucleoside.

The unsatisfactory results obtained above and the virtual failure of the other known phosphorylating agents led us to conclude that the phosphorylation of 2′,3′-*O*-isopropylidene guanosine (I) could be best accomplished with a powerful, monofunctional reagent which would not require basic catalysis. Tetra-*p*-nitrophenyl pyrophosphate, which is described in detail in the preceding communication,[17] was found to meet these requirements. The reagent was allowed to react with I in the presence of one equivalent of the free di-*p*-nitrophenyl hydrogen phosphate and, after a reaction period of 15 hours at 20°, 2′,3′-*O*-isopropylidene guanosine 5′-di-*p*-nitrophenyl phosphate (III) was isolated in a nearly quantitative yield. This successful phosphorylation in acidic medium would appear to support the belief that the 5′-hydroxyl group acquired "normal" reactivity when the 2-amino group in I was protonated.

As recorded in the preceding communication[17] the removal of one of the *p*-nitrophenyl groups from the neutral esters of the type III may be accomplished by very mild alkaline treatment; IV was thus obtained in a nearly quantitative yield, as estimated by spectrophotometric measurement of the liberated *p*-nitrophenol. The removal of the second *p*-nitrophenyl group was conveniently effected by digestion with crude rattlesnake venom, which is known to have a relatively unspecific and potent phosphodiesterase activity.[18]

(13) M. Viscontini and K. Ehrhardt, *Ang. Chem.*, **66**, 717 (1954).

(14) It also is possible that the polyphosphates are formed during decomposition of the excess of phosphorus oxychloride with aqueous pyridine (see Experimental).

(15) It might be argued that the free nucleoside found in the reaction products arose from the breakdown of an acid-labile phosphorylated derivative, *e.g.*, N^2-phosphate, during the acidic removal of the isopropylidene group. Thus, Levene and Tipson (*J. Biol. Chem.*, **121**, 131 (1937)) have recorded the isolation of an adenosine diphosphate after treatment of 2′,3′-*O*-isopropylidene adenosine with 2.2 equivalents of phosphorus oxychloride. Since one of the two phosphate groups in the above product was acid-labile, Levene and Tipson formulated the substance as adenosine N^6,5′-diphosphate. If N-phosphorylation were also to occur in the guanosine series, then by using an excess of phosphorus oxychloride N^2,O5′-diphosphate would have been obtained, which after mild acidic treatment would have afforded guanosine 5′-phosphate. In other words, an increase in the amount of the phosphorylating agent should have resulted in an increase in the yield of guanosine 5′-phosphate. Actually, this was found not to be the case. Furthermore, when the phosphorylation mixture was examined by paper chromatography *before* any acidic treatment, a large proportion of isopropylidene guanosine was found to be present.

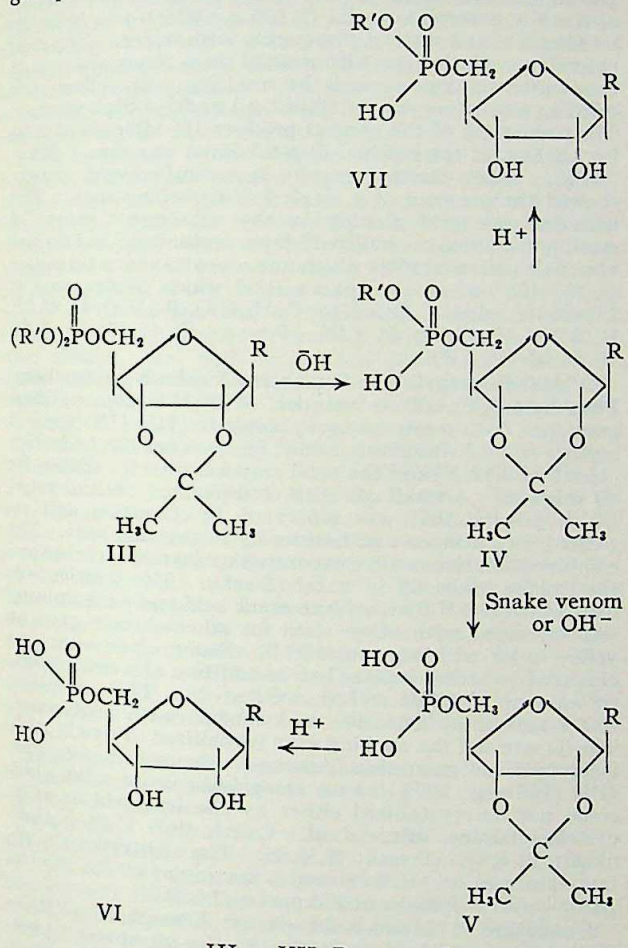
Treatment of the resulting V with dilute acid furnished guanosine 5′-phosphate which was isolated in yields of 65–75% based on isopropylidene guanosine. As was expected, the 5′-nucleotidase, which is also present in the crude snake venom, was inactive toward V, since the 3′-hydroxyl group[19] was protected by the isopropylidene

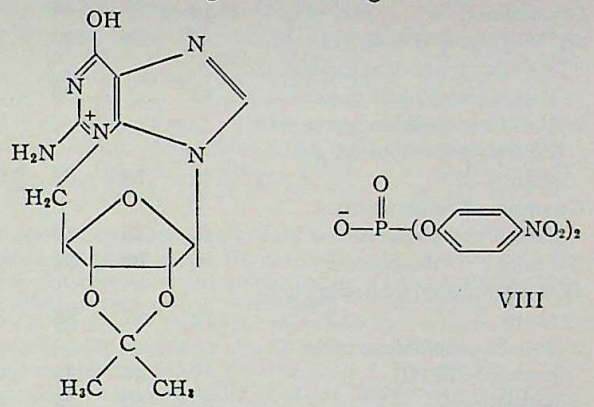


III → VII, R = guanine
III, IV and VII, R′ = *p*-nitrophenyl

group. However, it was fully active against guanosine 5′-phosphate (VI). Therefore, the removal of the protecting groups in the order IV → V → VI enabled the use of the crude snake venom.

The removal of the *p*-nitrophenyl group from IV also was accomplished by treatment with 1 *N* lithium hydroxide at 100° for about three hours. Some concomitant hydrolysis to inorganic phosphate also occurred under these conditions, but the product could be purified by fractional precipitation of the barium salt. The yield of guanosine 5′-phosphate prepared by alkaline hydrolysis was about 60%.

Two observations made during the course of the work on the neutral III may be mentioned. On heating its acetonitrile solution a new high-melting isomeric substance was produced. The product was concluded to be a quaternary ammonium salt of di-*p*-nitrophenyl phosphate, its formation being analogous to the quaternization reaction undergone by 2′,3′-*O*-isopropylidene adenosine 5′-*p*-toluenesulfonate.[20] While the structure VIII is tentatively advanced for this substance, the alternative possibility of cyclization with the 2-amino group in the guanine ring cannot be ignored.



Cyclization, instead of transesterification,[17] was also the preferred reaction when III was treated with sodium benzoxide in benzyl alcohol. Analogy for this reaction may again be found in the work of Brown, Todd and Varadarajan[21] who have recorded quaternization reactions of *p*-toluenesulfonic acid esters of uridine derivatives in methyl alcohol–ammonia.

Finally, the preparation of 2′,3′-*O*-isopropylidene guanosine, the starting material, by the published procedure[10c] was tedious and gave in our hands unsatisfactory yields. A simpler method of isolation which utilizes an ion-exchange resin for the removal of zinc ions is described in the Experimental Section. The procedure gave consistently 70–80% yields.

Experimental

Methods.—Paper chromatography was carried out with Whatman No. 1 paper, using mostly the descending technique. The solvent systems employed were: (1) *n*-butyl alcohol–acetic acid–water (4:1:5, v./v.)[22] (solvent I); (2) sopropyl alcohol–ammonia–water (7:1:2)[23] (solvent II); (3) isopropyl alcohol–1% ammonium sulfate solution (2:1, v./v.)[24] (solvent III); (4) pyridine–isoamyl alcohol–water (7:7:6, v./v.)[25] (solvent IV); (5) potassium dihydrogen phosphate solution (5%)–isoamyl alcohol[26] (solvent V); (6) isopropyl alcohol (75 ml.)–water (25 ml.)–trichloroacetic acid (5 g.)–ammonia (0.25 ml., sp. gr. 0.9)[27] (solvent VI); (7) isobutyric acid (100 ml.)–1 *N* ammonium hydroxide (60 ml.)–0.1 *M* ethylenediaminetetraacetic acid disodium salt[28] (1.6 ml.) (solvent VII). The R_f's of various compounds are given in Table I.

For paper electrophoresis, five inch strips of Whatman No. 3 MM paper were washed first with 2 *N* formic acid,[29] then with water and dried in air. The spots were applied and dried and the papers then sprayed with 0.02 *M* citrate buffer, *p*H 4.4, and then subjected to a potential of 12 volts/cm.

(19) The 5′-nucleotidase is inactive when the 3′-hydroxyl group is substituted. Thus, adenosine 3′,5′-diphosphate (A. Kornberg and W. E. Pricer, Jr., *J. Biol. Chem.*, **186**, 557 (1950)) is not attacked by the snake venom.

2′,3′-*O*-Isopropylidene cycloguanosine (VIII)	.47	.47	.49	.46
p-Nitrophenol	.89	.69	.83	.91

for two hours. The apparatus employed was a modification of Paigen's design,[30] in that the starch troughs were replaced by a glass baking dish (13.5″ × 8.5″ × 2″) filled with carbon tetrachloride. The paper strips were immersed in this bath during the run.

Spots were located on paper chromatograms by their ultraviolet absorption and by spraying the chromatograms with the molybdate–perchloric acid spray[31] and subsequently irradiating with ultraviolet light.[32] Total phosphorus determination was carried out by King's method,[33] while inorganic phosphate was determined by the method of Lowry and Lopez.[34]

Preparation of 2′,3′-*O*-Isopropylidene Guanosine.—Zinc chloride (56 g. of a freshly fused, anhydrous sample) was dissolved in anhydrous acetone (350 ml.). Twenty-two grams of guanosine (dried previously *in vacuo* at 100° over phosphorus pentoxide) was added and the mixture heated overnight under reflux with exclusion of moisture. The clear solution was then evaporated to a thick sirup and 8 *N* ammonium hydroxide was added until the initially formed precipitate redissolved and a clear solution resulted. Amberlite IR-120-ammonium form (100 ml.) was added and if a precipitate formed, it was dissolved by the gradual addition of concd. ammonia. The mixture was stirred for 15 minutes. The resin was then removed by filtration and washed twice with 50-ml. portions of very dilute ammonia. This whole process was repeated four times using 100–125 ml. portions of the wet resin each time. The total volume of the final filtrate was about 1000 ml. On evaporation of ammonia, either by keeping the solution in an open vessel for several days or by heating on a water-bath and then allowing the solution to cool, 2′,3′-*O*-isopropylidene guanosine crystallized. It was collected by filtration, washed with water and dried in air to give 15.2 g. of a crystalline, pure sample. The mother liquor was concentrated and retreated twice with 100-ml. portions of IR-120-ammonium form resin. A further amount (4.2 g.) of pure material was thus obtained; total yield 19.4 g., m.p. 296° (resolidification) (reported[10c] m.p. 299° dec.). This material could be recrystallized from hot water with negligible loss. Paper chromatography in four solvent systems (Table I) showed a single strong spot; guanosine could not be detected.

2′,3′-*O*-Isopropylidene Guanosine 5′-Di-*p*-nitrophenyl Phosphate (III).—Di-*p*-nitrophenyl phosphate[35] (4.2 g., *ca.* 12.4 mmoles) was dissolved in warm anhydrous dioxane (20 ml.) and the solution cooled to room temperature under running cold water with exclusion of moisture. Di-*p*-tolyl carbodiimide (1.10 g., 4.97 mmoles) was added, and the stoppered reaction flask was kept at room temperature for ten minutes. 2′,3′-*O*-Isopropylidene guanosine[35] (1.0 g., 3.1 mmoles) was quickly added and the sealed flask stored overnight in a desiccator. Di-*p*-tolylurea (1.080 g., theory 1.190 g.) was then removed by filtration and washed three times with 3-ml. portions of dioxane. The filtrate and the washings were evaporated and the resulting oil shaken with a mixture of chloroform (30 ml.) and 1 *M* lithium acetate buffer (*p*H 6.5, 10 ml.). The chloroform layer was separated and further extracted three times with the same buffer. During the extractions a part of the product III separated as a white amorphous solid (1.106 g.) which was collected by filtration and washed thoroughly with water. The clear chloroform solution was also washed three times with water, evaporated to dryness and the resulting pale yellow resin dried to a constant weight (0.982 g.) under a high vacuum. The total yield of the neutral product III after accounting for 110 mg. of the residual di-*p*-tolylurea was thus 1.898 g. (95%). Paper chromatography in several solvent systems showed the presence of a single fast-travelling spot. This material was used directly in the subsequent steps. A small portion was crystallized[36] from acetonitrile and formed very pale yellow needles which underwent a sharp transition at 161–163° to an amorphous solid which decomposed at 263–264°. *Anal.* Calcd. for $C_{25}H_{24}N_7O_{12}P\cdot 1H_2O$: C, 45.28; H, 3.95; N, 14.80; P, 4.68. Found: C, 45.57; H, 4.45; N, 15.00; P, 4.80.

2′,3′-*O*-Isopropylidene Guanosine 5′-Mono-*p*-nitrophenyl Phosphate (IV).—To a solution of 2′,3′-*O*-isopropylidene guanosine 5′-di-*p*-nitrophenyl phosphate (III) (180 mg.) in acetone (6 ml.) was slowly added aqueous barium hydroxide (16 ml. of 0.12 *N*) and the total reaction mixture shaken for 30 minutes. A small quantity of unreacted neutral ester, which precipitated, was separated by filtration and retreated with acetone and barium hydroxide as above. The combined solutions were evaporated to dryness *in vacuo* and the residue taken up in water (5 ml.). The solution was neutralized to *p*H 5 with dilute acetic acid and *p*-nitrophenol was extracted with ether until an ether extract gave no yellow color with aqueous alkali. Barium ions were precipitated as barium sulfate by the addition of a stoichiometric amount of dilute sulfuric acid at 0°. The precipitate was removed by filtration and washed with cold water. The filtrate and the washing were lyophilized to give 2′,3′-*O*-isopropylidene guanosine 5′-mono-*p*-nitrophenyl phosphate (IV) (155 mg., 85%) as an amorphous white solid which could not be crystallized either as the free acid or as its cyclohexylamine salt. *Anal.* Calcd. for $C_{19}H_{21}N_6O_{10}P\cdot 6H_2O$: P, 4.89. Found: P, 4.88. The ultraviolet absorption spectrum at *p*H 2 showed a maximum at 258 mμ (ϵ_{258} 15,100) with a shoulder at 276 mμ (ϵ_{276} 14,000).

Guanosine 5′-Mono-*p*-nitrophenyl Phosphate (VII).—2′,3′-*O*-Isopropylidene guanosine 5′-di-*p*-nitrophenyl phosphate (180 mg.) was hydrolyzed with barium hydroxide in aqueous acetone as above. After extraction of the *p*-nitrophenol with ether, the aqueous solution was adjusted to *p*H 2.7 with acetic acid and held in a boiling water-bath for 1.5 hours. Barium was removed with sulfuric acid and the aqueous solution lyophilized to give guanosine 5′-mono-*p*-nitrophenyl phosphate (VII) as a fluffy white solid (145 mg., 90%) which could not be crystallized. *Anal.* Calcd. for $C_{16}H_{17}N_6O_{10}P\cdot 5H_2O$: P, 5.38. Found: P, 5.34.

Guanosine 5′-Phosphate.—2′,3′-*O*-Isopropylidene guanosine (1.0 g.) was phosphorylated as described above to give the di-*p*-nitrophenyl phosphate ester III in 96% yield. This product was suspended in dioxane (25 ml.), lithium hydroxide (12 ml. of 1 *N*) was added and the suspension was shaken for ten minutes. More water (12 ml.) was added and the shaking was continued for 30 minutes. The yellow solution was neutralized with hydrochloric acid to *p*H 7–8, a little di-*p*-tolylurea was removed by filtration and the clear solution evaporated under reduced pressure. The residue was treated in either of the following two ways to remove the second *p*-nitrophenyl group.

(a) **Enzymatic Hydrolysis.**—The residue was dissolved in 25 ml. of tris[37]-buffer (0.1 *M*, *p*H 8.8) and filtered to remove a final trace of di-*p*-tolylurea. Magnesium acetate (25 ml. of 0.3 *M*) was added and the total volume brought to 150 ml. with the buffer solution. Crude rattlesnake

Digitized by Arya Samaj Foundation Chennai and eGangotri

venom[38] (62 mg.) was added and the solution was incubated at 37° for three hours.[39] The solution was cooled to room temperature, adjusted to *p*H 5 with glacial acetic acid and stirred for 20 minutes with 25 ml. of IR-120 ion-exchange resin (ammonium form) to remove magnesium ions. The resin was removed by filtration and washed thoroughly with water (the final volume of the filtrate was 260 ml.). Glacial acetic acid (28 ml.) was added and the solution adjusted to *p*H 2.7 (*p*H meter) by the dropwise addition of concentrated hydrochloric acid. The solution was heated in a boiling water-bath for 1 hour, cooled to room temperature and extracted seven times with 70-ml. portions of ether to remove *p*-nitrophenol. The aqueous solution was then evaporated to dryness under reduced pressure. The residue was taken up in water and adjusted to *p*H 8.5 with 4 *M* lithium hydroxide (total volume of solution *ca.* 25 ml.). Four ml. of 2 *M* barium acetate solution was added and the solution allowed to stand at room temperature for 1 hour. Barium phosphate was removed by centrifugation and the sediment washed with water. To the combined supernatants were added two volumes of 95% ethyl alcohol and the precipitation of the product was completed at −10° (1.5 hours). The barium salt of guanosine 5′-phosphate was collected by centrifugation, washed twice with cold 70% ethyl alcohol, then with 95% ethyl alcohol, acetone and finally ether. It was dried *in vacuo* over phosphorus pentoxide for several hours. The yield of this product which contained 8 moles of water of hydration varied between 1.263 and 1.377 g. (64–75%, based on 2′,3′-*O*-isopropylidene guanosine). *Anal.* Calcd. for $C_{10}H_{12}N_5O_8P\cdot Ba^{++}\cdot 8H_2O$ (mol. wt., 642.7): C, 18.69; H, 4.39; P, 4.82. Found in a reprecipitated sample: C, 18.59; H, 3.55; P, 4.67. A sample (117.48 mg.) of this material was dried overnight *in vacuo* at 100° over phosphorus pentoxide. The weight loss was 25.79 mg., corresponding to 7.8 moles of water. Paper chromatography in several solvent systems, paper electrophoresis (see above) and ion-exchange chromatography showed the sample to be homogeneous. R_f's in solvent systems not mentioned in Table I were as follows: solvent V, 0.63; solvent VI, 0.35; solvent VII, 0.28. Electrophoretic mobility under the conditions described above, 8.2 cm.

The above preparation has been carried out on three times the above scale and has given a 66% yield based on isopropylidene guanosine.

(b) **Alkaline Hydrolysis.**—The residue obtained above after mild alkaline hydrolysis of III was taken up in water (15 ml.), a final trace of di-*p*-tolylurea was removed by filtration and the solution evaporated again. The gummy residue was dissolved in 20 ml. of 1 *N* lithium hydroxide, the solution transferred to a polyethylene tube and heated in a boiling water-bath for 2.5 hours. The solution was cooled, adjusted to *p*H 2.7 with concentrated hydrochloric acid and heated in a boiling water-bath for 1.5 hours to remove the isopropylidene group. After cooling, the acidic solution was extracted repeatedly with ether until an extract gave no yellow color with alkali. The *p*H of the aqueous solution was then brought up to 8.5 with 4 *N* lithium hydroxide and the volume adjusted to *ca.* 25 ml. Four ml. of 2 *M* barium acetate was added and the precipitate (mixture of barium phosphate and some product) was collected by centrifugation and washed with water. Two volumes of ethyl alcohol were added to the combined supernatants and the precipitation was completed by storing at 0° for one hour. The white precipitate was collected by centrifugation, washed twice with 70% ethyl alcohol, once with 95% ethyl alcohol, then acetone and ether and dried at room temperature *in vacuo* over phosphorus pentoxide to give 1.00 g. of barium guanosine 5′-phosphate. Recovery of more product from the first precipitate was tedious, but could be accomplished as follows. The mixture of barium phosphate and guanosine 5′-phosphate was suspended in ice-water, cold hydrochloric acid was added until a clear solution resulted and the acidic solution was again neutralized to *p*H 8.5 with lithium hydroxide. The resulting precipitate was collected and again processed in the manner described above. Addition of two volumes of ethyl alcohol to the combined supernatants gave 163 mg. of an essentially pure product; total yield 1.163 g. (59%). Inorganic phosphate determination showed that this product contained 2.7% barium phosphate. One further reprecipitation gave a pure sample of barium guanosine-5′-phosphate (octahydrate); λ_{max} at *p*H 2, 256 mμ; ϵ_{max} 12,400; λ_{max} at *p*H 12, 260 mμ; ϵ_{max}, 12,100.

Quaternization of 2′,3′-*O*-Isopropylidene Guanosine 5′-Di-*p*-nitrophenyl Phosphate (III) to (VIII). (a) **By Heating the Neutral Ester III.**—2′,3′-*O*-Isopropylidene guanosine 5′-di-*p*-nitrophenyl phosphate (III) (45 mg.) was dissolved in acetonitrile (10 ml.) and heated under reflux for three hours. On cooling, very fine needles (30 mg.) separated and evaporation of the mother liquor gave more of the same material (10 mg., total yield 90%). This substance decomposed at 261–263°. *Anal.* Calcd. for $C_{25}H_{24}N_7O_{12}P$: C, 46.51; H, 3.75; N, 15.20. Found: C, 46.13; H, 4.10; N, 14.99.

Paper chromatography in four solvent systems (Table I) showed, as expected for the salt VIII, the presence of two spots, one corresponding to di-*p*-nitrophenyl phosphate and the other corresponding, presumably, to the cycloguanosine (R_f's in Table I). The ultraviolet absorption spectrum of the slower moving spot after elution from paper showed a single broad maximum (245–260 mμ) at *p*H 2. The spectra at *p*H 6.8 and 10.7 were essentially identical, there being strong end absorption (below 230 mμ) and a maximum at 266–267 mμ. Paper electrophoresis of VIII at *p*H 3.4 revealed the presence of the anion corresponding to di-*p*-nitrophenyl phosphate and a cation. Electrophoresis at *p*H 7.6, showed the presence of di-*p*-nitrophenyl phosphate ion and a second spot close to the origin and identical in behavior with guanosine, indicating the loss of a proton from the cation of cycloguanosine (VIII).

(b) Sodium benzoxide (40 mg. of sodium in 3 ml. of dry benzyl alcohol) was added to a solution of 2′,3′-*O*-isopropylidene guanosine 5′-di-*p*-nitrophenyl phosphate (300 mg.) in benzyl alcohol (2 ml.) and the resulting orange solution set aside for 15 minutes. Glacial acetic acid (0.15 ml.) was then added to the solution and benzyl alcohol removed under a high vacuum. The oily residue was taken up in 5% aqueous acetic acid, a trace of insoluble material removed by filtration and the solution extracted with ether until an extract gave no yellow color with alkali. Spectrophotometric analysis of the ethereal extracts showed that only 8 mg. of *p*-nitrophenol was present. Paper chromatography of the aqueous solution showed two major spots corresponding to the products obtained above in (a).

Phosphorylation of 2′,3′-*O*-Isopropylidene Guanosine with Phosphorus Oxychloride. (a) **Using One Equivalent of Phosphorus Oxychloride.**—The phosphorylation was carried out exactly as described by Michelson and Todd[10c] using 1.1 g. of 2′,3′-*O*-isopropylidene guanosine (one-fifth the scale used by the above authors). After the addition of water to the reaction mixture, the *p*H was brought to 9 with 4 *N* lithium hydroxide and the solvent was removed under reduced pressure. The residue was taken up in 50 ml. of 10% acetic acid and the *p*H of the solution adjusted to 2.7 (*p*H meter) by the addition of a little concentrated hydrochloric acid. The clear solution was heated for one hour in a boiling water-bath and then evaporated under reduced pressure. The white gel which resulted was dissolved in 30 ml. of water and the solution was lyophilized to a dry, light yellow powder (2.6 g.). This is designated as Product A.

(b) **Using 2.6 Equivalents of Phosphorus Oxychloride.**—Dry 2′,3′-*O*-isopropylidene guanosine (0.97 g., 3 mmoles) was dissolved in 15 ml. of freshly distilled dimethylformamide and 7 ml. of dry pyridine (distilled over calcium hydride) was added. The solution was cooled to −20° in an ice-salt bath and 0.72 ml. (7.8 mmoles) of freshly distilled phosphorus oxychloride was added in one batch, the temperature of the reaction mixture being maintained between −10 and −20°. Five-ml. aliquots were removed at intervals of 1 and 2 hours. These two aliquots and the remaining reaction mixture (after three hours reaction time) were worked up as described above in (a). These products of one, two and three hour reaction periods are designated as Products B, C and D, respectively.

Analysis of Products. (a) **Paper Chromatography and Paper Electrophoresis.**—Paper chromatography of Product A in solvents III and V showed the presence of five ultraviolet absorbing components. Three of these components were identified as guanine, guanosine and guanosine 5′-phosphate. The two other phosphorus-containing products corresponded in their R_f values to guanosine 5′-di- and tri-

(38) *Crotalus adamanteus*, Ross Allen's Reptile Farm, Silver Springs, Florida.

(39) Spectrophotometric estimation (440 mμ) of the liberated *p*-nitrophenol indicated 96% hydrolysis.

Digitized by Arya Samaj Foundation Chennai and eGangotri

phosphates.[7] The ultraviolet spectra (obtained by eluting the spots with 0.01 *N* hydrochloric acid) of these products were identical with that of guanosine 5′-phosphate. Hydrolysis with 0.1 *N* hydrochloric acid at 100° for 10 minutes gave, in both cases, guanine.

Paper electrophoresis of Product A revealed the presence of six ultraviolet-absorbing components. Three of these components were identified as guanine, guanosine and guanosine 5′-phosphate. The other three spots had mobilities relative to guanosine 5′-phosphate of 0.6, 1.2 and 1.7, the higher mobilities corresponding to those of guanosine 5′-di- and triphosphate,[7] respectively.

(b) **Ion-exchange Analysis.**—The following standard procedure was employed for quantitative analysis of the products obtained above. A 15-mg. sample of the lyophilized material was dissolved and the solution, after adjusting the *p*H to 8.5 with 1 *N* ammonium hydroxide, was applied to the top of a Dowex 2-chloride form (200–325 mesh) column (3 cm. × 0.8 cm. diameter). The column was washed first with water and then with 0.003 *N* hydrochloric acid to remove guanine and guanosine. Elution was then carried out using the linear gradient technique.[7] Five-ml. fractions were collected, using an automatic fraction cutter, and the optical density of the individual fractions at 260 mμ was determined using a Beckman spectrophotometer, model DU. The two peaks which emerged from the column after guanosine 5′-phosphate (GMP) were designated as G-X and G-Y. These two peaks corresponded in their positions to guanosine 5′-di- and triphosphate,[7] respectively. The results of these analyses are shown in Table II.

TABLE II

ION-EXCHANGE ANALYSIS OF PRODUCTS OF PHOSPHORYLATION OF 2′,3′-*O*-ISOPROPYLIDENE GUANOSINE WITH PHOSPHORUS OXYCHLORIDE

Product	% of total topical density at 260 mμ				
	Guanine	Guanosine	Guanosine 5′-phosphate	G-X	G-Y
A	1	49	31	14	5
B	3	61	17	18	1
C	4	55	23	17	1
D	4	52	19	16	9

Isolation of G-X and G-Y.—One gram of the lyophilized solid (Product A, see above) was triturated twice with 15-ml. portions of methyl alcohol to remove most of the inorganic salt (lithium chloride). The residual solid was dissolved in 25 ml. of water, adjusted to *p*H 8.5 with 1 *N* ammonium hydroxide and applied to a column (4 cm. × 2.2 cm. diameter) of Dowex-2 chloride form. The procedure used was as described in the preparation of guanosine 5′-di- and triphosphates.[7] The following fractions were obtained: guanosine 5′-phosphate; with 0.003 *N* HCl + 0.015 *M* NaCl (1,100 ml., 3,077, O.D. units at 260 mμ); G-X, with 0.003 *N* HCl + 0.1 *M* NaCl (1,000 ml., 1,674, O.D. units); G-Y, with 0.003 *N* HCl + 0.2 *M* NaCl (700 ml., 504, O.D. units). G-X was isolated as the barium salt (78 mg.) as described for guanosine 5′-diphosphate.[7] Since this product was found to be contaminated by inorganic pyrophosphate, purification was carried out as follows. Forty milligrams of the barium salt was shaken with Dowex-50-sodium form until it dissolved. The resin was removed by filtration and washed with water. The total solution (10 ml.) of sodium G-X was adjusted to *p*H 2.7 and stirred with 100 mg. of Darco-G-60 charcoal[40] (95% of the optical density was absorbed). The charcoal was washed with 3 portions of 0.003 *N* HCl to remove the last traces of pyrophosphate and then with three 5-ml. portions of ethyl alcohol–ammonia–water[41] to elute G-X. The ammoniacal solution was evaporated under reduced pressure and the product was precipitated as its barium salt at *p*H 7 from its aqueous solution. One reprecipitation was carried out by dissolving the barium salt in 0.5 ml. of 0.5 *N* HCl at 0° and adding ethyl alcohol.

Characterization of G-X.—(1) The above sample was converted to the sodium salt as described above and examined by paper chromatography and paper electrophoresis. Only one ultraviolet absorbing spot, corresponding to guanosine 5′-diphosphate,[7] could be detected. (2) The guanosine (ultraviolet absorption) to labile phosphorus to total phosphorus was found to be 0.9:1.0:2.0. (3) Tris-buffer (*p*H 7.5) and rattlesnake venom[38] were added to a small portion of the sodium salt solution. The mixture was incubated for 6 hours at 37° and then subjected to chromatography in solvent system III. The original spot of G-X (R_f, 0.12) had completely disappeared and a new spot corresponding to an authentic sample of guanosine (R_f, 0.44) had appeared. (4) The periodate–benzidine spray[42] gave a positive test for vicinal hydroxyl groups in both standard guanosine 5′-diphosphate and G-X.

G-Y was isolated by dissolving the solid obtained by lyophilization of the last ion-exchange fraction in 40 ml. of water and absorbing the nucleotide component on 100 mg. of charcoal (Darco-G-60) in two 50-mg. portions. The charcoal was collected by filtration through Celite, washed as above, and the nucleotidic material then eluted with four 5-ml. portions of 5% aqueous pyridine. The barium salt was prepared in the usual manner. Paper chromatography and paper electrophoresis indicated the presence of a major component, resembling guanosine 5′-diphosphate in behavior and a minor component which behaved like guanosine 5′-triphosphate.[7] Phosphorus analysis gave a ratio of labile to total phosphorus of 2:4.6; theory for guanosine 5′-triphosphate, 2:3.

Acknowledgments.—We wish to thank the National Research Council and the National Cancer Institute of Canada for grants in aid of this work.

Nucleoside Polyphosphates. V.[1] Syntheses of Guanosine 5′-Di- and Triphosphates

BY ROBERT WARNER CHAMBERS[2] AND H. G. KHORANA

RECEIVED JANUARY 12, 1957

The syntheses of guanosine 5′-di- and triphosphates by the reaction of guanosine 5′-phosphate and 85% phosphoric acid with dicyclohexyl carbodiimide are reported.

The condensation of an unprotected nucleoside 5′-monophosphate with orthophosphoric acid in the presence of a carbodiimide forms the basis of a simple method for the synthesis of nucleoside 5′-polyphosphates. The application of this method to the preparation of ADP, ATP,[3,4] UDP and

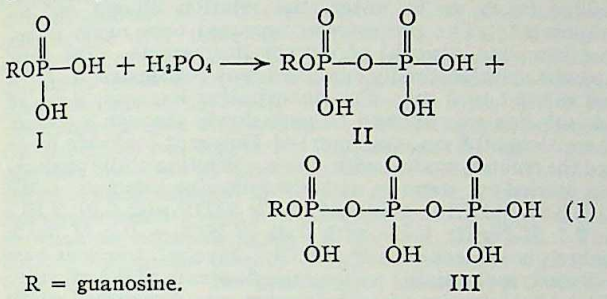
Digitized by Arya Samaj Foundation Chennai and eGangotri

UTP[3,5] has been recorded previously. In view of the increasing biochemical interest in the naturally occurring ribo- and deoxyribonucleoside 5′-polyphosphates[6] it was considered desirable to test further the generality of the method. Attention was turned, therefore, to the synthesis of guanosine 5′-di- (II) and triphosphate (III) from guanosine 5′-monophosphate[1] (I) (eq. 1)



R = guanosine. (1)

In order to determine the optimum conditions for the formation of GDP[3] and GTP[3] it was necessary to have a convenient and reliable method for analyzing the reaction mixtures. For this purpose, ion-exchange chromatography using a linear gradient elution apparatus, similar to that described by Paar,[7] proved satisfactory. Analytical columns, using Dowex-2 (chloride form) resin, were routinely run overnight and gave well separated sharp peaks of the various components. Use of the more expedient techniques of paper chromatography and paper electrophoresis was investigated in some detail but it was not possible to find a system which would separate GTP from higher guanosine polyphosphates.

The previous work on the condensation of nucleoside monophosphates with phosphoric acid has shown that in aqueous pyridine homogeneous reaction mixtures are not obtained. Since all of the reagent (DCC) must be present in the upper aqueous pyridine phase, this is the reaction phase. The lower "sirupy" phase contains a large proportion of the phosphoric acid as well as varying amounts of the nucleoside monophosphate, depending upon the pyridine–water ratio and the solubility of the nucleotide in pyridine. In this solvent system the rate of condensation was found to be, as expected, a function of the solubility of the nucleotide in the upper phase. Thus, UMP is soluble in anhydrous pyridine and the synthesis of uridine polyphosphates occurs rapidly even when the pyridine–water ratio is as high as fifteen. AMP, on the other hand, has a very low solubility in pyridine and, consequently, the formation of adenosine polyphosphates is much slower even when the pyridine–water ratio is as low as seven.

In the present work, GMP was found to be even less soluble in aqueous pyridine than AMP and, consequently, the rate of polyphosphate formation was very slow. Attempts, therefore were made to find an alternative solvent system. Freshly distilled dimethylformamide was found to give a homogeneous reaction mixture and the condensation was then, as expected, very rapid. Several experiments were performed using varying proportions of GMP, phosphoric acid and DCC. The results obtained in a typical experiment by removing aliquots from the reaction mixture at suitable time intervals are shown in Table I (Experimental Section). These experiments, as may be seen from the data, were disappointing in that GDP and/or GTP could not be obtained as major products of the reaction. Higher guanosine polyphosphates, which have not been investigated further, were formed rapidly after an initial lag period and accounted for more than 50% of the total nucleotidic material.

The lack of specificity in effecting condensation is a disadvantage of the carbodiimide method for the synthesis of nucleoside polyphosphates and this fact necessitates the use of a large excess of orthophosphoric acid. Therefore, large amounts of inorganic polyphosphates are concomitantly formed. As the reaction proceeds the concentration of these substances increases[8] leading to a complicated kinetic situation. Qualitatively, the above results are perhaps not surprising since the condensation of inorganic pyrophosphate, which may form quite rapidly in the homogeneous system, with either GDP or GTP, would lead directly to higher guanosine polyphosphates.

In view of these unsatisfactory results[9] the aqueous pyridine solvent system was investigated in more detail. As in previous work, many experiments were performed in which the proportion of the reactants, pyridine–water ratio and reaction time were varied. The results of three selected experiments are shown in Table I. In no experiment was a completely satisfactory yield of GDP and GTP[10] obtained. The best yield was about 25% each of GDP and GTP, representing a total of about 50% conversion of GMP to the desired products. These conditions were used on a preparative scale.[11]

The main problem in isolating nucleoside di- and triphosphates synthesized by the present method is the separation of the nucleotides from the inorganic polyphosphates. In the adenosine series, ADP and ATP were precipitated as mercury salts with Lohmann reagent. In the uridine series, the removal of the inorganic phosphates was accomplished by repeated precipitation of the free nucleotides from alcohol–ether mixtures. Neither of

(7) C. W. Paar, *Biochem. J.*, **56**, xxvii (1954).

(8) This will be so, especially, when homogeneous reaction mixtures are employed. In aqueous pyridine, the higher polyphosphates are, probably, removed from the reaction phase (see above) because of their greater insolubility.

(9) Attempts were also made to hydrolyze partially the higher guanosine 5′-polyphosphates to GDP and GTP by heating the reaction mixture at *p*H 4.5 and 100° as described by Lieberman [THIS JOURNAL, **77**, 3373 (1955)]. However, large amounts of GMP were formed and the yields were only slightly better than in the unhydrolyzed reaction mixture. The polyphosphates appeared to be stable on heating in 0.5 *N* sodium hydroxide at 100° for 1 hour.

(10) The optimum reaction time appeared to be 67–72 hours. Long reaction periods were also found necessary by Kennedy for the synthesis of cytidine diphosphate choline and related compounds [E. P. Kennedy, *J. Biol. Chem.*, **222**, 185 (1956)]. This also is due probably to the low solubility of the phosphate esters in the pyridine phase.

(11) The aqueous pyridine system required longer reaction time and much larger quantities of DCC than dimethylformamide reaction mixtures. However, the aqueous pyridine system was selected for the preparative scale since difficulty was experienced in obtaining clean ion-exchange separation of the products from the dimethylformamide runs (see Experimental).

Digitized by Arya Samaj Foundation Chennai and eGangotri

these methods was completely satisfactory, however, since they were attended by large losses of the nucleotides. A mild and general method for the above purpose utilizes the selective adsorption of the nucleotides by charcoal. The use of charcoal for the separation of nucleotides from salts and inorganic phosphates has previously been recorded by a number of workers[12] and the method was used successfully in the present work.[13] However, some irreversible adsorption of the nucleotides occurred and best recoveries, after trials with different kinds of charcoal and eluting agents, were about 65%.

Using charcoal purification in conjunction with ion-exchange chromatography, pure samples of GDP and GTP were obtained in about 10% overall yield, representing a 20% conversion of GMP to the desired compounds. The ultraviolet absorption spectra of the synthetic samples and their behavior on paper chromatography, paper electrophoresis and ion-exchange chromatography were identical with samples of GDP and GTP isolated from yeast.[14] Furthermore, both samples were biologically active in the assay system developed by Ayengar, *et al.*[14] Elemental analysis indicated that GDP, precipitated as the barium salt at an acidic *p*H, was best represented by the formula GDP·$Ba_{1/2}$·$3H_2O$ while dibarium GTP appeared to be the hexahydrate.[15]

While the yields of GDP and GTP were somewhat disappointing this work represents the first chemical synthesis of these newly discovered nucleoside polyphosphates. Furthermore the present experiments together with the independent work reported from other laboratories[16] serve to illustrate the general scope of the carbodiimide method in the synthesis of biologically important "anhydrides." It also seems clear that one limitation of the technique is the contrasting solubility properties of DCC, on the one hand, and the nucleotides and related compounds on the other, in aqueous pyridine. Nevertheless this is the only solvent system which has proved satisfactory so far. It might be expected that the situation would be improved in some cases by using a water-soluble carbodiimide. Experiments on the use of such reagents will be reported in a forthcoming communication.[13b]

Experimental

The Reaction of GMP and Phosphoric Acid with DCC. (a) In Dimethylformamide.—A series of experiments was carried out as follows: GMP (5 mg. of the free acid)[17] was dissolved in 0.4 ml. of freshly distilled dimethylformamide and the solution cooled to 0°. Five microliters (*ca.* 5 equiv.) of 85% phosphoric acid and 58 mg. of DCC were added and the resulting clear solution allowed to stand at 0° for various lengths of time. The reaction was stopped by the addition of water. Dicyclohexylurea was removed by filtration, washed three times with small portions of water and the combined filtrate adjusted to *p*H 8 with ammonium hydroxide. The solution was evaporated under reduced pressure, the residue taken up in water, the solution filtered and re-evaporated. The process was repeated once again to ensure complete removal of dimethylformamide. The clear aqueous solution finally obtained was readjusted to *p*H 8 and diluted to 5 ml. For quantitative analysis, 2 ml. of this solution was allowed to pass slowly through a column (2 cm. long, 0.8 cm. diameter) of Dowex 2 (chloride form) and the column washed with water. Elution of the products was carried out stepwise with the following solutions: GMP with 0.01 *N* HCl + 0.015 *M* NaCl; GDP with 0.01 *N* HCl + 0.1 *M* NaCl; GTP with 0.01 *N* HCl + 0.2 *M* NaCl; higher phosphates with 2 *N* HCl. Five-ml. fractions were collected, maintaining an average flow rate of 0.5 ml./min. The optical density of each fraction was determined at 260 mμ. The results of these experiments are shown in Table I.

TABLE I

REACTION OF GMP AND PHOSPHORIC ACID WITH DCC

Conditions				Products[a]			
Solvent	H_3PO_4[b]	DCC[b]	Time (hr.)	GMP	GDP	GTP	Higher phosphates
DMF	5	20	0.5	58	18	17	7
DMF	5	20	0.75	13	17	30	42
DMF	5	20	1.0	7	14	23	55
Pyridine–water ratio							
4:1[c]	5	50[e]	24	64	14	13	9

10:1	5	100[f]	67	28	26	25	20

[a] Expressed as percentages of the total optical density recovered from the column. [b] Equivalents based on GMP used. [c] Homogeneous reaction mixture. [d] These conditions are identical to those reported for the preparation of ADP and ATP (experiment 5, Table II[4]). [e] 10 equiv. at first, 10 equiv. each after 2, 4, 7 and 9 hours. [f] 40 equiv. at first, 40 equiv. DCC + 0.1 ml. water after 24 hours; 20 equiv. DCC + 0.1 ml. H_2O after 48 hours.

(b) In Aqueous Pyridine. General Method.—Monopyridinium[18] GMP (63 mg.)[19] was dissolved in an appropriate amount of water and enough pyridine was added to bring the solution to the desired pyridine–water ratio. The final volume of the solvent was 7 ml. in all of the reactions. Orthophosphoric acid (85%) and DCC were added as indicated in Table I and the mixture was shaken vigorously for the specified length of time. The reaction mixture was worked up as described above for the dimethylformamide reactions. Aliquots (0.3 ml.) were analyzed on the same size ion-exchange columns as described above, but using a linear gradient elution technique.[7,20,21] The mixing flask contained 500 ml. of 0.003 *N* hydrochloric acid while the reservoir contained an equal volume of 0.5 *M* sodium chloride solution in 0.003 *N* hydrochloric acid.

The results of the experiments using aqueous pyridine are given in Table I.

Isolation of GDP and GTP.—Monopyridinium GMP (635 mg.) was dissolved in 6 ml. of water and 60 ml. of py-

ridine was added, followed by phosphoric acid (0.5 ml. of 85%) and DCC (11.6 g.). The two phase reaction mixture was agitated vigorously using a mechanical shaker. After 24 hours, 11.6 g. of DCC and 1 ml. of water were added and the shaking was continued. A final addition of DCC (5.8 g.) and water (1 ml.) was made after 50 hours. After a total reaction time of 72 hours, the mixture was worked up as described above for the small scale experiments except that the filtrate and washings obtained after removal of the dicyclohexylurea were extracted twice with ether to remove a small amount of unchanged DCC. The clear aqueous solution (50 ml.; total optical density in 0.003 *N* hydrochloric acid at 260 mμ, 13,800 units) was adjusted to *p*H 2.8 (*p*H meter) with hydrochloric acid and to it were added five 0.5-g. portions of charcoal,[22] the solution being stirred for three minutes after each addition. After the final addition, the suspension was stirred for ten minutes and the charcoal was then collected by filtration through Celite. The total filtrate (optical density, 2570 units at 260 mμ) was treated in a similar manner with five 0.2-g. portions of charcoal and the charcoal collected again on the first filter bed. The filtrate (1000 optical density units) was retreated with 2 × 0.1 g. of charcoal. The final filtrate contained 200 optical density units and was discarded (total absorption, 97%). The total charcoal was washed free of inorganic phosphates by suspending it three times in 100-ml. portions of 0.003 *N* hydrochloric acid.[23] The total acidic filtrate (1640 optical density units) was treated twice with 0.3-g. portions of charcoal and the filtration and washing repeated. The nucleotidic material was recovered by batchwise elution of the charcoal with an ethyl alcohol–ammonia–water mixture.[12b] The combined eluates were concentrated using a Craig flash evaporator at bath temperature below 30°. The concentrated solution was filtered to remove a small amount of charcoal and some insoluble material. The *p*H of the filtrate (63 ml., containing 8760 optical density units; 64% recovery) was adjusted to 8.5 with ammonium hydroxide and the solution passed through a Dowex-2 (chloride form, 200–325 mesh) column (7 cm. high, 2.2 cm. diameter) at a flow rate of 1 ml./min. The column was washed with water (flow rate 4 ml./min.) until the optical density of the effluent dropped below 0.200 (total water wash, 180 ml. containing 35 optical density units). The nucleotides were eluted in a stepwise manner as follows. One hundred ml. fractions were collected and immediately adjusted to *p*H 7. Eluents were changed when the optical density of the effluent fell below 0.2. GMP with 0.003 *N* HCl + 0.015 *M* sodium chloride (1500 ml. containing 2460 optical density units; 28% of the total optical density applied to the column); GDP with 0.003 *N* HCl + 0.1 *M* sodium chloride (900 ml. containing 2182 optical density units, 25%); GTP with 0.003 *N* HCl + 0.2 *M* sodium chloride (1400 ml. collected, after discarding the first 500 ml., total optical density recovered, 2058 units, 23%); higher phosphates with 2 *N* HCl (800 ml. containing 1649 optical density units, 19%). Recovery of the optical density from the column was quantitative.

GDP and GTP fractions were concentrated to about 30 ml. using a flash evaporator (bath temperature, under 30°), the concentrate readjusted to *p*H 7 and lyophilized.

(22) Nuchar C was treated as described by D. Lipkin, P. T. Talbert and M. Cohn, THIS JOURNAL, **76**, 2871 (1954), for Darco G-60 except that drying was carried out at 60–70° for 48 hours.

(23) Washing with water caused excessive losses of ultraviolet absorbing material.

GDP was isolated as its barium salt by the procedure described by Hall and Khorana[5] for UDP except that 0.5 ml. of 2 *M* barium acetate was used. The product[24] after drying over phosphorus pentoxide *in vacuo* weighed 70 mg. A second crop (11 mg.) was obtained from the mother liquor by the addition of ethyl alcohol. Fifty milligrams of the first crop was dissolved in 0.7 ml. of 0.5 *N* hydrochloric acid at 0°, a small amount of insoluble material was removed by centrifugation and the *mono* barium salt was precipitated by the addition of ethyl alcohol. The product was dried over phosphorus pentoxide *in vacuo* (30 mg.) and then equilibrated with air before analysis. *Anal.* Calcd. for $C_{10}H_{14}N_5O_{11}P_2Ba_{1/2}\cdot 3H_2O$ (564.94): C, 21.26; H, 3.57; P, 10.97. Found: C, 21.30; H, 3.87; P, 11.12. The ratio of guanosine (using 12.4 × 10^3 as the E_{max} at 257 mμ): labile phosphorus:total phosphorus was 1:1:2. Paper chromatography in the four solvent systems mentioned above, paper electrophoresis (Table II) and ion-exchange chromatography showed a single ultraviolet absorbing component.

TABLE II

CHROMATOGRAPHIC AND ELECTROPHORETIC DATA

Compound[a]	R_f's in solvents III	V	VI	VII	Electrophoretic mobility[b]
GMP	0.24	0.63	0.35	0.28	8.2
GDP	.10	.75	.14	.18	14.9
GTP	.06	.78	.13	.15	16.2

[a] All the data recorded are on sodium salts prepared by shaking the barium salts with Dowex-50 sodium form and spotting the supernatant. [b] Centimeter movement toward anode in 2 hours. (For details see preceding paper.[1])

GTP was isolated as its barium salt, as described by Hall and Khorana[5] for the isolation of barium UTP, and dried over phosphorus pentoxide; 97 mg. *Anal.* Calcd. for $C_{10}H_{12}N_5O_{14}P_3Ba_2\cdot 6H_2O$ (902.02): C, 13.31; H, 2.68; P, 10.30. Found: C, 13.37; H, 3.30; P, 10.47. The ratio of labile phosphorus to total phosphorus was 2:3.

Paper chromatography, paper electrophoresis (Table II) and ion-exchange chromatography showed that the main ultraviolet absorbing component corresponded to GTP isolated from yeast.[14] A trace spot corresponding to GDP also was present. The ultraviolet spectra of synthetic GDP and GTP in 0.01 *N* hydrochloric acid were identical with that of GMP under the same conditions.

Paper Chromatography and Paper Electrophoresis.—Paper chromatography and paper electrophoresis were carried out as described in the preceding paper.[1] The solvent systems designated as III, V, VI and VII proved suitable in the present work. The R_f values and electrophoretic mobilities are listed in Table II.

Acknowledgment.—We wish to thank the National Research Council and the National Cancer Institute of Canada for grants in aid of this work.

The Beckmann Rearrangement of β-Dihydroumbellulone Oxime[1]

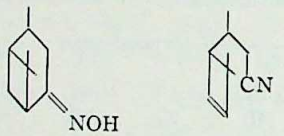
By W. Dickinson Burrows[2] and Richard H. Eastman

Received March 9, 1957

The course of the Beckmann rearrangement of the oxime of a bicyclic ketone having an α-carbon atom which is quaternary, a bridge-head and part of a cyclopropane ring system has been ascertained. The rearrangement proceeds in the usual fashion to produce a lactam, with the cyclopropyl group migrating.

Introduction

As a rule, bicyclic ketoximes having a bridge-head α-carbon atom yield, under the conditions of the Beckmann rearrangement, an unsaturated nitrile rather than the usual lactam.[3,4] One case of many[5] which is specially pertinent here is that of verbanone oxime (I)[6] which gives a poor yield of an unsaturated nitrile, presumably II.



I II

On a purely analogical basis, β-dihydroumbellulone oxime (III) might be expected to yield the cyclopropenyl nitrile IV. It gives, in fact, only the lactam V or products derived therefrom in excellent yield under a variety of rearrangement conditions.

The Structure of the Lactam.—That the product of the rearrangement was a bicyclic lactam and not an unsaturated nitrile was evident immediately from its saturated character and its infrared absorption spectrum (3.12 μ (NH), 6.04 μ (CO)), characteristic of a six-membered lactam.[7] However, the data permitted no unequivocal choice between the alternatives V and VI.[8] Accordingly the degradation of the lactam was undertaken. The attachment of the nitrogen atom to the cyclopropane ring was revealed when hydrolysis of the lactam in 50% sulfuric acid gave a nitrogen-free, saturated, *keto* acid of ten carbon atoms (V → VIII). When the keto acid was found to be 5-oxo-3,4,6-trimethylheptanoic acid (VIII) by study of its properties and further degradation, the structure assignment V to the lactam became unequivocal.

The keto acid VIII was obtained as a crystalline, dextrorotatory solid of m.p. 49.5–50°, $[\alpha]^{27}D$ +50°. In accord with the assigned structure which contains one labile (a) and one stable (b) asymmetric carbon atom, it underwent rapid mutarotation (+50° → −23°) on being dissolved in 10% potassium hydroxide solution. Furthermore, when oximation of the crystalline keto acid was carried out in pyridine a single oximino acid of m.p. 156° was obtained,[9] but when carried out in aqueous potassium hydroxide a mixture of stereoisomeric oximino acids was obtained that was separated into forms melting at 134° and 156°, the latter being identical with that from the reaction in pyridine. Oximation of the oily residue from the crystallization of the acid of m.p. 49.5–50° gave the oximino acid of m.p. 134°.

The relationship of the ketone and carboxyl groups in the keto acid VIII was demonstrated by preparation of the enol lactone IX which showed bands at 5.72 and 5.93 μ characteristic of a six-membered enol lactone,[10] yet no bands corresponding to =C—H out-of-plane deformation.[7] Permanganate oxidation of the enol lactone IX produced a keto γ-lactone assigned structure X on the basis of analysis, infrared spectrum and solubility properties. As a by-product of the oxidation, isobutyric acid was evident, and the integrity and position of the isopropyl group in the keto acid VIII was established by isolation of isobutyric acid and isopropylamine from the hydrolysis of the Beckmann rearrangement product of the aforementioned oximino acid derived from VIII.

One property of the keto acid VIII which is not at first glance in accord with its structure is its ability to produce bromoform in significant amounts in the haloform reaction. It is proposed that under the strongly alkaline conditions of the reaction, acetic acid is eliminated in a reverse Michael reaction, producing a double bond between carbon atoms a and b in formula VIII, and that the resulting α,β-unsaturated ketone, $(CH_3)_2CHCOC(CH_3)=CHCH_3$, provides acetaldehyde for the haloform reaction through retrograde aldol condensation.[11]

(2) Taken from the Doctoral Dissertation of W. D. Burrows in the Department of Chemistry, Stanford University.

(3) A. H. Blatt, *Chem. Revs.*, **12**, 218 (1933).

(4) It is to be noted that the α-carbon atom involved need not be at a bridge-head since menthone oxime gives both unsaturated nitrile and normal lactam depending on conditions [O. Wallach, *Ann.*, **277**, 157 (1893); **312**, 197 (1900)].

(5) For some other examples see A. Weiner and A. Piquet, *Ber.*, **37**, 4308 (1904); O. Wallach, *Ann.*, **315**, 289 (1901); W. H. Glover, *J. Chem. Soc.*, **93**, 1299 (1908).

(7) L. J. Bellamy, "The Infrared Spectra of Complex Molecules," John Wiley and Sons, Inc., New York, N. Y., 1954, p. 176.

(8) The preparation of the *p*-toluenesulfonate and *p*-bromobenzenesulfonate derivatives of the oxime III and their conversion to the lactam indicated structure V if it was assumed that bulk considerations required a *trans* orientation of the sulfonate group and the bridge-head connection, and that the rearrangement proceeded by the usual migration of *trans*-oriented groups.

(9) The oximino acid of m.p. 156° was found to be identical in rotatory power and infrared absorption with an oximino acid (m.p. 154°) reported earlier (R. H. Eastman and J. C. Selover, This Journal, **76**, 4118 (1954)) as an anomalous product of the nitrosation of β-dihydroumbellulone.

(10) G. I. Fujimoto and J. Prager, *ibid.*, **75**, 3259 (1953).

(11) Reversal of the aldol condensation under the conditions of the haloform test has been observed for pulegone which gives a similar anomalous positive result in the test [O. Wallach, *Ann.*, **289**, 337 (1896)]. As precedent for the retrograde Michael condensation may be cited the formation of tanacetophorone from α-tanacetonedicarboxylic ester ["The Terpenes," R. H. Eastman and C. R. Noller in Gilman's "Organic Chemistry," John Wiley and Sons, Inc., New York, N. Y., 1953, Vol. IV, p. 632].

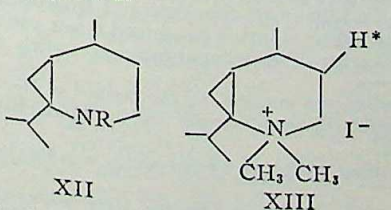
Products Derived from the Lactam.—The smooth hydrolytic degradation of the lactam V to the keto acid VIII came only at the end of a series of unsuccessful degradations whose course became clear with the structure of the lactam established. Some observations on the properties of the compounds prepared are of interest.

When the lactam V, dihydroumbellulone oxime (III) or its *p*-toluenesulfonate were heated at the steam-bath in concentrated sulfuric acid, sulfur dioxide was evolved and the pyridone XI was produced in good yield, presumably through oxidation by the sulfuric acid of the intermediate VII. In accord with the structure assigned, the pyridone (m.p. 220°) was optically inactive, weakly basic, inert to neutral permanganate and had ultraviolet maxima at 232 mμ (ε 6020), and 308 mμ (ε 6620) similar to those reported for 2-pyridone.[12] It showed one active hydrogen by the Zerevitinov method, was not reduced by lithium aluminum hydride and could be distilled through zinc dust intact.

Lithium aluminum hydride reduction of the lactam V proceeded smoothly to the bicyclic amine XII (R = H) which was cleanly methylated by the formic acid–formaldehyde method, then quaternized to XIII with methyl iodide. The ultraviolet absorption spectrum of the tertiary amine XII (R = CH_3) showed λ_{max}^{alc} 213 mμ (ε 1450) comparable to that reported[13] for 1-methylpiperidine, λ_{max}^{alc} 213 mμ (ε 1600), to be contrasted with that for 1-ethyl-2-methyl-Δ^2-tetrahydropyridine,[13] λ_{max}^{alc} 231 mμ (ε 5100), and further indicative[9] of the inability of the cyclopropane ring to act as an electron acceptor as does a vinyl group[14] in establishing a chain of conjugation.



Surprisingly, and in contradistinction to the behavior of cyclopropyltrimethylammonium hydroxide which yields cyclopropene under the conditions of the Hofmann elimination,[14a] the methiodide XIII reverted to the tertiary amine XII (R = CH_3) with loss of methanol. Failure of β-elimination to occur is not rationalized readily on steric grounds, for a nearly coplanar four-center transition state involving the starred hydrogen atom in XIII can be obtained with an approximate model of the system. The situation parallels that found for the quaternary salt of tetrahydroquinoline which also eliminates methanol under the conditions of the Hofmann degradation.[15] The two systems have in common an electron-rich, highly polarizable group attached to the quaternary nitrogen which may so diffuse the positive pole on the nitrogen as to reduce the acidity of the starred proton on the β-carbon below the level required for elimination.[16]

As a base, the secondary amine XII (R = H) (pK_B' 4.9) was 1.6 pK_B' units weaker than piperidine (pK_B' 3.3)[17] and comparable in strength with cyclopropylamine (pK_B' 5.34).[18] The low basic strength of the amine XII (R = H) relative to piperidine can as well be attributed to the base-weakening effect of the cyclopropane ring attachment[18] and a decrease in solvation of the ammonium ion on account of blocking by the isopropyl group as to any specific interaction of the bicyclic system.[19]

The lactam V, absorbing maximally at 211 mμ (ε 5190), showed only a moderate exaltation over ε-caprolactam, absorbing maximally at 208 mμ (ε 3700), definitely not of the magnitude found for the unsaturated lactam, 7-oxo-3,5,5-trimethyl-Δ^2-tetrahydroazepine which contains the system

(17) The pK_B' values are apparent values obtained by titration of the amines in 50% by volume ethanol using a Beckman pH meter standardized against aqueous buffers in the manner of Roberts and Chambers (ref. 18).
(18) J. D. Roberts and Vaughan C. Chambers, THIS JOURNAL, **73**, 5031 (1951).
(19) A. F. Trotman-Dickenson, *J. Chem. Soc.*, 1293 (1949). The difference of 1.6 in pK_B' values between the amine XII (R = H) and piperidine is only slightly greater than that of 1.0 pK_B' unit between dimethylcyclopropylamine (pK_B' 6.3) and cyclopropylamine (pK_B' 5.3) (ref. 18). The small increment may be attributed to less hindrance to solvation in the dimethyl compound than that encountered in XII (R = H).

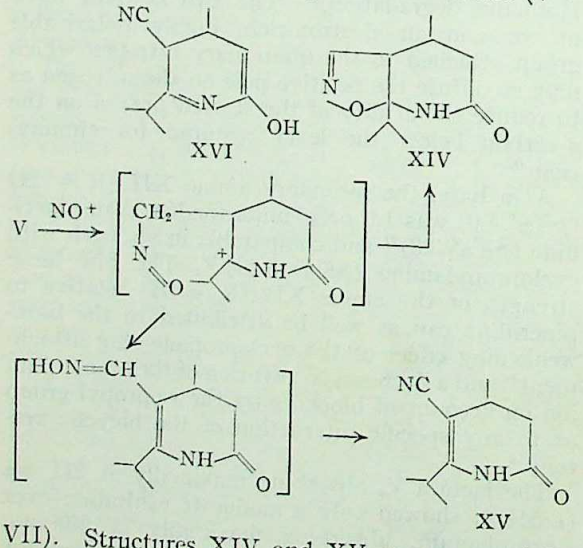
C=C—NH—COR and is reported[20] to absorb maximally at 218.5 mμ (ε 10,700). The absorption of the vinylamide is what might be expected of the dienoid system, $C{=}C{-}\overset{+}{N}H{=}C{-}O^{-}$, an important contributor to both ground and photoexcited states. The bathochromic shift in absorption from that observed for a saturated lactam may be attributed to stabilization of the photo-excited state by contribution of $\overset{-}{C}{-}C{=}\overset{+}{N}H{-}C{=}O$ in which the vinyl group acts as an electron acceptor but not by contributions wherein the double bond is an electron donor, since $\overset{+}{C}{-}C{=}\overset{+}{N}H{-}\overset{-}{C}{-}O^{-}$ would be of disproportionately high energy as a consequence of adjacent like-charges. Since the cyclopropane system apparently operates efficiently only as a donor of electrons[21] to adjacent unsaturated centers, the small shift observed is not unexpected.

Nitrosation of the lactam V either by the use of nitrogen tetroxide or nitrosyl chloride failed to produce an N-nitrosoamide for rearrangement with nitrogen elimination to the corresponding lactone according to the method of White,[22] but gave instead products resulting from attack of the nitrosating agent on the cyclopropane ring in the same sense as that envisioned for the attack of a proton in the sulfuric acid hydrolysis of the lactam (V→



VII). Structures XIV and XV are proposed for two of the products on the basis of properties and spectroscopic data. The substance assigned structure XIV was a colorless solid, m.p. 164°, which was optically active, insoluble in dilute acid or base, not readily oxidized by permanganate in acetone, and of ultraviolet absorption essentially identical with that of the lactam V. The infrared absorption spectrum showed bands characteristic[7] of the NH (3.12, 3.22), amide carbonyl (5.94) and C=N (6.21) groups.

The compound assigned structure XV was a white solid, m.p. 156°, which was optically active and insoluble in dilute acid or base. It reduced permanganate in acetone instantly but did not readily react with bromine in carbon tetrachloride. The infrared absorption spectrum revealed bands at 3.12–3.22, 4.53, 5.92 and 6.12 μ attributed[7] to NH, C≡N, C=O and C=C groups, respectively. The ultraviolet absorption spectrum showed maxima at 261 mμ (ε 9200) and 280 mμ (ε 8150). Surprisingly, hydrogen cyanide, detected by the formation of prussian blue, was one of the products of hydrolysis of the nitrile XV. This bizarre property is not unreasonable in terms of the tautomeric structure XVI which reveals the nitrile as the product of the addition of hydrogen cyanide across one of the double bonds of the enol form of a pyridone. Difficulty in obtaining the nitrile precluded further investigation of this unusual property.

Acknowledgment.—We wish to express our sincere appreciation to the Eli Lilly Co. and the Nichols Fellowship donor for their generous aid to W. D. B. during this investigation.

Experimental

The Beckmann Rearrangement of Dihydroumbellulone Oxime: Preparation of 5-Methyl-1-isopropyl-2-azabicyclo-[4.1.0]heptanone-3 (V).—Dihydroumbellulone oxime[23] (III) (14.4 g.) was dissolved in 30 ml. of dry pyridine, cooled to 0°, and added to a chilled solution of 25 g. of *p*-toluenesulfonyl chloride (or *p*-bromobenzenesulfonyl chloride), in 30 ml. of dry pyridine. The mixture was allowed to stand one hour, then heated on a steam-bath. After 20 min. of heating the mixture turned dark red and began boiling. Heating was continued another 10 min., and the reaction mixture was allowed to stand at room temperature about two hours, after which it was poured on a mixture of 25 ml. of sulfuric acid and 120 g. of ice. The product solidified in two hours and was separated and washed with cold water, leaving 10.3 g. of white, crystalline material with a soapy odor. Ether extraction of the filtrate and washings yielded another 2.7 g. The product melted at 102.2–102.7°[24] after recrystallization from cyclohexane and had $[\alpha]^{27}D$ +60 ± 1° (*l* 0.5, *c* 4, 95% ethanol); spectra[25]: λ_{max}^{alc} 211 mμ, ε 5190; λ_{max}^{mull} 3.12, 6.04 μ.

Anal.[26] Calcd. for $C_{10}H_{17}NO$: C, 71.81; H, 10.25; N, 8.38. Found: C, 71.92; H, 10.14; N, 8.48.

Dihydroumbellulone Oxime *p*-Toluenesulfonate.—Two grams of oxime III was dissolved in 5 ml. of dry pyridine. The solution was cooled to 0° and added to a chilled solution of 4.0 g. of toluenesulfonyl chloride in 5 ml. of pyridine. After standing at room temperature for four hours the mixture was poured into 50 ml. of 3 *N* sulfuric acid, chilled and extracted with ether. Recrystallization of the product from medium boiling petroleum ether yielded 1.0 g. of white solid melting at 84.6–85.3°.

Anal. Calcd. for $C_{17}H_{23}NO_3S$: C, 63.52; H, 7.21; N, 4.36; S, 9.97. Found: C, 63.31; H, 7.41; N, 4.52; S, 10.18.

When the oxime toluenesulfonate was heated with dry pyridine a slow decomposition to tarry products was the result. The addition of concentrated hydrochloric acid to the heated pyridine solution produced a fair yield of the lactam V. Heating the toluenesulfonate with aqueous or

ethanolic potassium hydroxide produced dihydroumbellulone as the major product.

5-Oxo-3,4,6-trimethylheptanoic Acid (VIII).—The lactam V (10.0 g.) dissolved in 60 g. of 50% sulfuric acid was heated on a steam-bath for six hours. The reaction mixture was poured on ice, made basic with sodium hydroxide, extracted with ether, reacidified, and extracted with chloroform. The chloroform was removed under vacuum leaving 9.0 g. of pale-yellow, odorless oil, about 25% of which crystallized when diluted with one volume of hexane and chilled to −10°. The material melted at 49.5–50° after recrystallization from hexane; $[\alpha]^{27}D$ +50 ± 0.5° (*l* 0.5, *c* 4, 95% ethanol); spectrum: λ_{max}^{mull} 5.82 (sh.), 5.85, 6.04 (sh.) μ.

The oxime was prepared by refluxing 0.25 g. of the crystalline keto acid, 0.25 g. of hydroxylamine hydrochloride, 2 ml. of dry pyridine and 2 ml. of absolute alcohol two hours on a steam-bath. The solvents were evaporated in a current of air, and the residue was stirred with 5 ml. of cold water until the oxime crystallized. After recrystallization from 50% ethanol–water, the oxime melted at 154–156° and had $[\alpha]^{26}D$ +6.9 ± 0.1° (*l* 0.5, *c* 4, 95% ethanol). The liquid portion of the lactam hydrolysate similarly treated yielded an oxime melting at 132–134° after repeated recrystallizations. The latter was submitted for combustion analysis.

Anal. Calcd. for $C_{10}H_{19}NO_3$: C, 59.66; H, 9.52. Found: C, 59.88; H, 9.60.

To 5.0 g. of a mixture of both oximes of VIII dissolved in 15 ml. of dry pyridine was added a chilled solution of 6.0 g. of toluenesulfonyl chloride in 15 ml. of pyridine. The resulting solution was allowed to stand 45 min., then heated 30 min. on a steam-bath, after which it was poured on a mixture of 25 g. of concentrated sulfuric acid and ice. Extraction with ether and evaporation of the solvent left 4.5 g. of very thick, red sirup, which was hydrolyzed, without purification, by boiling it with 50% sulfuric acid for 4 hours. The hydrolysis mixture was extracted with ether, the aqueous portion was set aside and the ether extract was distilled at atmospheric pressure, then redistilled at 20 mm. into two fractions. The low-boiling fraction was shown to be isobutyric acid by its odor, infrared spectrum and index of refraction. The high-boiling fraction was not characterized.

The aqueous portion from the hydrolysis was made strongly basic with 50% sodium hydroxide and was immediately steam distilled into 10% hydrochloric acid, about 50 ml. of distillate being collected. The distillate was evaporated to dryness, leaving 0.5 g. of red, hygroscopic solid. This material was decolorized with Norit in absolute ethanol and left in a drying pistol two hours at 100° and 20 mm. The dry, colorless solid melted at 136–139° dec. in a sealed capillary and was thereby identified as isopropylamine hydrochloride.

2-Oxo-4,5-dimethyl-6-isopropyl-3,4-dihydropyran (IX).—Two grams of the keto acid VIII was refluxed for five hours with 6 ml. of acetic anhydride. The acetic acid and most of the acetic anhydride were then distilled off, and the residue was dissolved in ether and extracted with sodium carbonate solution. The ether solution was evaporated and the residual oil was distilled at 15–20 mm. with bath temperature near 125°, yielding 1.2 g. of colorless, fragrant oil. The oil, purified by liquid–vapor partition chromatography, had $n^{24}D$ 1.4583; spectrum, λ_{max}^{film} 5.72, 5.93 μ.

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.58. Found: C, 71.49; H, 9.42.

One gram of enol lactone IX was suspended in 25 ml. of water with 2 g. of sodium bicarbonate in a 100-ml. r.b. flask equipped with a mechanical stirrer, and 1.25 g. of potassium permanganate was added in small portions. The color produced by 0.1 g. of additional permanganate was not dispelled after one hour of stirring. The reaction mixture was filtered through Celite and the manganese dioxide cake was washed with water. Filtrate and washings were acidified to *p*H 1 with sulfuric acid, resulting after 20 min. in the separation of an oil. The oil was extracted with chloroform and the extract was distilled at 20 mm. with bath temperature near 125° to yield 0.5 g. of colorless oil with a camphor-like odor. The product, purified by liquid–vapor partition chromatography, had $n^{20.2}D$ 1.4519, and is assigned the structure of β,γ-dimethyl-γ-isobutyryl-γ-butyrolactone (X); spectrum, λ_{max}^{film} 5.65, 5.86 μ.

Anal. Calcd. for $C_{10}H_{16}O_3$: C, 65.19; H, 8.75. Found: C, 64.84; H, 8.67.

4,5-Dimethyl-6-isopropyl-2-pyridone (XI).—Five grams of lactam V was dissolved in 25 ml. of concentrated sulfuric acid and heated on a steam-bath one hour. The reaction mixture was poured on 100 g. of ice and extracted with ether to remove acidic and neutral material. The aqueous portion was diluted with water to 250 ml., made basic with sodium carbonate, and continuously extracted four days with ether. Most of the product crystallized out on the sides of the ether reservoir, and by evaporation of the solvent there was obtained 1.63 g. of white, crystalline solid melting at 219–220° with rapid sublimation and having $[\alpha]D$ 0.0 ± 0.2° (*l* 0.5, *c* 4, chloroform); spectra, λ_{max}^{alc} 232 mμ (ε 5190), 308 mμ (ε 6620); λ_{max}^{mull} 3.20 (sh.), 6.03, 6.50 μ.

Anal. Calcd. for $C_{10}H_{15}NO$: C, 72.70; H, 9.15. Found: C, 72.98; H, 9.08.

Dihydroumbellulone oxime (III), treated with sulfuric acid as described above for the lactam V, gave a 12% yield of the pyridone.

5-Methyl-10-isopropyl-2-azabicyclo[4.1.0]heptane (XII, R = H).—To 20 g. of lactam V in 750 ml. of absolute ether was added in small portions 12 g. of lithium aluminum hydride. The mixture was refluxed gently for five hours, then allowed to stand at room temperature 12 hours, and finally decomposed with 100 ml. of ethanol followed by 100 ml. of water. The ether was decanted and the residual hydroxides were washed with several hundred milliliters of absolute ether. The ethereal portions were combined, evaporated on a steam-bath, and the residual product was distilled, yielding 11.1 g. of colorless oil with an odor like crushed geraniums, boiling at 35–35.5° at 2–3 mm., $[\alpha]^{24}D$ +108.5 ± 0.5° (*l* 0.5, neat), d^{20}_4 0.864, $n^{20}D$ 1.4561.

Anal. Calcd. for $C_{10}H_{19}N$: C, 78.35; H, 12.50; N, 9.15. Found: C, 78.44; H, 12.31; N, 9.18.

The picrate, m.p. 164.5–166.5° (Found: C, 50.42; H, 5.91), and the benzenesulfonamide, m.p. 98.8–99.8° (Found: C, 65.58; H, 7.86), were prepared in the usual ways.

2,5-Dimethyl-1-isopropyl-2-azabicyclo[4.1.0]heptane (XII, R = CH_3).—To 4.8 g. of reduced lactam (XII, R = H) were added, with cooling, 4.5 g. of 85% formic acid and 3.0 g. of 36–38% formaldehyde. The solution was allowed to stand overnight, then heated two hours on a steam-bath, after which 3 ml. of concentrated hydrochloric acid was added. The mixture was evaporated on a steam-bath to remove excess formaldehyde and formic acid. The residue was diluted with several volumes of water, made strongly basic with 20% sodium hydroxide, and steam distilled. The distillate was made strongly basic with solid potassium hydroxide, extracted with ether, and the extract was distilled without ebullator to give in about 50% yield a colorless oil boiling at 57–59° at 7 mm., $[\alpha]^{24}D$ +34.4 ± 0.1° (*l* 0.5, neat), d^{27}_4 0.867, $n^{20}D$ 1.4578.

Anal. Calcd. for $C_{11}H_{21}N$: C, 78.96; H, 12.65; N, 8.38. Found: C, 78.86; H, 12.40; N, 8.44.

The picrate, m.p. 160–165° dec., was prepared by adding the amine to a hot, saturated solution of picric acid in ethanol.

The methiodide XIII was prepared by refluxing 0.51 g. of XII, R = CH_3, with a fivefold excess of methyl iodide. The product (0.58 g.), recrystallized from methanol, decomposed above 280° and had $[\alpha]^{25}D$ −29.2 ± 0.4° (*l* 0.5, *c* 5, methanol).

Anal. Calcd. for $C_{12}H_{24}NI$: C, 46.60; H, 7.82. Found: C, 46.49; H, 7.96.

The Hofmann elimination was attempted by boiling this methiodide (0.10 g.) under reflux with 10 ml. of 50% sodium hydroxide solution for 10 minutes followed by steam dis-

tillation of the oil which had separated. The oily layer from the steam distillate was identical in infrared absorption characteristics with the tertiary amine XII, R = CH_3.

Nitrosation of the Lactam V with Nitrogen Tetroxide.—Five grams of lactam dissolved in 25 ml. of glacial acetic acid was chilled to 0° and saturated with dry nitrogen tetroxide. After standing one hour at room temperature the solution was poured on 100 g. of ice. A yellow solution resulted which turned red-brown when made basic with 50% sodium hydroxide. The basic solution was extracted with ether and the aqueous portion was set aside. In the best run, evaporation of the ether extract left about 0.25 g. of white, crystalline solid melting at 162–164° after recrystallization from ethyl acetate. The solid had $[\alpha]^{26}D$ +288 ± 5° (*l* 0.5, *c* 4, 95% ethanol), and is assigned structure XIV; spectrum, λ_{max}^{mull} 3.12, 3.22, 5.94, 6.21 μ.

Anal. Calcd. for $C_{10}H_{16}N_2O_2$: C, 61.20; H, 8.22. Found: C, 61.33; H, 8.33.

The aqueous portion from the extraction was acidified with concentrated sulfuric and extracted with ether. The extract was evaporated on a steam-bath to remove ether, then under reduced pressure to remove acetic acid. A black tar remained that slowly crystallized to yield 0.75 g. of white needles melting at 155–156° after recrystallization from ethanol–water; $[\alpha]^{26}D$ −104 ± 5° (*l* 0.5, *c* 4, 95% ethanol). This compound is assigned structure XV; spectra: λ_{max}^{alc} 261 mμ (ϵ 9200), 280 mμ (ϵ 8150); λ_{max}^{mull} 3.12, 4.52, 5.92, 6.12 μ.

Anal. Calcd. for $C_{10}H_{14}N_2O$: C, 67.38; H, 7.92; N, 15.72. Found: C, 67.71; H, 7.88; N, 15.55.

When the nitrile XV (0.20 g.) was warmed for 15 minutes with 10 ml. at 10% sodium hydroxide a colorless solution was obtained. Acidification of the hydrolysis mixture caused an oil to separate and when this oil was dissolved in dilute sodium bicarbonate solution, carbon dioxide and hydrogen cyanide, detected by the formation of prussian blue, were evolved.

Synthesis of Poly-β-alanine from Acrylamide. A Novel Synthesis of β-Alanine[1]

BY DAVID S. BRESLOW, GEORGE E. HULSE AND ALBERT S. MATLACK

RECEIVED MARCH 15, 1957

Poly-β-alanine has been prepared by the base-catalyzed polymerization of acrylamide. By fractionation samples with weight-average molecular weights as high as about 80,000 have been prepared. Acid hydrolysis of the polymer constitutes a simple preparation of β-alanine in yields of 90% starting with acrylamide. Substituted acrylamides and analogous sulfonamides yield polymers of much lower molecular weight. An unusual mechanism for the polymerization is proposed.

Poly-β-alanine has been prepared previously by the elimination of HX from a β-alanine derivative, $H_2NCH_2CH_2COX$, where X is NH_2,[2] OC_2H_5,[3] Cl[4] or OH,[5] or by the elimination of thiophenol and carbon dioxide from N-carbothiophenyl-β-alanine.[6] It is questionable whether any of these methods give high molecular weight polymers.[7] Poly-β-alanine has now been prepared by the base-catalyzed polymerization of acrylamide, a readily available compound.

Preparation of Polymers.[9]—Poly-β-alanine formed a mixture of water-soluble and water-insoluble polymers when acrylamide, usually in an inert diluent, was contacted with a strong base in the presence of an inhibitor for radical-induced polymerization. The technique of polymerization was similar in most cases, typical examples being given in the Experimental section.

The effects of certain variables on the polymerization are shown in Table I.

The highest molecular weight water-insoluble polymer was obtained in pyridine. The largest amount of water-insoluble polymer was formed in the absence of solvent. Phenyl-β-naphthylamine was superior to hydroquinone as a radical inhibitor, presumably because hydroquinone acted as a chain terminator for basic polymerization. It was possible to carry out small-scale preparations without an inhibitor, but in larger runs the presence of an inhibitor was advantageous. Sodium *t*-butoxide in *t*-butyl alcohol appeared to be the best catalyst; apparently the alcohol did not terminate polymer chains. Dilution lowered the yield and molecular weight of water-insoluble polymer somewhat.

Properties of Poly-β-alanine.—Each polymerization yielded a spectrum of products with fractions soluble in pyridine, fractions soluble in water and fractions soluble only in solvents such as formic acid being obtained. The pyridine-soluble material consisted largely of monomer and dimer, the latter analyzing reasonably well for CH_2=CH-$CONHCH_2CH_2CONH_2$. This polymerized much like acrylamide itself on addition of base.

Both the water-soluble and the water-insoluble polymers were highly crystalline, melting at about 325° and about 340°, respectively, with considerable decomposition. Both gave the same well-defined X-ray diffraction pattern, the water-insoluble polymer being somewhat more crystalline than the water-soluble. The lattice spacings of 4.6, 3.9 and 3.55 Å. had relative intensities of 60, 10 and 100, respectively, for the water-insoluble polymer.

The water-insoluble polymer showed typical polyamide solubility. Thus, it was soluble in for-

(7) Noguchi and Hayakawa reported a molecular weight of 43,500 for their sample of poly-β-alanine. However, their intrinsic viscosity of 0.063 in formic acid is remarkably low for this molecular weight. Recently Weymouth[8] has shown that several polypeptides made by this procedure have relatively low molecular weights, of the order of 1000–5000.

mic acid, dichloroacetic acid, phenol containing 11% water and concentrated aqueous salt solutions. It was also soluble in phenol at 100°, in boiling ethylene glycol and in boiling glycerol. Viscosities were higher in anhydrous formic acid than in 90% formic acid; this behavior has been observed with other polyamides.[10]

Poly-β-alanine has been prepared with weight-average molecular weights of about 80,000 (by light scattering in 90% formic acid). The molecular weight of the water-insoluble polymer could be raised by solution and reprecipitation. Thus, a sample of molecular weight 58,000, corresponding to a 1% specific viscosity of 0.500 and an intrinsic viscosity of 0.416 (both in 90% formic acid), after solution in formic acid and precipitation by water, had a molecular weight of 76,000, corresponding to a specific viscosity of 0.639.

Structure of Poly-β-alanine and the Mechanism of Polymerization.—Acrylamide might polymerize with base in a manner analogous to that of methacrylonitrile[11]; the product would then be polyacrylamide. That the polymer was essentially linear poly-β-alanine was proved by hydrolysis of the polymer with 50% sulfuric acid. This constitutes a convenient synthesis of β-alanine from acrylamide, a readily available starting material, in essentially one step, since it is only necessary to heat acrylamide with a base and hydrolyze the reaction mixture. Yields of about 90% based on acrylamide can be obtained.[12]

The presence of an olefinic double bond as an end group in poly-β-alanine was shown by both hydrogenation and polarographic reduction. However, in the absence of data on the number-average molecular weight of these polymers, the presence of some alkoxy end groups cannot be ruled out entirely. The presence of a $-CONH_2$ end group was shown by carrying out a hydrolysis with hydrochloric acid and determining the ammonium chloride formed.

Two alternative modes of initiation must be considered for the base-catalyzed polymerization of acrylamide.

$$CH_2{=}CHCONH_2 + B^- \rightleftharpoons CH_2{=}CHCONH^\ominus + BH \quad (1)$$

$$CH_2{=}CHCONH_2 + B^- \rightleftharpoons B{-}CH_2\overset{\ominus}{C}HCONH_2 \rightleftharpoons B{-}CH_2CH_2CONH^\ominus \quad (2)$$

Equation 1 is preferred as the major source of initiation for several reasons. One is the olefinic end group found in the polymer. More important, however, is the isolation of the unsaturated dimer from the reaction mixture. If initiation were by equation 2, B-$CH_2CH_2CONH_2$ should be present and none was found. It must be admitted, however, that the unsaturated dimer could be formed from equation 2 by a scheme such as the following, the proton migrating in a *quasi* six-membered ring.

$$B{-}CH_2CH_2CONH^\ominus + CH_2{=}CHCONH_2 \longrightarrow B{-}CH_2{-}CHCO(NH)\ (H^\ominus)\ H_2NOC{-}CH{-}CH_2 \longrightarrow CH_2{=}CHCONHCH_2CH_2CONH_2 + B^- \quad (3)$$

Two possible methods of growth must be considered, too. One would involve a continuation of the process depicted in the first part of reaction sequence 3, the anion transferring its charge from carbon to nitrogen as shown in equation 2, and

[a] Polymerization of 10 g. of monomer in 100 ml. of solvent, 0.1 g. of sodium as catalyst, overnight at 100°, except as noted. [b] 0.01 g. of hydroquinone (HQ) or 0.02 g. of phenyl-β-naphthylamine (PBNA). [c] Of water insoluble-polymer. [d] Of 1% solutions in anhydrous formic acid (A), 90% formic acid (F) or dimethylformamide (D) at 25°. [e] Five days at 100°. [f] Exothermic reaction allowed to subside. [g] Two days at 100°. [h] Mixture heated gradually to 220°, then cooled; it was not fractionated. [i] Sodium methoxide catalyst (5%). [j] Heated 6 hr., purified by ether extraction. [k] Sodium catalyst (5%), polymer extracted with hot ethanol, viscosity of 0.5% solution at 150°. [l] 25% solution. [m] Polymer extracted with hot acetone.

growth continuing on the amide part of the chain. This could be initiated by the anion shown in equation 1 in exactly the same manner. Chain termination would involve reaction of the growing chain with BH, regenerating the base B^-, or with any other active hydrogen compound present. This mechanism differs from the usually accepted mechanism for the base-catalyzed polymerization of acrylates[11] only in the necessity for a proton migrating from nitrogen to carbon for each addition. A second possibility exists, however, for the initiating species shown in equation 1. This involves essentially a chain transfer reaction in each growth step, as shown in reaction sequence 4.

$$CH_2{=}CHCONH^{\ominus} + CH_2{=}CHCONH_2 \longrightarrow CH_2{=}CHCONHCH_2\overset{\ominus}{C}HCONH_2 \quad (4)$$

$$CH_2{=}CHCONHCH_2\overset{\ominus}{C}HCONH_2 + CH_2{=}CHCONH_2 \longrightarrow CH_2{=}CHCONHCH_2CH_2CONH_2$$

$$+ CH_2{=}CHCONH^{\ominus} \longrightarrow CH_2{=}CHCONHCH_2\overset{\ominus}{C}HCO(NHCH_2CH_2CO)_nNH_2$$

Although the sequence has been depicted with the growing anion chain abstracting a proton from acrylamide, it could abstract a proton from any acidic species present, such as the unsubstituted amide end group of an already formed polymer chain[13]; the chain could grow, therefore, from either end. This unusual polymerization is in essence an addition polymerization which should have all the attributes of a condensation polymerization[14]; the polymerization should be relatively slow and the molecular weight should increase with conversion. Our preference for this mode of polymerization is at present based on only one observation. It would appear to us highly unlikely that, in any usual type of polymerization, one could isolate both a dimer and a high molecular weight polymer from the same reaction mixture. If chain transfer were so prevalent as to form a dimer, a high molecular weight polymer should not be found. Inasmuch as both were isolated, the molecular weight distribution must be unusually broad, and it seems that at least the major amount of polymer must be formed by this chain-transfer route.

Other Polymers.—The polymerization of several other monomers containing both an active hydrogen and an activated double bond is summarized in Table II. Any substituent in the acrylamide molecule decreased both the rate and degree of polymerization, a substituent on the nitrogen showing the greatest effect, on the β-carbon next and on the α-carbon least. The sulfonamides appeared to give lower molecular weight polymers than their carbon analogs. A factor influencing the molecular weight of all these polymers may be the inherent reversibility of addition reactions of α,β-unsaturated systems.

Experimental[15]

Materials.—Acrylamide (American Cyanamid Co.) was sublimed *in vacuo* before use. Methacrylamide was obtained from Rohm and Haas Co. The following compounds were prepared by described procedures: crotonamide,[16] 3,4,5,6-tetrahydrobenzamide,[17] 2-propene-1-sulfonamide,[18] ethylenesulfonanilide[19] and acrolein oxime.[20] The synthesis of ethylenesulfonamide will be reported elsewhere.

To prepare *p*-acrylamidobenzenesulfonamide a solution of 5.0 g. of sulfanilamide hydrochloride (Matheson Co.) in 70 ml. of water at 50° was treated with 4.0 g. of acrylic anhydride[21] and a solution of 2.05 g. of sodium acetate in 12 ml. of water. The mixture was stirred for 20 minutes at 65°, cooled to 0° and the product collected by filtration; the yield was quantitative. After two recrystallizations from aqueous ethanol (containing a trace of phenyl-β-naphthyl-

(13) Since alkyl groups are electron-donating, the hydrogen on a terminal amide group should be more acidic than one on a substituted amide group in the chain. If this were not so, a highly branched polymer would result. N-Substituted acrylamides have been found to polymerize much less readily under these conditions.

(14) Flory would actually classify this as a condensation polymerization (P. J. Flory, "Principles of Polymer Chemistry," Cornell University Press, Ithaca, N. Y., 1953, pp. 37–40).

amine) at 60°, colorless needles melting at 215° were obtained.

Anal. Calcd. for $C_9H_{10}SO_3N_2$: C, 47.77; H, 4.46. Found: C, 47.70; H, 4.55.

Polymerization of Acrylamide in Pyridine.—Acrylamide (10 g.) was added with stirring at 100° to a solution of 0.02 g. of phenyl-β-naphthylamine in 100 ml. of pyridine (dried over barium oxide). When the acrylamide had dissolved, a solution of 0.1 g. of sodium in 10 ml. of *t*-butyl alcohol was added. Polymer began to form on the walls in 4 minutes. After heating for 16 hr., the polymer was removed by filtration, extracted with boiling water for an hr. and dried *in vacuo* at 80° (4.8 g.). After neutralization with acetic acid, the aqueous extract was evaporated to dryness. The residue (3.6 g.) was purified by pouring an aqueous solution into methanol; 2.6 g. of polymer was isolated.

After the addition of phenyl-β-naphthylamine (0.02 g.) the mother liquor was evaporated to dryness *in vacuo*. On sublimation of the residue at 0.1 mm., acrylamide (0.4 g., m.p. 81–83°) was obtained, leaving behind 1.2 g. of solid.

Anal. Calcd. for $C_6H_{10}O_2N_2$: H_2 absorption, 1.42; NH_3, 12.0. Found: H_2 absorption, 1.18; NH_3, 12.5.

Application of the above polymerization procedure to this dimer fraction converted it into a mixture of polymer fractions similar to the one described.

Bulk Polymerization of Acrylamide.—To a solution of 0.4 g. of sodium in 15 ml. of *t*-butyl alcohol was added 40 g. of acrylamide and 0.04 g. of hydroquinone. The alcohol was removed *in vacuo* at 40°, and the residue was cautiously heated (while being stirred with a thermometer) to form a homogeneous melt. In a short time the temperature began to rise rapidly as a vigorous exothermic reaction set in. After polymerization was complete (three minutes), the solid foam was extracted with boiling water for 1 hr., yielding 26 g. of water-insoluble polymer with a specific viscosity of 0.23 (1% in anhydrous formic acid).

β-Alanine.—A solution of 30 g. of crude polymer prepared by bulk polymerization (before water extraction) in 120 ml. of 50% sulfuric acid was refluxed for 4 hr. The cooled solution was diluted with water and adjusted to *p*H 7 with hot aqueous barium hydroxide. After removal of the barium sulfate by filtration, the filtrate was evaporated to dryness. The residue (34 g., 90.5% yield based on acrylamide) melted at 191–193°. One recrystallization from aqueous methanol raised the melting point to 195–196°; a mixed melting point with authentic β-alanine showed no depression. The compound was further identified by conversion to the β-naphthalenesulfonamide derivative, m.p. 136–137° (lit.[22] m.p. 135.5–136.5°).

Polymerization of 2-Propene-1-sulfonamide.—A mixture of 2-propene-1-sulfonamide (1.30 g.), phenyl-β-naphthylamine (0.01 g.) and sodium (0.03 g.) was heated overnight at 100°. The product, a brittle resin, was extracted with 2% acetic acid, taken up in acetone and poured into ether. After drying overnight *in vacuo* the polymer weighed 0.50 g.

Alkaloids of *Rauwolfia Canescens* Linn. IV.[1] The Structure of Pseudoreserpine

BY M. W. KLOHS, F. KELLER, R. E. WILLIAMS AND G. W. KUSSEROW

RECEIVED MARCH 20, 1957

The isolation and characterization of pseudoreserpine ($C_{32}H_{38}O_9N_2$), a new alkaloid possessing hypotensive and sedative activity, is reported. On methanolysis pseudoreserpine yielded methyl 3,4,5-trimethoxybenzoate and a new alkamine designated methyl pseudoreserpate, which has been shown to be methyl 17-nor-reserpate by conversion to the 17,18-diacetyl derivative of methyl 17-nor-3-isoreserpate and through the conversion of reserpine to methyl pseudoreserpate.

A continuation of our investigation of the crude reserpine fraction obtained from the roots of *Rauwolfia canescens* Linn. has resulted in the isolation of **pseudoreserpine,** a new reserpine-like alkaloid, possessing hypotensive and sedative activity.

Further development of the chromatogram which had previously yielded deserpidine and reserpine[2] afforded an additional fraction from which crystalline pseudoreserpine was obtained. As a test for homogeneity, this compound was submitted to a 24-plate countercurrent distribution between 5% acetic acid and chloroform–methyl-chloroform (60:40) and gave a single peak which corresponded well with the theoretical curve for a single substance.

The analyses of pseudoreserpine and its derivatives, as well as equivalent weight determinations, were in accord with the empirical formula $C_{32}H_{38}O_9N_2$. The infrared spectrum of pseudoreserpine showed certain similarities to the spectrum of reserpine in exhibiting ester carbonyl absorption at 5.86 μ and a band at 6.13 μ, attributed to polarization of an indole nucleus by a methoxyl group in the 6-position.[3] The region of >NH, –OH absorption showed two discrete bands at 2.81 and 2.90 μ, one of which could be attributed to an indole >NH, and the other to the possible presence of a hydroxyl group. The existence of the latter group was further demonstrated by the formation of an O-acetyl derivative. The ultraviolet spectrum of pseudoreserpine was identical to that of reserpine and indicated that it also contained the 3,4,5-trimethoxybenzoyl and 6-methoxyindole chromophores.

On treatment with sodium methoxide, pseudoreserpine yielded methyl 3,4,5-trimethoxybenzoate and a new alkamine, methyl pseudoreserpate. The analysis of this new base was in agreement with the empirical formula $C_{22}H_{28}O_5N_2$ and showed the presence of two methoxyl groups. The infrared spectrum of methyl pseudoreserpate revealed a single strong broad band in the >NH, –OH region (2.95 μ) indicative of hydrogen bonding, ester carbonyl absorption at 5.74 μ, and the 6-methoxyindole band at 6.10 μ. The ultraviolet spectrum was identical to that of methyl reserpate, the alkamine of reserpine.

Lithium aluminum hydride reduction of pseudoreserpine afforded the corresponding triol which

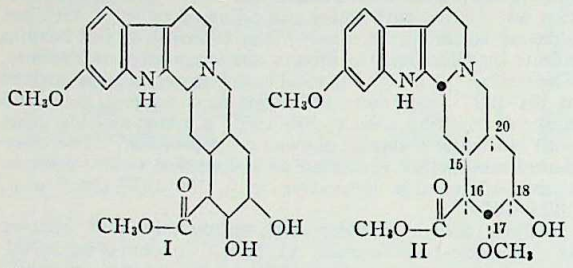
was transparent in the carbonyl region of the infrared spectrum.

The above data and biogenetic considerations suggested that the basic structure of methyl pseudoreserpate was closely related to that of methyl reserpate (II) and differed by the presence of a hydroxyl, rather than a methoxyl group at the C-17 position in ring E, as shown in structure I.



Since the structure of methyl reserpate has been proven conclusively by degradation[4] and synthesis[5] it was desirable, in order to obtain experimental evidence in support of the above hypothesis, to attempt the conversion of these two compounds to a common degradation product. The 17,18-diacetyl derivative of methyl 17-nor-3-isoreserpate was chosen as the intermediate for this purpose, since its formation would appear to follow a straight forward path and permit the bulk of the work to be carried out on the more abundant starting material, reserpine. The first step toward this objective was the preparation of methyl 17-nor-3-isoreserpate (IV) through the demethylation and concomitant C-3 epimerization[6] of reserpine (III) with aqueous hydrobromic acid followed by methylation with diazomethane.

A comparison of the physical and spectral properties of methyl pseudoreserpate and methyl 17-nor-3-isoreserpate showed them to be dissimilar[7] which was not unexpected; however, since it was presumed, in view of the biological activity of pseudoreserpine,[8] that methyl pseudoreserpate possessed the less stable β-oriented hydrogen at C-3. For this reason, methyl pseudoreserpate was treated under conditions known to effect epimerization at C-3, *i.e.*, by extended refluxing in acetic anhydride[6] to yield the epimeric diacetyl derivative. A comparison of this compound with the diacetyl derivative of methyl 17-nor-3-isoreserpate showed them to be identical on the basis of their physical and spectral properties. Conclusive evidence was thus available for the assignment of the basic ring system in methyl pseudoreserpate, as well as the location of its functional groups as shown in structure I.

After establishing this portion of the structure for methyl pseudoreserpate, the stereochemical implications of the above transformations on the six asymmetric centers at C-3, C-15, C-16, C-17, C-18 and C-20 remained to be considered. The assignment of a *cis* relationship for the hydrogen atoms at C-15, C-16 and C-20 as in methyl reserpate seemed unambiguous, but the chemical evidence in favor of the β-configuration at C-3 could not be considered conclusive in view of the possibility that inversion at C-17 and C-18 by epoxide formation and opening, rather than a simple isomerization at C-3, might have occurred during the prolonged treatment of methyl pseudoreserpate with acetic anhydride. It was, therefore, deemed advisable to obtain additional experimental evidence prior to the definite assignment of configuration at these centers.

Further work by direct chemical methods was hindered at this stage by the exhaustion of our supply of pseudoreserpine; however, the opportune report of the conversion of 3-isoreserpine to reserpine[9] by oxidation with mercuric acetate followed by reduction with zinc in aqueous acetic acid afforded a facile route through which methyl 17-nor-3-isoreserpate could be converted to methyl pseudoreserpate and thereby clarify the stereochemical ambiguities in question. By this procedure, methyl 17-nor-3-isoreserpate (IV) was converted to methyl pseudoreserpate which was identified by comparison with an authentic sample prepared through the methanolysis of pseudoreserpine. The lithium aluminum hydride reduction product of VII was also identical with that obtained through the reduction of pseudoreserpine. With these data at hand, it is now possible to assign configurations to the asymmetric centers of methyl pseudoreserpate and thus postulate its complete structure as VII.

Conclusive evidence is not available to place the site of attachment of the 3,4,5-trimethoxybenzoyl linkage on methyl pseudoreserpate in forming pseudoreserpine; however, by analogy with the other members of this series, reserpine, rescinnamine and deserpidine, we favor C-18 VI.

Pharmacology.—Pharmacological studies show that the cardiovascular and sedative effects of pseudoreserpine are very similar to, but weaker than, those of reserpine.[10]

Experimental[11]

The Isolation of Pseudoreserpine.—The crude reserpine fraction (100 g.) obtained from the roots of *Rauwolfia canescens* Linn. as previously described,[12] was chromatographed on a 3-inch column, using Merck acid-washed alumina (3 kg.) as the adsorbent. The column was developed with benzene–chloroform (3:1) and the percentage of chloroform was increased until straight chloroform and finally mixtures of chloroform–methanol were used as eluting solvents, the progress of the column being followed by spot testing the

(7) In our previous communication[1] we noted the more negative molecular rotation of methyl pseudoreserpate as compared to methyl 17-nor-3-isoreserpate and made mention of this as being contrary to that observed for C-3 isomers of reserpine and its derivatives. Dr. C. F. Huebner has kindly pointed out, in a private communication, that while there is a negative shift in going from reserpine to 3-isoreserpine, the opposite holds true for methyl reserpate and its C-3 isomer; thus the change in rotation observed for methyl 17-nor-3 isoreserpate was to be expected for this derivative.

(8) It has been shown previously[4] that reserpine loses its characteristic physiological activity upon epimerization at the C-3 center.

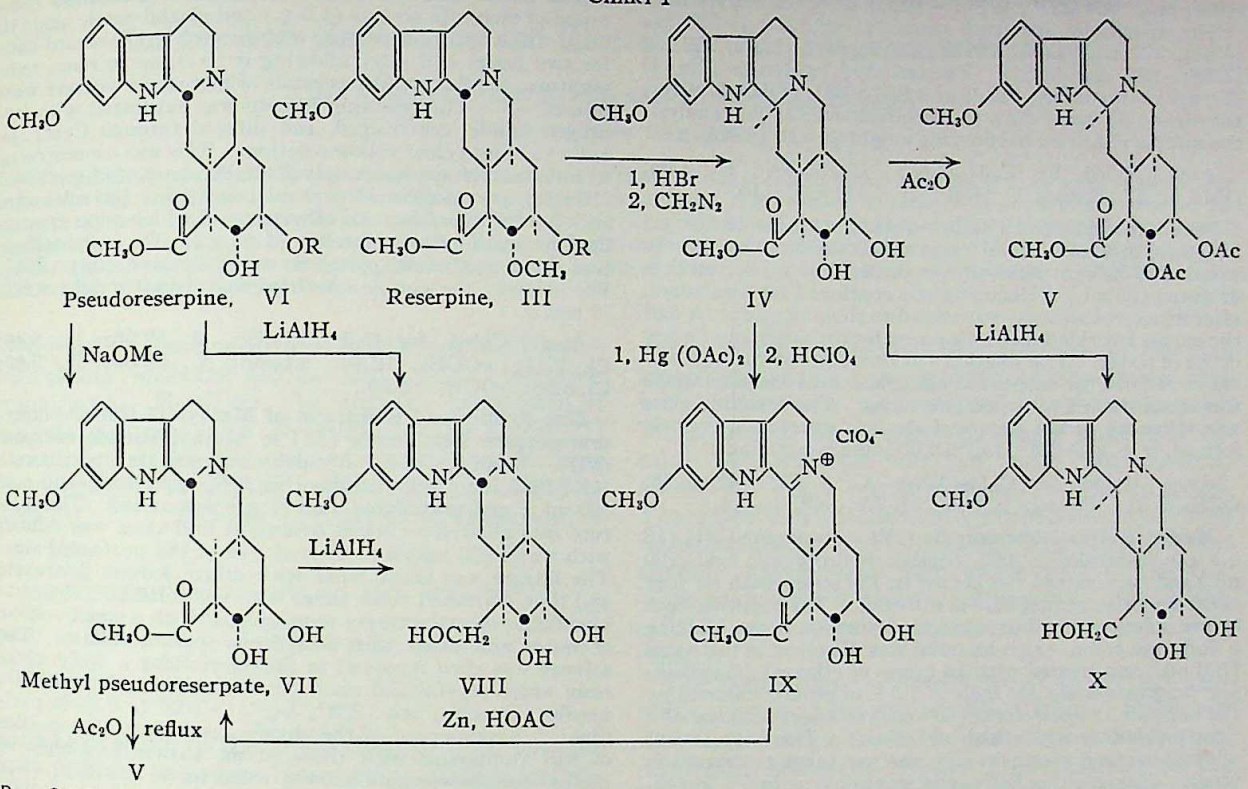
CHART I



R = 3,4,5-trimethoxybenzoyl

eluents with Frohde reagent and by the use of infrared spectra. Deserpidine was obtained from the fraction eluted with benzene–chloroform (1:1); on reaching the solvent system chloroform–methanol (99:1) a new alkaloid was encountered in trace amounts, m.p. 152–154°, $[\alpha]^{24}D$ −187° in $CHCl_3$. Further elution of the column with chloroform–methanol (95:5) yielded reserpine, followed by a fraction which behaved like reserpine on crystallization and spot tests, but showed differences in its infrared spectrum. This compound was further purified as described below.

Pseudoreserpine.—The crude resin fraction obtained above (1.2 g.) on dissolving in methanol (10 ml.) yielded crystalline pseudoreserpine; after several recrystallizations from dilute acetone, pseudoreserpine melted at 257–258°, $[\alpha]^{24}D$ −65 ± 2° (*c* 1.0 in $CHCl_3$). A 24-plate countercurrent distribution in a Craig glass apparatus between 5% aqueous acetic acid and chloroform–methylchloroform (60:40), gave a single band (K = 0.85) which corresponded with the theoretical curve for a single substance. The ultraviolet spectrum showed: λ^{alc}_{max} (log ϵ) 218 mμ (4.76), 268 mμ (4.22), 296 mμ (4.02); λ^{alc}_{min} (log ϵ) 246 mμ (3.98), 288 mμ (3.99). The infrared spectrum (Nujol) showed well defined and characteristic bands at 2.81 μ, 2.90 μ (>NH, OH); 5.86 μ (ester carbonyl); 6.13 μ (6-methoxyindole); 6.26 and 6.63 μ (aromatic). For analysis the sample was dried to constant weight at room temperature (2 mm.).

Anal.[13] Calcd. for $C_{32}H_{38}O_9N_2$: C, 64.63; H, 6.44; N, 4.71; 5-OCH_3, 26.10; mol. wt., 594.64. Found: C, 64.36; H, 6.44; N, 4.63; $-OCH_3$, 26.34; equiv. wt.,[14] 598.

On diluting the methanol mother liquors obtained above with water, an additional crystalline alkaloid was obtained which was purified further by recrystallization from dilute methanol. On the basis of its physical constants and spectral data, the compound appeared to be identical with rauvoscine.[15]

Pseudoreserpine Nitrate.—Pseudoreserpine (50 mg.) was suspended in methanol (2 ml.) and the solution was made acid with concentrated nitric acid. The addition of acid solubilized the suspended pseudoreserpine; however, on standing, fine needles separated. The crystals (35 mg.) were collected by filtration, washed with water and dried to constant weight at room temperature (2 mm.), m.p. 253–255°.

Anal. Calcd. for $C_{32}H_{38}O_9N_2 \cdot HNO_3$: C, 58.44; H, 5.97; N, 6.39. Found: C, 58.32; H, 6.03; N, 6.16.

Acetylpseudoreserpine.—Pseudoreserpine (100 mg.) was dissolved in anhydrous pyridine and acetic anhydride (1 ml.) was added; the solution, after standing overnight under anhydrous conditions, was concentrated to dryness under vacuum. The resulting light colored residue was dissolved in chloroform (25 ml.) and extracted with equal portions of dilute sodium carbonate and then water. The chloroform solution was filtered through anhydrous sodium sulfate and concentrated to dryness *in vacuo*. The product was crystallized first from dilute methanol and then from dilute acetone as clusters of platelets (80 mg.), m.p. 150–154°. The infrared spectrum (Nujol) showed well defined bands at 3.0 (>NH), 5.78, 5.81 (ester carbonyl), 6.18 (6-methoxyindole) and 6.30 and 6.70 μ (aromatic). For analysis the sample was dried to constant weight at room temperature (2 mm.)

Anal. Calcd. for $C_{34}H_{40}O_{10}N_2$: C, 64.14; H, 6.33; N, 4.40; acetyl, 6.83. Found: C, 64.12; H, 6.46; N, 4.48; acetyl, 6.80.

Methanolysis of Pseudoreserpine to Methyl 3,4,5-Trimethoxybenzoate and Methyl Pseudoreserpate.—Pseudoreserpine (0.85 g.) was suspended in anhydrous methanol (50 ml.) to which sodium (0.15 g.) had previously been added. The mixture was refluxed for two hours. At the end of this time, the clear solution was concentrated *in vacuo* to a volume of approximately 5 ml. and water was added (50 ml.). The solution was made acid to congo red paper by the addition of concentrated hydrochloric acid and was then extracted two times with ether (50-ml. portions.) The dried ether extracts (sodium sulfate) yielded crystals of methyl 3,4,5-trimethoxybenzoate upon being taken to dryness *in vacuo* (identified by comparison with an authentic sample).

The aqueous layer obtained above was made basic with ammonium hydroxide and extracted three times with chloroform (50-ml. portions). The combined chloroform extracts were dried over anhydrous sodium sulfate and upon removal of the solvent *in vacuo*, a fluffy resin was obtained. This material was quite difficult to crystallize and only yielded a small quantity of needles upon treatment with

ether; m.p. 234–237°, $[\alpha]^{24}D$ −102 ± 3° (*c* 0.5 in pyridine).

The ultraviolet spectrum showed: λ_{max}^{alc} (log ε) 228 mμ (4.54), 270 mμ (3.68), 298 mμ (3.79); λ_{min}^{alc} (log ε) 252 mμ (3.56), 282 mμ (3.60). The infrared spectrum (Nujol) showed characteristic bands at 2.95 (>NH, –OH), 5.74 (ester carbonyl) and 6.20 μ (6-methoxyindole). For analysis the sample was dried to constant weight at 100° (2 mm.).

Anal. Calcd. for $C_{22}H_{28}O_5N_2$: C, 65.98; H, 7.05; OMe, 15.5. Found: C, 65.67; H, 7.31; OMe, 15.7.

Pseudoreserpinediol (VIII).—Pseudoreserpine (0.244 g.) in tetrahydrofuran (25 ml.) was added slowly to a refluxing solution of lithium aluminum hydride (0.25 g.) in tetrahydrofuran (35 ml.). Refluxing was continued for four hours, after which the solution was cooled to room temperature and the excess hydride was decomposed by the addition of a few drops of water. The solution was then filtered through Celite to remove the suspended aluminum salts and the filtrate was concentrated to dryness *in vacuo*. The resulting glass was taken up in hot isopropyl alcohol, whereupon crystals formed, m.p. 230–231°, $[\alpha]^{24}D$ 0.0° (*c* 0.5 in pyridine).

Anal. Calcd. for $C_{21}H_{28}O_4N_2$: C, 67.72; H, 7.58; OCH_3, 8.33. Found: C, 68.0; H, 7.9; $-OCH_3$, 8.4.

Methyl 17-Nor-3-isoreserpate (IV).—Reserpine (III) (18 g.) was suspended in 48% aqueous hydrobromic acid (100 ml.) and the mixture was heated on the steam-bath for four hours under an atmosphere of nitrogen. The resulting light brown solution was then taken to dryness *in vacuo*, yielding a fluffy tan resin. This material was dissolved in methanol (100 ml.) and treated with an excess of ethereal diazomethane (approximately one mole in 1.5 l. of ether), followed by the addition of chloroform (100 ml.) to effect solution of a light precipitate which had settled out. The mixture was allowed to stand overnight and then was taken to dryness *in vacuo*. The resulting fluffy resin was taken up in 5% methanol in chloroform and applied to a chromatographic column containing 500 g. of Merck acid-washed alumina. The initial eluates consisted mainly of methyl 3,4,5-trimethoxybenzoate identified by comparison with an authentic sample. The fractions immediately following this, and those eluted with 10% methanol in chloroform, yielded a light fluffy resin which crystallized from methanol yielding needles (2.75 g.), m.p. 265–266°, $[\alpha]^{24}D$ −69° (*c* 0.5 in pyridine). For analysis the sample was dried to constant weight at 100° (2 mm.).

Anal. Calcd. for $C_{22}H_{28}O_5N_2$: C, 65.98; H, 7.05; $-OCH_3$, 15.50. Found: C, 65.82; H, 7.10; $-OCH_3$, 15.54.

17,18-Diacetyl Methyl-17-nor-3-isoreserpate (V).—Methyl 17-nor-3-isoreserpate (IV) (200 mg.) was dissolved in anhydrous pyridine (20 ml.) and acetic anhydride (6 ml.) was added. The mixture was refluxed for one hour under anhydrous conditions and then concentrated to dryness *in vacuo*. The amorphous residue was dissolved in chloroform (25 ml.) and the solution was extracted with equal portions of dilute ammonium hydroxide and then with water; the chloroform layer was dried over anhydrous sodium sulfate and then evaporated to dryness *in vacuo*. On addition of methanol to the residue, a white powder (191 mg.) was obtained which was recrystallized from dilute acetone, m.p. 290–291°, $[\alpha]^{24}D$ −88.2° (*c* 0.5 in $CHCl_3$). For analysis the sample was dried to constant weight at 100° (2 mm.).

Anal. Calcd. for $C_{26}H_{32}O_7N_2$: C, 64.45; H, 6.66; O-acetyl, 17.8. Found: C, 64.62; H, 6.57; O-acetyl, 17.4.

Acetylation and Epimerization of Methyl Pseudoreserpate.—Methyl pseudoreserpate (VII) (275 mg.) was refluxed for six hours with acetic anhydride (10 ml.) under anhydrous conditions. The reaction mixture was then worked up as described above for V to yield an amorphous residue. On addition of methanol, a white powder was obtained (57 mg.) which on recrystallization from dilute acetone, melted at 292–293°, $[\alpha]^{24}D$ −86.9° (*c* 0.5 in $CHCl_3$). A mixture melting point with the diacetyl derivative of methyl 17-nor-3-isoreserpate obtained above gave no depression; a comparison of their infrared and ultraviolet spectra showed them to be identical.

Methyl 17-Nor-$\Delta^{3,4}$-dehydroreserpate Perchlorate (IX).—Methyl 17-nor-3-isoreserpate (IV) (1.2 g.), dissolved in glacial acetic acid (10 ml.), was added to a solution composed of mercuric acetate (1.3 g.) and glacial acetic acid (10 ml.). The resulting mixture was warmed on the steam-bath for two hours and after allowing it to come to room temperature, the flaky white crystals of mercurous acetate were filtered off. The resulting filtrate was saturated with hydrogen sulfide, centrifuged, and filtered through Celite, finally yielding a clear yellow solution. This was concentrated to a volume of approximately 2 ml. *in vacuo*, and methanol (10 ml.), perchloric acid (0.6 ml.) and ether (30 ml.) were added in that order. An oil separated which soon crystallized as small yellow platelets (1.48 g.). On recrystallization from methanol, platelets were obtained, m.p. 258°. For analysis, the sample was dried to constant weight at 60° (2 mm.).

Anal. Calcd. for $C_{22}H_{27}O_9N_2Cl$: C, 52.96; H, 5.46; Cl, 7.11; $-OCH_3$, 12.44. Found: C, 52.66; H, 5.65; Cl, 6.98; $-OCH_3$, 12.35.

Zinc–Acetic Acid Reduction of Methyl 17-Nor-$\Delta^{3,4}$-dehydroreserpate Perchlorate (IX) to Methyl Pseudoreserpate (VII).—Methyl 17-nor-$\Delta^{3,4}$-dehydroreserpate perchlorate (IX) (285 mg.) was dissolved in 50% aqueous acetic acid (20 ml.), and granulated zinc (1 g.) was added. The mixture was allowed to stand overnight and then was diluted with water (50 ml.) and filtered free of the unreacted zinc. The filtrate was made basic with dilute sodium hydroxide and then extracted three times with chloroform. The combined chloroform extracts were washed with a small volume of water and dried with anhydrous sodium sulfate. The solvent was then removed *in vacuo*, yielding a fluffy white resin which crystallized upon the addition of ether as white needles (70 mg.), m.p. 228°, $[\alpha]^{26}D$ −100° (*c* 0.29 in pyridine). A comparison of the physical and spectral properties of this compound with those of an authentic sample of methyl pseudoreserpate showed them to be identical. For analysis the material was dried to constant weight at 100° (2 mm.).

Anal. Calcd. for $C_{22}H_{28}O_5N_2$: C, 65.98; H, 7.05. Found: C, 65.82; H, 7.29.

Lithium aluminum hydride reduction of this compound was carried out as reported above for pseudoreserpinediol and yielded needles, m.p. 233°. A mixture melting point with pseudoreserpinediol obtained by reduction of pseudoreserpine gave no depression and the infrared spectra of the two preparations were identical. The optical rotations also agreed, $[\alpha]^{26}D$ 0.0° (*c* 0.3 in pyridine).

3-Isopseudoreserpinediol (X).—Methyl 17-nor-3-isoreserpate (IV) (107 mg.) was dissolved in tetrahydrofuran (25 ml.) and added to a refluxing solution of lithium aluminum hydride (100 mg.) in tetrahydrofuran (25 ml.). The solution was kept at reflux for four hours and then the reaction mixture was worked up as for pseudoreserpinediol. White needles (46 mg.) were obtained, which were recrystallized several times from isopropyl alcohol, m.p. 286–287°, $[\alpha]^{27}D$ −107° (*c* 0.2 in pyridine). This material easily formed solvates and did not lose all of its solvent of crystallization even when dried at 120° (2 mm.).

Anal. Calcd. for $C_{21}H_{28}O_4N_2 \cdot {}^1/_2H_2O$: C, 66.12; H, 7.66. Found: C, 65.43; H, 7.82.

Treatment of Pseudoreserpine with Mercuric Acetate.—Pseudoreserpine (50 mg.) was dissolved in glacial acetic acid (4 ml.), and mercuric acetate (50 mg.) in glacial acetic acid (4 ml.) was added. The mixture was heated on the steam-bath for 0.5 hour and at the end of this time the solution remained clear. In contrast 3-isoreserpine gave a copious precipitate of mercurous acetate within three to five minutes. Reserpine itself gave a precipitate only on prolonged warming, presumably because of isomerization occurring at C-3.

Acknowledgment.—We wish to express our thanks to Messrs. C. H. Stimmel and A. Shimamura and Miss M. Roper in the Analytical Section, Research Division, Riker Laboratories, for the optical rotations, spectral data and equivalent weight determinations.

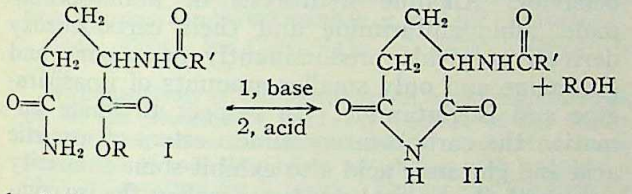
Imides from Asparagine and Glutamine. II. α-Aminoglutarimide[1]

BY ERNEST SONDHEIMER AND ROBERT W. HOLLEY

RECEIVED FEBRUARY 7, 1957

Hydrogenolysis of carbobenzoxy-DL-α-aminoglutarimide in the presence of hydrochloric acid yields DL-α-aminoglutarimide hydrochloride. Some of the properties of this compound are described. With weaker bases than those previously employed, the cyclization of carbobenzoxy-L-glutamine methyl ester gives carbobenzoxy-α-aminoglutarimide with partial retention of configuration. Treatment of the methyl esters of carbobenzoxy-L-glutamine and carbobenzoxy-L-isoglutamine with aqueous sodium hydroxide followed by hydrogenolysis gives mixtures of partially racemized glutamine and isoglutamine. This reaction was studied quantitatively.

Normally, treatment of N-acylamino acid esters with alkali yields the alcohol and a salt of the acylamino acid. However, the alkaline hydrolysis of N-acylasparagine and N-acylglutamine esters (I) is complicated by the ease of cyclization of these compounds to succinimide and glutarimide derivatives (II).[2-4] Alkaline hydrolysis of these imides



leads to opening of the imide rings in both possible ways. Thus, the over-all process of alkaline hydrolysis gives mixtures of products and is, in the case of the glutamine derivative, further complicated by racemization.[2,3] Because of the possible significance of these reactions during peptide synthesis and the cleavage of peptide chains,[3] studies of the reactions and of the properties of the imides are of importance.

As reported earlier,[2] hydrogenolysis of carbobenzoxy-DL-α-aminoglutarimide does not give pure α-aminoglutarimide. The hydrogenolysis product turns violet when exposed to air and becomes more intensely colored during storage at room temperature after evaporation of the solvent. That an aqueous solution of this mixture still contained large amounts of unchanged aminoglutarimide could be shown by paper chromatography. The solution had one broad absorption band in the visible region with a peak at 560 mμ, $E_{1cm}^{1\%}$ 60. The solution could be decolorized by catalytic hydrogenation or by treatment with sodium hydrosulfite. It seems likely that the pigment is a conversion product of aminoglutarimide, possibly formed by aerobic oxidation.

When the hydrogenolysis of the carbobenzoxy-DL-α-aminoglutarimide was carried out in the presence of a slight excess of hydrochloric acid, colorless, crystalline, water-soluble DL-α-aminoglutarimide hydrochloride was obtained. The hydrochloride has much less of a tendency to give the violet material and is not as readily hydrolyzed in water to glutamine and isoglutamine as the free aminoglutarimide. Hydrolysis of the imide with hot hydrochloric acid yielded DL-glutamic acid. When heated on a micro-hot-stage aminoglutarimide hydrochloride did not melt, but changed above 220° to a violet material which sublimed. The imide can be chromatographed on paper with water-saturated phenol, R_f 0.9, and with *n*-butyl alcohol, acetic acid and water (4:1:5), R_f 0.2. With ninhydrin it gives a salmon-red color, which exhibits an absorption maximum at 523 mμ in 95% ethanol.

The conditions previously used[2] to prepare carbobenzoxy-α-aminoglutarimide from carbobenzoxy-L-glutamine methyl ester gave completely racemized material. Since the formation of the imide from carbobenzoxyglutamine methyl ester does not involve direct reaction on the asymmetric carbon atom, it seemed possible that ring closure might be effected without racemization, if cyclization were catalyzed by the weakest base possible. No imide formation could be detected with triethylamine as the base. But by using equivalent amounts of ester and sodium methoxide in methanol at 0°, optically active carbobenzoxy-α-aminoglutarimide, $[\alpha]^{24}D$ −24.6° (*c* 1, methanol), was obtained. Imide with somewhat higher rotation, $[\alpha]^{24}D$ −35.3° (*c* 1, methanol), could be prepared by the addition of an equivalent amount of N-methylacetamide to the sodium methoxide. This effect of N-methylacetamide is attributed to its ability to lower the base strength. On the other hand, with excess sodium methoxide in methanol the optical rotation of the imide was lower, $[\alpha]^{24}D$ −10.7° (*c* 1, methanol). By hydrogenolysis of carbobenzoxy-α-aminoglutarimide which had a rotation of $[\alpha]^{24}D$ −35.3° (*c* 1, methanol) optically active α-aminoglutarimide hydrochloride was obtained, $[\alpha]^{24}D$ −53.5° (*c* 1, methanol). Acid hydrolysis to glutamic acid showed that approximately 40% of the material has been converted to the racemic form. The purity of these optically active preparations was checked chromatographically and by analysis.

We have shown earlier that treatment of carbobenzoxy-L-glutamine methyl ester and carbobenzoxy-L-isoglutamine methyl ester with aqueous sodium hydroxide does not lead to the isolation of an imide.[2] However, evidence for intermediate imide formation was obtained since alkaline hydrolysis followed by hydrogenolysis gave a mixture of glutamine and isoglutamine from either ester. In order to determine what fraction of the ester was hydrolyzed by way of the imide, the ratio of glutamine

TABLE I

PRODUCTS FROM ALKALINE HYDROLYSIS FOLLOWED BY HYDROGENOLYSIS

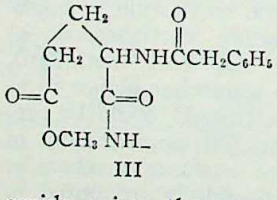
	Yield glutamine Mg.	σ	Yield isoglutamine Mg.	σ	Ratio glutamine/ isoglutamine	Hydrolysis through the imide, %	Racemization, %
Carbobenzoxy-DL-α-aminoglutarimide[a]	10.52[c]	1.54	2.24	0.84	4.7:1	..	..
Carbobenzoxy-L-glutamine methyl ester[b]	10.60[d]	0.97	2.25	.71	4.7:1	100	53
Carbobenzoxy-L-isoglutamine methyl ester[b]	8.34[e]	1.40	4.17	.58	2.0:1	80	43

[a] From 26.2 mg. of imide. [b] From 29.4 mg. of ester. [c] Mean of 14 determinations. [d] Mean of 23 determinations. [e] Mean of 11 determinations. σ Standard deviation. By the use of Student's *t* test it could be shown that the yields of glutamine and isoglutamine from carbobenzoxy-L-glutamine methyl ester and carbobenzoxy-DL-α-aminoglutarimide were not significantly different and that yields of the products from carbobenzoxy-L-isoglutamine methyl ester were different at the 99% level from those obtained with the other two compounds.

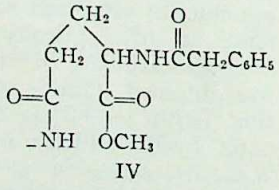
to isoglutamine, obtained after alkaline hydrolysis and hydrogenolysis, was determined by quantitative paper chromatography. By comparing these values to the ratio of glutamine to isoglutamine obtained on alkaline hydrolysis and hydrogenolysis of carbobenzoxy-DL-aminoglutarimide, the contribution that imide formation makes to the total hydrolysis of the esters could be calculated. Information on the extent of racemization during aqueous alkaline hydrolysis was also obtained. The results are summarized in Table I.

The hydrolysis and hydrogenolysis of carbobenzoxyaminoglutarimide yielded predominantly glutamine. This was the expected result since the lower electron density of the carbonyl group closest to the carbobenzoxyamido group favors attack by the hydroxyl ions at that site.[5]

The greater participation of the imide in the total de-esterification of carbobenzoxy-L-glutamine methyl ester as compared with carbobenzoxy-L-isoglutamine methyl ester is most likely due to differences in the nucleophilic character of the amide anions III and IV. The more nucleophilic the



III



IV

amide anion, the greater the extent of imide formation,[6] since competition between the anion and hydroxyl ion determines the proportion of hydrolysis through the imide for each ester. The location of the carbobenzoxyamido group would be expected to make III less nucleophilic than IV and therefore imide formation would be favored with IV.

De-esterification of the two esters with aqueous sodium hydroxide is accompanied by partial racemization. Of the various species present it would appear most likely that only the intermediate carbobenzoxy-α-aminoglutarimide is subject to racemization. This assumption is in accord with the experimental data. From Table I it is seen that the percentage hydrolysis through the imide is 20% greater for carbobenzoxy glutamine methyl ester than for the iso compound and that the extent of racemization is increased by an almost identical amount, 19%.

A comparison of the properties of the imides from glutamine and asparagine shows a number of similarities but also pronounced differences in behavior. Alkaline hydrolysis of aminosuccinimide, aminoglutarimide and their carbobenzoxy derivatives yields predominantly asparagine and glutamine and only smaller amounts of isoasparagine and isoglutamine. In respect to imide formation the carbobenzoxy amido esters of aspartic acid and glutamic acid also exhibit some similarity since with the normal amides as well as the iso compounds, imide formation was favored over normal saponification.

In common with the unsubstituted 5- and 6-membered cyclic imides[7] α-aminoglutarimide is much more rapidly hydrolyzed in alkali than aminosuccinimide. This difference in the rate of hydrolysis is explained by the generalization of Brown, Brewster and Schechter[8] that 6-membered rings with exo double bonds appear to be generally less stable and more susceptible to ring opening than 5-membered rings of this kind. Another striking difference in the behavior of the imides from asparagine and glutamine derivatives is that carbobenzoxy-α-aminoglutarimide is much more easily racemized than carbobenzoxyaminosuccinimide. This observation also seems to be in accord with the above generalization[8] since enolization should be favored in the 6-membered ring.

Another difference in the behavior of the two imides is that pigment formation has been observed only with aminoglutarimide and not with the 5-membered analog. Possibly this is also related to differences in the ring size since dehydrogenation of aminoglutarimide could lead to 2,6-dihydroxypyridine derivatives, compounds known to be oxidized to colored products.[9]

It seemed of interest to obtain some information on the growth response of a biological system to aminoglutarimide. The utilization of DL-α-aminoglutarimide by *Lactobacillus plantarum* var. *arabinosus* in glutamic acid-free, synthetic medium was therefore investigated. The growth response obtained was somewhat similar to that of glutamine. However, the amount of cell growth obtained per microgram imide was much less than that given by an equivalent quantity of glutamine. It was

(5) Similar results were obtained by Clayton, Kenner and Sheppard[4] who reported that the alkaline hydrolysis of the imide from benzoyl-DL-glutamylglycine cyclohexylamide yielded 85% of the γ-isomer and 13% of the α-compound.

(6) Differences in the electrophilic character of the carbomethoxy groups of the two esters might be expected to have little effect on the extent of de-esterification through saponification or imide formation, since both these processes are competing for the same carbomethoxy group.

found, though, that cell growth could be increased somewhat by increasing the initial *p*H of the medium, by increasing its buffer capacity or by adding the imide to the medium several hours before inoculation. Since *L. plantarum* produces acids during growth these observations indicate that hydrolysis precedes utilization of the imide. It was therefore concluded that DL-α-aminoglutarimide is not utilized as such, that it is not a potent growth inhibitor and that the observed growth is due to non-enzymatic hydrolysis of the imide to glutamine and isoglutamine.

Experimental[10]

Reaction of Carbobenzoxy-DL-α-aminoglutarimide with Ammonia.—To 100 mg. of carbobenzoxy-DL-α-aminoglutarimide was added with shaking 2 ml. of 28% aqueous ammonia. The product started to precipitate before all the starting material had dissolved. The mixture was filtered after overnight storage at room temperature. The yield of carbobenzoxy-DL-glutamic acid diamide was 77 mg. (71%), m.p. 181–183°, m.p. was unchanged by recrystallization from aqueous dimethylformamide or from 95% ethanol.

Anal. Calcd. for $C_{13}H_{17}N_3O_4$: N, 15.05. Found: N, 14.8.

Hydrogenolysis of Carbobenzoxy-DL-α-aminoglutarimide. (a) In the Absence of Acid.—A mixture of 200 mg. of carbobenzoxy-DL-α-aminoglutarimide in 5 ml. of methanol and 50 mg. of palladium black was shaken with hydrogen at room temperature for 2 hours. During the filtration the solution turned violet. Evaporation of the solvent in vacuum yielded crystals which were tinted violet at the surface, m.p. approximately 120° with decomposition to a violet solid. Storage of the hydrogenolysis product at room temperature caused a measurable increase in the color intensity. The amount of pigment could be increased further by periodically dissolving the material in water and evaporating the solvent in vacuum. In 13 days $E^{1\%}_{1\,cm.}$ at 560 mμ in water increased from 0.75 to 60. However, the preparation still consisted predominantly of unchanged aminoglutarimide. An aqueous solution of this mixture could be decolorized by hydrogenation with palladium black at room temperature and atmospheric pressure, with nitrous acid, and with sodium hydrosulfite. Cupric nitrate precipitates the colored material. DL-α-Aminoglutarimide hydrolyzes slowly at room temperature in aqueous solution to a mixture of glutamine and isoglutamine.

(b) In the Presence of Hydrochloric Acid.—Hydrogen was bubbled at room temperature and atmospheric pressure through a mixture of 1.05 g. of carbobenzoxy-DL-α-aminoglutarimide in 4.1 ml. of 0.99 *N* hydrochloric acid and 15 ml. of methanol in the presence of 200 mg. of palladium black. Sufficient water was added during the hydrogenolysis to keep the product in solution. After 1.5 hours the mixture was filtered and the filtrate concentrated in vacuum below 50° to 5 ml. On the addition of 20 ml. of *n*-propyl alcohol and storage overnight at 0° the product crystallized, yielding 0.565 g. (86%) of DL-α-aminoglutarimide hydrochloride. The latter was recrystallized in 70% yield on the addition of 15 ml. of propanol to the filtrate from 0.550 g. of crude product in 3.5 ml. of water. The compound, which does not melt, is changed to a violet, water-insoluble material above 220°. The hydrochloride is optically inactive and forms no more than traces of violet material on storage at room temperature for 12 months; the amino group has a pK_a 6.8 in water.

Anal. Calcd. for $C_5H_8N_2O_2 \cdot HCl$: C, 36.49; H, 5.51; N, 17.02; neut. equiv., 164.6. Found: C, 36.75; H, 5.87; N, 16.75; neut. equiv., 166.

Preparation of Optically Active Carbobenzoxy-α-aminoglutarimide.—Under the previously described conditions for cyclization[2], sodium methoxide in benzyl alcohol, only racemized imide was obtained. Therefore the cyclization was attempted under milder conditions.

Refluxing 294 mg. of carbobenzoxy-L-glutamine methyl ester with 5 ml. of triethylamine for 2 hours yielded only unchanged starting material. Since the ester was only partially soluble in the hot triethylamine, the cyclization attempt was repeated with a mixture of 1,4-dioxane and triethylamine. Again only unchanged ester was obtained after reflux.

Optically active imide was obtained by adding at 0°, 294 mg. of carbobenzoxy-L-glutamine methyl ester to a solution of 1.5 ml. of methanol containing sodium methoxide from 23.0 mg. of sodium. After 15 minutes at 0°, 0.1 ml. of acetic acid was added followed by 10 ml. of water. The mixture was stored at 0° overnight, yielding 230 mg. (84%) of carbobenzoxy-α-aminoglutarimide, m.p. 134–136° (transition 121°), $[\alpha]^{24}D$ −24.6° (*c* 1, methanol).

Anal. Calcd. for $C_{13}H_{14}N_2O_4$: C, 59.53; H, 5.33; N, 10.7. Found: C, 59.15; H, 5.19; N, 10.3.

Under similar conditions the addition of one equivalent of N-methylacetamide to this system gave imide with a somewhat higher rotation, $[\alpha]^{24}D$ −35.3° (*c* 1, methanol).

Preparation of Optically Active α-Aminoglutarimide Hydrochloride.—Hydrogen was bubbled at room temperature and atmospheric pressure for two hours through a mixture of 80 mg. of carbobenzoxy-α-aminoglutarimide, $[\alpha]^{24}D$ −35.3° (*c* 1, methanol), in 5 ml. of methanol and 0.5 ml. of 1 *N* hydrochloric acid plus 30 mg. of palladium black. The mixture was filtered, the catalyst washed with methanol and the combined washings and filtrate concentrated in vacuum. The yield of crystalline α-aminoglutarimide hydrochloride was 44.7 mg., 87% of the theoretical yield, $[\alpha]^{24}D$ −53.5° (*c* 1, methanol). By chromatographic analysis the material was shown to be indistinguishable from the racemized product and was practically free of glutamine and isoglutamine. It was recrystallized from aqueous solution by the addition of *n*-propyl alcohol for analysis.

Anal. Calcd. for $C_5H_8N_2O_2 \cdot HCl$: C, 36.49; H, 5.51; N, 17.02. Found: C, 36.76; H, 5.66; N, 17.2.

A solution of 68.3 mg. of the above α-aminoglutarimide hydrochloride in 2 ml. of 6 *N* hydrochloric acid was refluxed 3 hours, cooled and the volume adjusted to 5 ml. with 6 *N* hydrochloric acid. The resulting glutamic acid solution had a specific rotation of $[\alpha]^{24}D$ +18.4° (*c* 1.2 in 6 *N* hydrochloric acid), indicating approximately 40% conversion to the racemic form.

Alkaline Hydrolysis of Carbobenzoxy-L-glutamine Methyl Ester, Carbobenzoxy-L-isoglutamine Methyl Ester and Carbobenzoxy-DL-α-aminoglutarimide.—The addition of 1.1 ml. of 0.97 *N* sodium hydroxide to 29.4 mg. of ester or 26.2 mg. of imide (0.1 millimole) caused the compounds to go rapidly into solution. After storage at room temperature for 2 hours the solution was acidified with 1.15 ml. of 0.97 *N* hydrochloric acid, 15 mg. of palladium black was added and hydrogen was bubbled through the mixture at room temperature for one hour. The mixture was filtered, the catalyst washed with water and the combined washings and filtrate made up to 10 ml. Aliquots of 5, 10 and 20 microliters were chromatogramed on Whatman No. 1 paper for 16 hours with *n*-butyl alcohol, acetic acid and water (4:1:5). The papers were dried at room temperature. The amino acid spots were detected by spraying with a 1% ninhydrin solution in 95% ethanol containing 2% collidine–lutidine mixture (1:3) and developed for one hour in a 40° cabinet through which water-saturated air was passed. Immediately after development the spots were cut out and the pigment was extracted with 50% ethanol. After storage in the dark for one hour the optical density at 570 mμ was determined. Chromatograms with known concentrations of glutamine and isoglutamine were run with each unknown and these served for the construction of calibration curves. The only products detected were glutamine and isoglutamine. The absence of glutamic acid could be shown by chromatograming with water-saturated phenol. Hydrogenolysis of carbobenzoxyglutamine and carbobenzoxyisoglutamine gave only glutamine and isoglutamine, respectively.

Estimation of the Extent of Racemization of Carbobenzoxy-L-glutamine Methyl Ester and Carbobenzoxy-L-isoglutamine Methyl Ester during Alkaline Hydrolysis.—To 294 mg. (1 millimole) of the carbobenzoxy esters 1.2 ml. of 1 *N* sodium hydroxide was added and the solution stored at room temperature overnight. After acidification with 2 ml. of concentrated hydrochloric acid, the mixture was refluxed eight hours, cooled and extracted with benzene to remove benzyl alcohol. The aqueous phase was diluted

(10) All melting points were determined on a microscope hot-stage and are corrected. Analyses are by Dr. G. Weiler and Dr. F. B. Strauss, Oxford, England.

Digitized by Arya Samaj Foundation Chennai and eGangotri

with 20 ml. of water and passed over a column of 5 g. of Dowex 2 in the hydroxide form (20–50 mesh). The column was washed with water until the effluent was neutral. The glutamic acid was eluted with 0.25 *N* hydrochloric acid. Five-ml. fractions were collected and the fractions giving a positive ninhydrin test (usually fractions 5 through 9) were combined, the solvent was evaporated in vacuum and the crystalline residue was freed from excess hydrochloric acid by repeated additions and evaporations of 5-ml. portions of water. After drying in a vacuum desiccator over phosphorus pentoxide and potassium hydroxide the material was weighed and the optical rotation in 6 *N* hydrochloric acid determined. In order to show that the decrease in the specific rotation of the glutamic acid was caused by the alkaline treatment of the esters, hydrolysis to glutamic acid was also brought about by refluxing carbobenzoxy-L-glutamine methyl ester without prior treatment with alkali. The yields of glutamic acid averaged 93%. The glutamic acid obtained from alkaline de-esterification of carbobenzoxy-L-glutamine methyl ester had a specific rotation of $[\alpha]^{24}D$ +14.2° (*c* 1 in 6 *N* hydrochloric acid) and, from carbobenzoxy-L-isoglutamine methyl ester, $[\alpha]^{24}D$ +17.1° (*c* 1 in 6 *N* hydrochloric acid). Acid hydrolysis of carbobenzoxy-L-glutamine methyl ester yielded glutamic acid with a specific rotation of $[\alpha]^{24}D$ +30.0° (*c* 1 in 6 *N* hydrochloric acid) and carbobenzoxy-DL-α-aminoglutarimide, $[\alpha]^{24}D$ 0° (*c* 1 in 6 *N* hydrochloric acid).

Growth Response of *Lactobacillus plantarum* to DL-Aminoglutarimide.—The general procedure used has been described previously.[11] In the synthetic medium DL-aminoglutarimide was substituted for L-glutamic acid. A lag phase of from 4 to 6 hours was observed. This is similar to that obtained with L-glutamine.[11] The maximum amount of growth obtained with DL-α-aminoglutarimide at *p*H 6.1 was only 20–30% of that given by an equivalent amount of L-glutamine. A small increase in the maximum amount of growth could be obtained with the imide, by raising the *p*H of the growth medium, by increasing its buffering capacity, or by storing the growth medium at 35° prior to inoculation.

Acknowledgment.—We wish to thank Mrs. Carole B. Karash for technical assistance and Dr. R. S. Shallenberger for the statistical analysis.

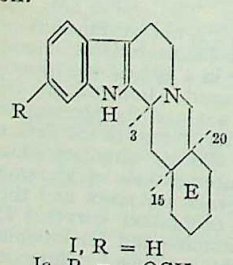
New Total Synthesis of *dl*-Alloyohimbane and *dl*-Epialloyohimbane and their 11-Methoxy Derivatives

BY RICHARD T. RAPALA, EDWARD R. LAVAGNINO, EDWIN R. SHEPARD AND EUGENE FARKAS

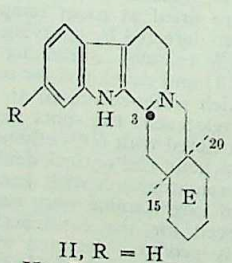
RECEIVED FEBRUARY 20, 1957

Racemic alloyhimbane and epialloyohimbane and the 11-methoxy analogs have been prepared by a series of facile reactions. The key bicyclic (ring DE) intermediate, a *cis*-fused decahydroisoquinoline-3-carboxylic acid, was obtained by hydrogenation of 1,2,3,4-tetrahydroisoquinoline-3-carboxylic acid using rhodium-on-alumina catalyst.

This paper describes a convenient synthesis of *dl*-allo- and epialloyohimbane (I and II) and the corresponding 11-methoxy derivatives (Ia and IIa). The starting point for this synthesis was 1,2,3,4-tetrahydroisoquinoline-3-carboxylic acid which constitutes the potential D and E rings of the pentacyclic bases. Since these pentacyclic ring systems occur as the nuclei of reserpine,[1a] deserpidine[1b] and related alkaloids, it is important to be able to prepare such systems by a general unequivocal method capable of producing ring E substituted derivatives for pharmacological evaluation.



I, R = H
Ia, R = —OCH_3



II, R = H
IIa, R = —OCH_3

Previously the pentacyclic bases *dl*-alloyohimbane (I) (C_3, C_{15}, C_{20} *cis*) and its isomer epialloyohimbane (II) (C_3 *trans*; C_{15}, C_{20} *cis*) have been obtained through total synthesis by Stork and Hill[2] and through partial synthesis by Wenkert and Liu[3] as well as by LeHir, Janot and Goutarel.[4] Racemic 11-methoxyalloyohimbane (Ia) has been prepared by E. E. van Tamelen, *et al.*,[5a] and Huebner, *et al.*[1b] Huebner[5b] has shown that prolonged acid treatment of this allo isomer provides *dl*-11-methoxyepialloyohimbane as the major product.

Our approach to a general synthesis depended upon the unambiguous preparation of suitably substituted *cis*-decahydroisoquinolines which would serve as the D and E rings of the pentacyclic ring skeleton. Previous attempts[6] toward the preparation of these *cis* ring systems indicated that the reduction of hydroxyisoquinolines with noble metals in acetic acid proceeded to the *cis*-decahydroisoquinolines but with concomitant loss of the hydroxyl group. Hydrogenations of similar compounds over Raney nickel catalyst yielded mixtures of the stereoisomeric decahydroisoquinolines.[7]

In the present work the desired *cis* isomer was obtained by catalytic hydrogenation of a selected tetrahydroisoquinoline using rhodium-on-alumina catalyst. That this substance possessed the *cis* configuration in the bicyclic form was evidenced by its conversion through a series of reactions to the

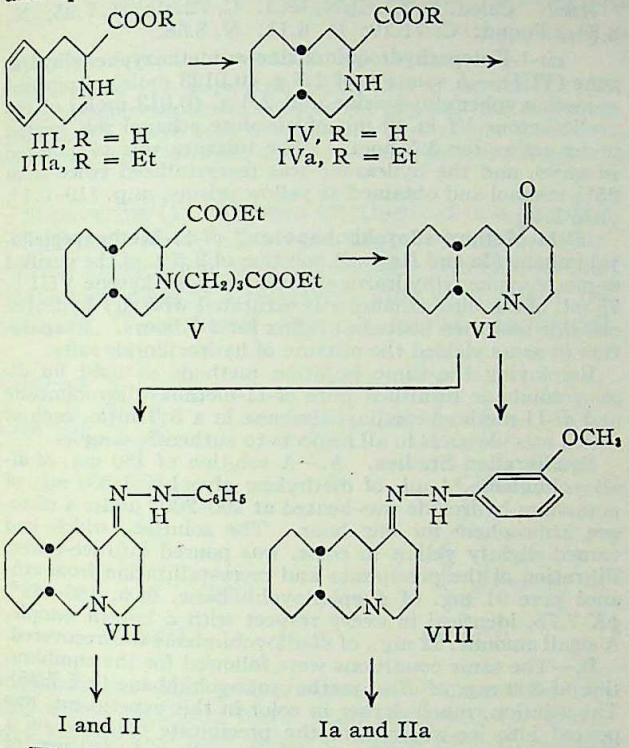
known *dl*-allo- and epialloyohimbanes. This same procedure, with slight modifications, was employed for the facile synthesis of *dl*-11-methoxyallo- and epialloyohimbane.



When 1,2,3,4-tetrahydroisoquinoline-3-carboxylic acid[8] was hydrogenated over 5% rhodium-on-alumina catalyst at 50°, three moles of hydrogen was consumed, and the crystalline *cis*-decahydroisoquinolinecarboxylic acid IV was isolated in 41% yield.

The substituents on the tetrahydroisoquinoline molecule have a great influence on the outcome of the rhodium-on-alumina reduction, for when the corresponding ester IIIa is employed, the alcohol results and no ring reduction occurs. However, preliminary evidence shows that tetrahydroisoquinolines substituted in the aromatic portions of the molecule are reduced in the desired manner and the substituents are retained.

By a series of reactions, analogous to those employed by Swan[9] for the synthesis of yohimbone, the ethyl ester IVa was alkylated with ethyl γ-bromobutyrate yielding the diester V. Dieckmann cyclization with sodium hydride in toluene, followed by acid hydrolysis and decarboxylation, converted the diester to the tricyclic ketone, *cis*-1-keto-perhydroquinolizine (VI). The reaction of VI with phenylhydrazine and subsequent treatment of the hydrazone VII with hot ethanolic hydrochloric acid furnished the desired *dl*-allo- and epialloyohimbane (I and II) as a mixture of hydrochlorides. Basification and chromatographic separation of the mixed bases yielded the pure isomers, the allo predominating. Under Huang-Minlon reduction conditions,[10] this allo isomer was epimerized to a large extent to epialloyohimbane. The interconversion of these isomers can be explained by the acidic and basic equilibration studies of Wenkert and Liu[3] which indicate that mixtures of bases can be expected.

The *m*-methoxyphenylhydrazone, which formed readily upon treatment of the ketone VI with *m*-methoxyphenylhydrazine, underwent the Fischer indole reaction giving *dl*-11-methoxyallo- and epialloyohimbane (Ia and IIa) as a mixture of hydrochlorides. The free bases were obtained by neutralization and chromatographic separation, the major portion, as before, being the allo isomer. Again, this allo isomer under alkaline conditions was epimerized to the epiallo isomer.

The successful applications of this method to the synthesis of the pentacyclic bases are encouraging and experiments are in progress to determine the generality of this procedure for obtaining derivatives substituted at various positions in these ring systems.

During these investigations *l*-yohimbane was required for comparison studies. The ethanedithiol derivative of *l*-yohimbone was formed readily, and upon treatment with freshly prepared W-7 Raney nickel catalyst in dioxane was converted to *l*-yohimbane. Previous attempts to desulfurize *l*-yohimbone ethanethiol were reported to be unsuccessful.[11]

Acknowledgments.—We gratefully acknowledge valuable assistance by: Messrs. G. M. Maciak, W. L. Brown, H. L. Hunter and Miss G. Beckmann, elemental analysis; Dr. H. E. Boaz, Messrs. P. W. Landis, R. C. Reed and Miss M. Hofman, physicochemical measurements; Dr. H. A. Rose and Miss A. Van Camp, X-ray data.

Experimental

3-Carboxy-1,2,3,4-tetrahydroisoquinoline (III).—The modified procedure of Julian[8] was followed for the condensation of phenylalanine with formaldehyde to furnish the isoquinolinecarboxylic acid in 70% yield. The corresponding ethyl ester IIIa was prepared by the method of Archer.[12]

***cis*-3-Carboxydecahydroisoquinoline (IV).**—A mixture of 20 g. 3-carboxy-1,2,3,4-tetrahydroisoquinoline in 300 ml. of 50% ethanol and 5 g. of 5% rhodium-on-alumina catalyst (J. T. Baker Chemical Co.) absorbed three moles of hydrogen at 50–100° and 15 atmospheres. The catalyst was removed by filtration, and the filtrate was evaporated *in vacuo*. The product was recrystallized three times from ethanol, m.p. 256–257°, yield 8.2 g. (41%).

Anal. Calcd. for $C_{10}H_{17}NO_2$: C, 65.54; H, 9.55; N, 7.64. Found: C, 65.45; H, 9.35; N, 7.46.

The hydrochloride salt was crystallized from ethanol–ether, m.p. 235–236°.

Anal. Calcd. for $C_{10}H_{17}NO_2 \cdot HCl$: C, 54.67; H, 8.26; N, 6.38. Found: C, 54.66; H, 8.49; N, 6.10.

3-Hydroxymethyl-1,2,3,4-tetrahydroisoquinoline.—A solution of 20.3 g. (0.1 mole) of ethyl 1,2,3,4-tetrahydroisoquinoline-3-carboxylate in 50 ml. of absolute ethanol was hydrogenated over 5 g. of rhodium-on-alumina catalyst at 50° and 50 atmospheres for 17 hours. The product was isolated by distillation followed by crystallization from benzene as colorless plates, m.p. 82–83.5°, yield 6.0 g. (36%).

Anal. Calcd. for $C_{10}H_{13}NO$: C, 73.59; H, 8.03; N, 8.58. Found: C, 73.72; H, 8.22; N, 8.49.

The hydrochloride salt was crystallized from ethanol–ether, m.p. 185–188°.

Anal. Calcd. for $C_{10}H_{13}NO \cdot HCl$: C, 60.15; H, 7.07; N, 7.02. Found: C, 59.84; H, 7.29; N, 6.78.

Ethyl *cis*-Decahydroisoquinoline-3-carboxylate Hydrochloride (IVa).—By the procedure of Brenner and Huber,[13] 1.3 ml. of thionyl chloride in 10 ml. of absolute ethanol was allowed to react with 2.0 g. of *cis*-decahydroisoquinoline-3-carboxylic acid. Recrystallization from benzene–ether gave 1.5 g. (56%) of ester as colorless solid, m.p. 166–168°.

Anal. Calcd. for $C_{12}H_{21}NO_2 \cdot HCl$: C, 58.65; H, 9.02; N, 5.70. Found: C, 58.42; H, 8.99; N, 5.48.

Ethyl 2-(γ-Carbethoxypropyl)-*cis*-decahydroisoquinoline-3-carboxylate (V).—A mixture of 100 g. (0.475 mole) of the above ester, 92.5 g. (0.475 mole) of ethyl γ-bromobutyrate and 65.5 g. (0.475 mole) of anhydrous potassium carbonate was heated with stirring for 27 hours. The mixture was cooled, poured onto crushed ice and the mixture extracted with ether. The residue obtained on evaporation of the ether was distilled, b.p. 168–172° (0.75 mm.), $n^{25}D$ 1.4768, yield 110.6 g. (75.5%).

Anal. Calcd. for $C_{18}H_{31}NO_4$: C, 66.43; H, 9.60; N, 4.30. Found: C, 66.26; H, 9.57; N, 4.57.

***cis*-1-Ketoperhydroquinolizine (VI).**—To a suspension of 4.8 g. (0.2 mole) of sodium hydride in 25 ml. of dry toluene was added dropwise a solution of 32.5 g. (0.1 mole) of diester V in toluene over a period of 45 minutes. Following the addition, the reaction mixture was heated at reflux for 5 hours. To the stirred, cooled mixture was added cautiously 10 ml. of ethanol followed by 10 ml. of water. Concentrated hydrochloric acid (200 ml.) was then introduced, and the reaction mixture was heated under reflux for 17 hours. The mixture was evaporated to dryness *in vacuo*, the residue dissolved in 50 ml. of water and then basified with solid potassium carbonate. Ether extraction followed by drying and evaporation of the solvent left a residue which crystallized as colorless needles from absolute ethanol, m.p. 103–104°, yield 10.6 g. (51%).

Anal. Calcd. for $C_{13}H_{21}NO$: C, 75.31; H, 10.31; N, 6.76. Found: C, 74.86; H, 10.33; N, 6.57.

The hydrochloride salt was crystallized from ethanol–ether, m.p. 208–210°.

Anal. Calcd. for $C_{13}H_{21}NO \cdot HCl$: C, 64.05; H, 9.10; N, 5.75. Found: C, 63.71; H, 9.23; N, 5.52.

***cis*-1-Ketoperhydroquinolizinephenylhydrazone (VII).**—A solution of 1.1 g. (0.01 mole) of purified phenylhydrazine and 2.0 g. (0.0096 mole) of tricyclic ketone VI in 10 ml. of absolute ethanol was heated under reflux for 2.5 hours. The mixture was evaporated *in vacuo*, and the residue was recrystallized twice from absolute ethanol–ether and obtained as yellow prisms, m.p. 127–129°, yield 1.4 g.

***dl*-Alloyohimbane and *dl*-Epialloyohimbane (I and II).**—A solution of 1.4 g. of the recrystallized phenylhydrazone of the tricyclic ketone VII in 75 ml. of absolute ethanol was saturated with dry hydrogen chloride and then heated at reflux for 3 hours. The mixture of hydrochloride salts was obtained by evaporation *in vacuo*. Careful neutralization with sodium hydroxide solution followed by ether extraction and chromatography of the residue on alumina furnished the pure *dl*-alloyohimbane and *dl*-epialloyohimbane in about a 5:1 ratio. Each of these were identical in all respects (X-ray, infrared and ultraviolet spectra, and melting points) to previously prepared bases.[14]

The allo isomer hydrochloride was obtained directly from the mixed hydrochlorides by several recrystallizations from aqueous ethanol, m.p. 294–297°.

Anal. Calcd. for $C_{19}H_{24}N_2 \cdot HCl$: C, 72.01; H, 7.95; N, 8.84. Found: C, 71.79; H, 8.11; N, 8.68.

***cis*-1-Ketoperhydroquinolizine-*m*-methoxyphenylhydrazone (VIII).**—A solution of 1.7 g. (0.0123 mole) of purified *m*-methoxyphenylhydrazine and 2.6 g. (0.013 mole) of tricyclic ketone VI in 10 ml. of absolute ethanol was heated under reflux for 2.5 hours. The mixture was evaporated *in vacuo*, and the hydrazone was recrystallized twice from 95% ethanol and obtained as yellow prisms, m.p. 119–121°, yield 1.4 g.

***dl*-11-Methoxyalloyohimbane and *dl*-11-Methoxyepialloyohimbane (Ia and IIa).**—A solution of 2.5 g. of the purified *m*-methoxyphenylhydrazone of the tricyclic ketone VIII in 75 ml. of absolute ethanol was saturated with dry hydrogen chloride and then heated at reflux for 2.5 hours. Evaporation *in vacuo* yielded the mixture of hydrochloride salts.

Employing the same isolation methods as used for *dl*-alloyohimbane furnished pure *dl*-11-methoxyalloyohimbane and *dl*-11-methoxyepialloyohimbane in a 5:1 ratio, each of which was identical in all respects to authentic samples.

Equilibration Studies. A.—A solution of 180 mg. of *dl*-alloyohimbane, 4 ml. of diethylene glycol and 500 mg. of potassium hydroxide was heated at 190–200° under a nitrogen atmosphere for one hour. The solution, which had turned slightly yellow in color, was poured into ice-water. Filtration of the precipitate and recrystallization from ethanol gave 91 mg. of *dl*-epialloyohimbane, m.p. 186–188°, *pK* 7.75, identical in every respect with a known sample. A small amount, 22 mg., of *dl*-alloyohimbane was recovered.

B.—The same conditions were followed for the equilibration of 300 mg. of *dl*-11-methoxyalloyohimbane (*pK* 7.35). The solution, much darker in color in this experiment, was poured into ice-water, and the precipitate collected on a filter. After recrystallization from methanol, 110 mg. of *dl*-11-methoxyepialloyohimbane was obtained, m.p. 203–205°, *pK* 7.90. In this case also, a small amount of starting material was obtained.

***l*-Yohimbone Ethanedithiol.**—Dry hydrogen chloride was bubbled into a cold solution of 1.0 g. of *l*-yohimbone and 5 ml. of ethanedithiol in 40 ml. of glacial acetic acid for 15 minutes, and the reaction mixture was allowed to remain at room temperature overnight. The product was removed by filtration, added to water and basified with ammonium hydroxide solution to liberate the free base as a colorless solid, m.p. 158–161°, yield 1.03 g.

Anal. Calcd. for $C_{21}H_{26}N_2S_2$: N, 7.56. Found: N, 7.27.

***l*-Yohimbane.**—A mixture of 200 mg. of the ethanedithiol derivative, 50 ml. of purified dioxane and 2 ml. of a dense Raney nickel suspension (freshly prepared W-7) was stirred and heated at reflux for 16 hours. The catalyst was removed by filtration, and the filtrate evaporated *in vacuo*. Chromatography of the residue on alumina furnished 60 mg. of *l*-yohimbane, m.p. 207–208°, identical with material obtained by Huang-Minlon reduction conditions on *l*-yohimbone.

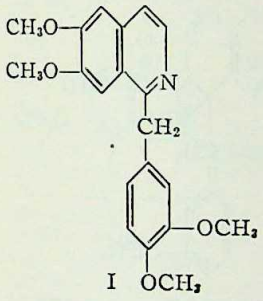
Syntheses of Papaverine, Papaverinol and Papaveraldine from Reissert Compounds

BY FRANK D. POPP AND WILLIAM E. MCEWEN

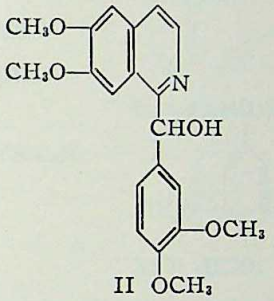
RECEIVED JANUARY 21, 1957

Papaverine (I), papaverinol (II) and papaveraldine (III) have been synthesized from 2-benzoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile (IV) as the key starting material. Improved methods for the preparation of 6,7-dimethoxyisoquinoline (V) have been developed. Several new Reissert compounds have been prepared and subjected to characteristic acid-catalyzed hydrolysis and base-catalyzed condensation, displacement or rearrangement reactions.

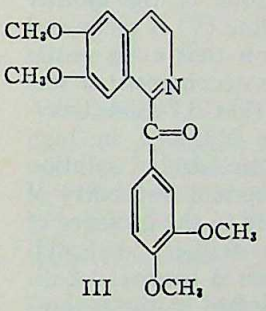
Papaverine (I) has been synthesized in a number of different ways, all of the reported methods requiring application of a ring-closure reaction as one of the last steps of a relatively long sequence of reactions.[1] There are several known industrial methods for the preparation of papaverine (I), and these methods have been reviewed by Burger,[2] Dickenson[3] and Wahl.[4] Since procedures are known[5-15] for the interconversion of papaverine (I), papaverinol (II) and papaveraldine (III), syntheses of the latter two compounds may also be considered equivalent to syntheses of papaverine (I).[16,17]



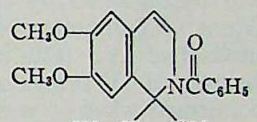
I



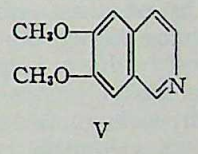
II



III



IV



V

Owing to a number of recently discovered reactions of Reissert compounds,[18] it appeared likely that papaverine (I), papaverinol (II) and papaveraldine (III) could all be synthesized quite readily from 2-benzoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile (IV)[19] as the key starting material. The first requirement, however, was to develop a convenient method of synthesis of 6,7-dimethoxyisoquinoline (V), from which the Reissert compound IV may be prepared.[19]

On the basis of reports in the literature it appeared that 6,7-dimethoxyisoquinoline (V) could be prepared from homoveratrylamine (VI) in about 35% yield by a Bischler–Napieralski reaction of the N-formyl derivative of VI, followed by catalytic dehydrogenation of the resulting dihydro derivative of V.[20-24] 6,7-Dimethoxyisoquinoline (V) also has been prepared in 19% yield by oxidative cyclization of veratrylaminoacetal (VII) with arsenic pentoxide and sulfuric acid.[25,26] It was stated[25] that veratrylideneaminoacetal (VIII) would not undergo a normal Pomeranz–Fritsch reaction. By appropriate modifications of the previously reported[20-24] procedures it has now been found that 6,7-dimethoxyisoquinoline (V) may be prepared in about 70% yield by the Bischler–Napieralski ring-closure and catalytic dehydrogenation route. Also, by use of a mixture of polyphosphoric acid and phosphorus oxychloride as the cyclizing agent, veratrylideneaminoacetal (VIII) has been converted to 6,7-dimethoxyisoquinoline (V) in about 55% yield. Other workers have found that Pomeranz–Fritsch ring-closure reactions may sometimes be effected by use of polyphosphoric acid when the usual sulfuric acid method fails.[27]

By reaction of 6,7-dimethoxyisoquinoline (V), benzoyl chloride and aqueous potassium cyanide, Haworth and Perkin[19] obtained a 35% yield of

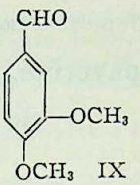
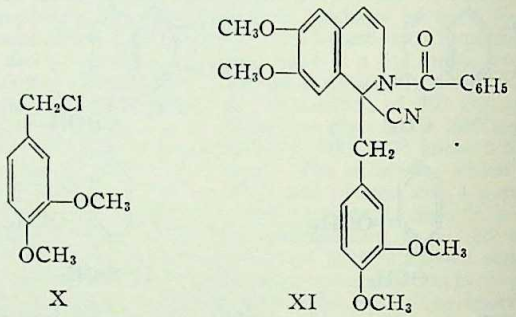
crude 2-benzoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile (IV). We have found that crude material can be obtained in as high as 90% yield, but that purification of the product by recrystallization from ethanol leads to a marked diminution of the yield. Furthermore, no Reissert compound can be obtained by concentration of the mother liquor; 6,7-dimethoxyisoquinoline (V) is recovered instead of IV. The implication that even gentle heating of IV brings about its decomposition was confirmed when it was found that 6,7-dimethoxyisoquinoline picrate could be obtained in high yield by warming pure IV in an alcohol solution containing picric acid. The thermal instability of IV must be due in large measure to the presence of the methoxyl groups because neither 2-benzoyl-1,2-dihydroisoquinaldonitrile nor 1-benzoyl-1,2-dihydroquinaldonitrile gave a picrate of the heterocyclic base upon being warmed in an alcohol solution containing picric acid. The lithium salt of IV, prepared by a metal–hydrogen exchange reaction of IV and phenyllithium, proved to be even less stable than the Reissert compound itself. Even at −10°, the characteristic red color of the lithium salt in ether–dioxane solution rapidly disappeared. However, at a temperature of −20°, the red color persisted for an appreciable period of time.

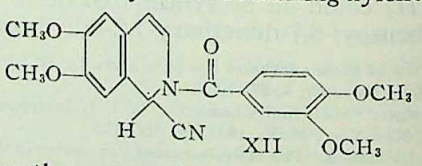
In view of the thermal instability of 2-benzoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile (IV) and its lithium salt, it was felt that a synthesis of papaverine (I) or one of its derivatives could best be effected by use of reactions which occur at low temperatures. A recent finding,[28] namely, that the lithium salt of 2-benzoyl-1,2-dihydroisoquinaldonitrile would react with benzaldehyde at an initial temperature of −20° to give eventually the benzoate of phenyl-1-isoquinolylcarbinol, suggested a method for the synthesis of papaverinol (II). The lithium salt of 2-benzoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile, prepared by metalation of IV with phenyllithium in ether–dioxane solution, was caused to condense with one equivalent of veratraldehyde (IX) at an initial temperature of −20°. Alkaline hydrolysis of the resultant product afforded papaverinol (II) in 67% yield. When the lithium salt of IV was treated with an excess of veratraldehyde (IX) and the reaction mixture later refluxed with aqueous alcoholic potassium hydroxide solution, papaveraldine (III) rather than papaverinol (II) was obtained in 67% yield. Evidently the excess veratraldehyde (IX) functions as an oxidizing agent for the conversion of II to III in a strongly alkaline medium.

Owing to the fact that 3,4-dimethoxybenzylchloride (X) is highly reactive in nucleophilic displacement reactions, it was felt that an alkylation reaction similar to that reported by Boekelheide and co-workers[29−31] might be carried out at a low temperature. Treatment of the lithium salt of 2-benzoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile (IV) with X at an initial temperature of −20° gave the condensation product, XI, which was not purified; alkaline cleavage of crude XI afforded papaverine (I) in 22% yield.





Due to the relatively high temperature required to bring about the base-catalyzed rearrangement of a Reissert compound to the α-acyl derivative,[29,32,33] it did not seem likely that papaveraldine (III) could be synthesized by application of such a method. This proved to be the case. 2-(3,4-Dimethoxybenzoyl)-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile (XII) was prepared in 73% yield by the Grosheintz and Fischer method,[34] but no papaveraldine (III) was obtained on treatment of XII with sodium hydride in refluxing xylene.



During the course of these studies, a number of new Reissert compounds were prepared and some of their characteristic reactions investigated. In addition to XII, the new compounds included 2-(3,4-dimethoxybenzoyl)-1,2-dihydroisoquinaldonitrile, 2-cinnamoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile and 2-anisoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile. Papaverinol (II) could be obtained from the latter two compounds in the same manner as described earlier for the preparation of II from 2-benzoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile (IV). All four Reissert compounds gave aldehydes in high yield upon acid-

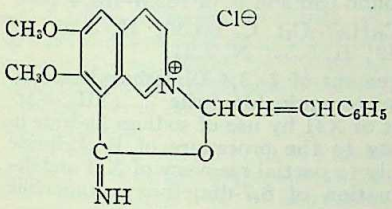
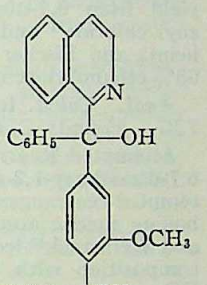
catalyzed hydrolysis. By reaction of 2-cinnamoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile with anhydrous hydrogen chloride, there was obtained a red solid of molecular formula $C_{21}H_{21}N_2O_4Cl$. This corresponds to the monohydrate of the salt of structure XIII (or a tautomer), the type of intermediate anticipated on the basis of the mechanism recently proposed[35] for the acid-catalyzed hydrolysis of Reissert compounds. Although 2-(3,4-dimethoxybenzoyl) - 1,2 - dihydroisoquinaldonitrile would not undergo reaction with sodium hydride to form 1-(3,4-dimethoxybenzoyl)-quinoline, reaction with phenyllithium gave phenyl-3,4-dimethoxyphenyl-1-isoquinolylcarbinol (XIV), proving that a rearrangement reaction could be effected under the right conditions.



XIII



XIV

Prior to the reactions cited earlier, those leading to the preparation of papaverine (I), papaverinol (II) and papaveraldine (III), some model reactions were carried out with the readily available[36] Reissert compound, 2-benzoyl-1,2-dihydroisoquinaldonitrile (XV). Reaction of the lithium salt of XV with one equivalent of veratraldehyde (IX) gave the benzoate XVI of 3,4-dimethoxyphenyl-1-isoquinolylcarbinol XVII in 86% yield, whereas reaction of the lithium salt of XV with an excess of veratraldehyde (IX), with subsequent alkaline hydrolysis of the crude product, gave a mixture of XVII and 1-(3,4-dimethoxybenzoyl)-quinoline (XVIII). Alkylation of the lithium salt of XV with 3,4-dimethoxybenzyl chloride (X), with subsequent alkaline cleavage of the initially formed product, gave 1-(3,4-dimethoxybenzyl)-isoquinoline (XIX) in 53% yield.

Acknowledgment.—This investigation was supported by a research grant, H-2155, from the National Heart Institute of the National Institutes of Health, Public Health Service.

Experimental[37]

6,7-Dimethoxy-3,4-dihydroisoquinoline.—This compound was prepared in 97% yield from homoveratrylamine (VI) by the same procedure used by Haworth[38] to prepare 5,6-dimethoxy-3,4-dihydroisoquinoline from β-(2,3-dimethoxyphenyl)-ethylamine. Its picrate melted at 207–208° (reported[39] m.p. 206–208°).

6,7-Dimethoxyisoquinoline (V).—To a solution of 10.3 g. (0.054 mole) of crude 6,7-dimethoxy-3,4-dihydroisoquinoline in 31.5 cc. of decalin was added 5.7 g. of 10% palladium-on-charcoal catalyst, and the mixture was refluxed for 1.5 hr. The suspension was extracted with 15% hydrochloric acid, the acid solution filtered, made alkaline and extracted with ether. Distillation of the ether afforded 8.34 g. (82%) of crude 6,7-dimethoxyisoquinoline (V); picrate, m.p. 222–224° (reported m.p. 218–220°,[25] 226–227°[21]). Distillation of 37.3 g. of crude material gave 33 g. of purified 6,7-dimethoxyisoquinoline (V), b.p. 152–158° (0.8–0.9 mm.).

Preparation of 6,7-Dimethoxyisoquinoline (V) by the Pomeranz–Fritsch Method.—Veratrylideneaminoacetal (VIII) was prepared in quantitative yield from veratraldehyde (IX) and aminoacetal by the method of Forsyth, Kelly and Pyman.[26] To a solution of 25 g. of phosphorus oxychloride in 160 g. of polyphosphoric acid maintained at 23–26° was added with stirring during a 10-minute period 25 g. (0.087 mole) of veratrylideneaminoacetal (VIII). The mixture was stirred for an additional 2 hr. at 23–26°, then added to ice-water. The acid solution was washed with ether, made alkaline and extracted with chloroform. Distillation of the chloroform left a dark, viscous oil, which was extracted with ether. Distillation of the ether afforded 8.25 g. (53%) of crude 6,7-dimethoxyisoquinoline (V); picrate, m.p. 220–221°.

2-Benzoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile (IV).—To an ice-cold mixture of 5.3 g. (0.081 mole) of potassium cyanide, 30 cc. of water and 5.1 g. (0.027 mole) of 6,7-dimethoxyisoquinoline (V) was added with stirring 7.6 g. (0.054 mole) of benzoyl chloride during a period of seven minutes. The mixture was stirred for an additional 1.7 hr. at room temperature, then the aqueous solution was decanted from an orange solid. After having been washed with water, 10% hydrochloric acid, water again and ether, and dried, the solid weighed 8.0 g. and had a m.p. of 130–135°. One crystallization from absolute ethanol gave 2.66 g. (31%) of 2-benzoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile (IV), m.p. 153–155° (reported[19] m.p. 164°). This material was sufficiently pure to be used in the reactions to be described below.

In another run, the anhydrous method of Grosheintz and Fischer[34] was employed. From a mixture of 37.84 g. (0.20 mole) of 6,7-dimethoxyisoquinoline (V), 10 cc. of liquid hydrogen cyanide and 14.06 g. (0.10 mole) of benzoyl chloride in anhydrous benzene there was obtained 27.0 g. of gummy material. One crystallization from absolute ethanol gave 6.05 g. (19%) of 2-benzoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile (IV), m.p. 156–157°.

Reaction of the Lithium Salt of 2-Benzoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile with 1.16 Equivalents of Veratraldehyde (IX).—To a solution of 2.00 g. (0.0062 mole) of 2-benzoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile (IV) in 15 cc. of anhydrous ether and 25 cc. of anhydrous dioxane was added slowly an ether solution of phenyllithium prepared from 1.62 g. of bromobenzene, the solution being stirred and maintained at a temperature of −20° and under a nitrogen atmosphere during this and the subsequent operation. To the deep red solution was added slowly 1.20 g. (0.0072 mole) of veratraldehyde (IX). The mixture was stirred for 1 hr. at −20° and then for 12 hr. at room tem-

perature. The mixture was extracted with 20-cc. portions of water, 2% hydrochloric acid solution and water once again.

The aqueous acid solution was made alkaline and extracted with chloroform. Distillation of the chloroform left a residue of 0.77 g. of papaverinol (II), m.p. 137–138° (reported[13] m.p. 137°), which did not depress the m.p. of an authentic sample of papaverinol (II), prepared by the action of mercuric acetate on papaverine (I).[13] The infrared spectrum of the material was taken in chloroform solution and found to be identical with that of the authentic papaverinol (II).

After distillation of the solvents from the original ether–dioxane solution, there remained 2.80 g. of a gummy material. Most of this material readily dissolved in ethanol, but 0.30 g. of crystalline material, m.p. 209.5–211.0°, remained undissolved. Further purification by crystallization from a relatively large amount of ethanol gave material of m.p. 211.0–211.8°. This was not papaveraldine (III) since the m.p. of authentic papaveraldine (III), prepared by oxidation of papaverine (I) with potassium dichromate in acetic acid,[7] was depressed on admixture with the compound. Also, the infrared spectra of the two compounds, taken in chloroform solution, were not identical. However, the compound, m.p. 211.0–211.8°, had an absorption peak at 1650 cm.$^{-1}$, indicating the presence of a keto group.

Anal. Found: C, 68.80; H, 5.39; N, 8.37.

A solution of 0.88 g. of potassium hydroxide in 50 cc. of water was added to the ethanol solution of the gummy material cited above and the mixture was refluxed for 1.7 hr. The ethanol was distilled *in vacuo* and the aqueous solution extracted with chloroform. Evaporation of the chloroform gave 0.72 g. of papaverinol (II), m.p. 133–135°. The total yield of papaverinol (II) was 1.49 g. (67%).

Reaction of the Lithium Salt of 2-Benzoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile with an Excess of Veratraldenyde (IX).—A reaction was carried out with the lithium salt prepared from 2.70 g. (0.0084 mole) of 2-benzoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile (IV) and 6.50 g. (0.039 mole) of veratraldehyde (IX) in the same manner as described above. After the washing operation with water and 2% hydrochloric acid (no organic material obtained on making the acid wash alkaline), the solvent was distilled from the organic layer. The residual oil was added to a solution of 1.17 g. of potassium hydroxide in 60 cc. of 33% ethanol, and the resulting mixture was refluxed for 1 hr. Most of the alcohol was removed by distillation *in vacuo*, and the residual mixture was extracted with chloroform. The chloroform solution was extracted with 10% hydrochloric acid, then the aqueous acid solution was made alkaline and extracted with fresh chloroform. Removal of the chloroform by distillation gave 1.99 g. (67%) of papaveraldine (III), m.p. 195–200° (reported[8,9] m.p. 210°). Recrystallization from absolute ethanol gave material of m.p. 208–209°, which did not depress the m.p. of authentic papaveraldine (III).[7] The infrared spectrum of the compound was taken in chloroform solution and found to be identical with that of the authentic material.

3,4-Dimethoxybenzyl Chloride (X).—This compound, m.p. 49–51°, was prepared in 73% yield by the method of Kindler and Gehlhaar.[40]

Synthesis of Papaverine (I).—To a solution of 3.20 g. (0.01 mole) of 2-benzoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile (IV) in 25 cc. of anhydrous ether and 30 cc. of anhydrous dioxane maintained at −20° was added with stirring an ether solution of phenyllithium prepared from 1.93 g. of bromobenzene. The solution was maintained under an atmosphere of pure nitrogen during this and the subsequent operation. To the exchange mixture was added a solution 2.33 g. (0.0125 mole) of 3,4-dimethoxybenzyl chloride in 5 cc. of ether. The reaction mixture was stirred at −20° for 2 hr., then at room temperature for 12 hr. The mixture was washed with 25-cc. portions of water, 0.5 *M* hydrochloric acid and water once again. Distillation of the solvent gave 5.63 g. of gummy material. Upon addition of ethanol to this material, 0.33 g. of starting material, 2-benzoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile (IV), m.p. 159.5–161.0°, crystallized and was collected by filtration. To the filtrate was added a solution of 1.40 g. of potassium hydroxide in 60 cc. of water, and the resulting mixture was refluxed for 1.5 hr. Most of the alcohol was removed by distillation *in vacuo*, and the residue was extracted with ether. Distillation of the ether gave 3.62 g. of gummy solid. This was dissolved in chloroform, extracted with 10% hydrochloric acid and the acid solution made alkaline by addition of sodium bicarbonate. Extraction of the alkaline mixture with benzene afforded 2.06 g. of gummy material. Trituration of this material with absolute ethanol gave as the residue 0.68 g. (22%) of papaverine (I), m.p. 140–144°, reported[15] m.p. 146–147°. Recrystallization from ethanol gave material of m.p. 145–147° which did not depress the m.p. of an authentic sample of papaverine (I). The infrared spectrum of the material was taken in chloroform solution and found to be identical with that of authentic papaverine (I).

Addition of picric acid to the alcohol solution from the trituration step caused 0.46 g. of the picrate of 6,7-dimethoxyisoquinoline (V) to precipitate. The m.p. was found to be 225–226°, also in admixture with authentic V.

2-(3,4-Dimethoxybenzoyl)-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile (XII).—The compound was prepared in 73% yield from 6,7-dimethoxyisoquinoline, 3,4-dimethoxybenzoyl chloride[41] and liquid hydrogen cyanide by the Grosheintz and Fischer method.[34] After recrystallization from 95% ethanol the compound had a m.p. of 152.0–152.4°.

Anal. Calcd. for $C_{21}H_{20}N_2O_5$: C, 66.30; H, 5.30; N, 7.37. Found: C, 66.49; H, 5.53; N, 7.21.

Attempted Rearrangement of 2-(3,4-Dimethoxybenzoyl)-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile (XII).—Attempted rearrangement of XII by use of sodium hydride in boiling xylene according to the procedure of Boekelheide and Weinstock[29] led only to partial recovery of XII and decomposition with formation of 6,7-dimethoxyisoquinoline (V).

2-(3,4-Dimethoxybenzoyl)-1,2-dihydroisoquinaldonitrile.—To a mixture of 13.5 g. (0.207 mole) of potassium cyanide, 80 cc. of water and 8.90 g. (0.069 mole) of isoquinoline was added with stirring 26.2 g. (0.138 mole) of freshly prepared 3,4-dimethoxybenzoyl chloride[41] during a period of 15 minutes. The mixture was stirred for an additional 50 minutes. A solid material which had formed was collected by filtration and washed with water, 10% hydrochloric acid and ether. This treatment provided 16.16 g. (73%) of crystalline 2-(3,4-dimethoxybenzoyl)-1,2-dihydroisoquinaldonitrile, m.p. 193.5–196.5°. Recrystallization from glacial acetic acid, then absolute ethanol gave pure material, m.p. 202.3–202.6°.

Anal. Calcd. for $C_{19}H_{16}O_3N_2$: C, 71.24; H, 5.04; N, 8.75. Found: C, 71.02; H, 5.26; N, 8.80.

2-Cinnamoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile.—The compound was prepared in 68% yield from 6,7-dimethoxyisoquinoline (V), cinnamoyl chloride and liquid hydrogen cyanide by the Grosheintz and Fischer method.[34] Upon recrystallization from absolute ethanol there was obtained yellow crystalline material of m.p. 164.8–165.4°.

Anal. Calcd. for $C_{21}H_{18}N_2O_3$: C, 72.82; H, 5.24; N, 8.09. Found: C, 73.05; H, 5.21; N, 7.91.

2-Anisoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile.—Prepared in 78% yield by the Grosheintz and Fischer method,[34] the compound was crystallized from absolute ethanol, giving material of m.p. 156.4–157.2°.

Anal. Calcd. for $C_{20}H_{18}N_2O_4$: C, 68.56; H, 5.18; N, 8.00. Found: C, 68.69; H, 4.95; N, 8.16.

Acid-catalyzed Hydrolysis of the Reissert Compounds.—Each of the Reissert compounds was subjected to acid catalyzed hydrolysis in a hydrochloric acid solution of 2,4-dinitrophenylhydrazine as previously described.[42] From 2-benzoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile (IV) there was obtained an 84% yield of benzaldehyde 2,4-dinitrophenylhydrazone; from 2-(3,4-dimethoxybenzoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile (XII), 87% of veratraldehyde 2,4-dinitrophenylhydrazone; from 2-(3,4-dimethoxybenzoyl-1,2-dihydroisoquinaldonitrile, 91% of veratraldehyde 2,4-dinitrophenylhydrazone; from 2-cinnamoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile, 98% of cinnamaldehyde 2,4-dinitrophenylhydrazone; and from 2-anisoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile, 89% of anisaldehyde 2,4-dinitrophenylhydrazone.

Reaction of 2-Cinnamoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile with Anhydrous Hydrogen Chloride.—When anhydrous hydrogen chloride was passed into a pure chloroform solution of 2-cinnamoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile at 0° and in an atmosphere of pure nitrogen, the solution first turned yellow, then orange and finally a red solid precipitated. This was washed with ether and dried over calcium chloride *in vacuo*. It is thought that the substance is a monohydrate of XIII or its tautomer. The substance decomposed at 190–192°.

Anal. Calcd. for $C_{21}H_{21}N_2O_4Cl$: C, 62.92; H, 5.28; N, 6.99; Cl, 8.85. Found: C, 61.92; H, 5.18; N, 6.84; Cl, 9.53.

Preparation of Papaverinol (I) from 2-Anisoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile and from 2-Cinnamoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile.—The condensation reactions with veratraldehyde (IX) were carried out in the same manner as described above for the reaction of the lithium salt of 2-benzoyl-6,7-dimethoxy-1,2-dihydroisoquinaldonitrile (IV) with 1.16 equivalents of veratraldehyde (IX). The yields of papaverinol (I) were about the same as when IV was employed.

Base-catalyzed Rearrangement of 2-(3,4-Dimethoxybenzoyl)-1,2-dihydroisoquinaldonitrile.—Only starting material was recovered after an attempt to prepare 1-(3,4-dimethoxybenzoyl)-isoquinoline by treatment of 2-(3,4-dimethoxybenzoyl)-1,2-dihydroisoquinaldonitrile with sodium hydride in boiling xylene according to the procedure of Boekelheide and Weinstock.[29]

To a solution of 5.12 g. (0.016 mole) of 2-(3,4-dimethoxybenzoyl)-1,2-dihydroisoquinaldonitrile in 18 cc. of anhydrous dioxane and 5 cc. of anhydrous ether maintained at −10° and in an atmosphere of nitrogen, there was slowly added with stirring an ether solution of phenyllithium prepared from 3.70 g. of bromobenzene. The deep red reaction mixture was stirred for an additional 15 minutes at −10°, for 3.5 hr. at room temperature, for 15 minutes at 100°, then allowed to stand at room temperature for 12 hr. The mixture was washed with water, then extracted with 10% hydrochloric acid. The acid solution was made alkaline, and ether extraction provided 1.76 g. of very crude phenyl-3,4-dimethoxyphenyl-1-isoquinolylcarbinol (XIV). This material was converted to the picrate, m.p. 172.5–173.5° after several recrystallizations from ethanol.

Anal. Calcd. for $C_{30}H_{24}N_4O_{10}$: C, 60.00; H, 4.03; N, 9.33. Found: C, 60.25; H, 4.02; N, 9.25.

The picrate was decomposed with lithium hydroxide solution and extracted with chloroform. From the chloroform extract there was obtained phenyl-3,4-dimethoxyphenyl-1-isoquinolylcarbinol (XIV), m.p. 135–136° after recrystallization from ethanol.

Anal. Calcd. for $C_{24}N_{21}NO_3$: C, 77.60; H, 5.70; N, 3.77. Found: C, 77.73; H, 5.82; N, 3.84.

Concentration of the organic layer remaining after the extraction with hydrochloric acid gave 2.27 g. of a viscous oil. Sublimation at 0.4 mm. afforded 0.5 g. of isoquinaldonitrile, m.p. 86–87° after recrystallization from petroleum ether (reported[36] for isoquinaldonitrile, m.p. 89.0–89.5°). This product did not depress the m.p. of a sample of authentic isoquinaldonitrile. The infrared spectrum of the material was taken in chloroform solution and found to be identical with that of authentic isoquinaldonitrile.

Condensation of 2-Benzoyl-1,2-dihydroisoquinaldonitrile (XV) with Veratraldehyde (IX).—To a solution of 10.41 g. (0.04 mole) of 2-benzoyl-1,2-dihydroisoquinaldonitrile (XV) in 60 cc. of anhydrous dioxane and 20 cc. of anhydrous ether, maintained at −15° and under an atmosphere of nitrogen, was added slowly with stirring an ether solution of phenyllithium prepared from 7.22 g. of bromobenzene. To the deep red exchange mixture there was added slowly 6.65 g. (0.04 mole) of veratraldehyde (IX). The mixture was stirred at −15° for 2 hr., then at room temperature for 12 hr. The reaction mixture was washed with successive 25-cc. portions of water, 0.5 *M* hydrochloric acid and water. Distillation of the solvent left a residue of viscous oil. Addition of ethanol caused 13.76 g. (86%) of 3,4-dimethoxyphenyl-1-isoquinolylcarbinyl benzoate (XVI) to precipitate, m.p. 121–130°. Recrystallization from ethanol gave material of m.p. 134–135°.

Anal. Calcd. for $C_{25}H_{21}NO_4$: C, 75.17; H, 5.30; N, 3.51. Found: C, 75.06; H, 5.07; N, 3.77.

In a second run, a fourfold excess of veratraldehyde (IX) was employed. The benzoate XVI was isolated in 45% yield upon addition of ethanol to the residual oil as described above. The alcohol mother liquor was diluted to 40 cc. by addition of fresh ethanol, and then a solution of 3.2 g. of potassium hydroxide in 75 cc. of water was added. The mixture was refluxed for 5.5 hr. Ether extraction provided an oil, which was dissolved in chloroform and extracted with 10% hydrochloric acid. The acid solution was made alkaline and extracted with chloroform. Distillation of the chloroform gave an oil which was probably a mixture of 3,4-dimethoxy-1-isoquinolylcarbinol (XVII) and 1-(3,4-dimethoxybenzoyl)-isoquinoline (XVIII), since the infrared spectrum showed a characteristic carbinol peak at 3335 cm.$^{-1}$ and a characteristic ketone peak at 1685 cm.$^{-1}$.

Saponification of 3,4-Dimethoxyphenyl-1-isoquinolylcarbinyl Benzoate (XVI).—To a solution of 5.00 g. of the benzoate XVI in 50 cc. of ethanol was added a solution of 1.75 g. of potassium hydroxide in 100 cc. of water, and the mixture was refluxed for 6 hr. Ether extraction, followed by removal of the solvent gave 3.32 g. (90%) of 3,4-dimethoxyphenyl-1-isoquinolylcarbinol (XVII), m.p. 89–90°. The m.p. was not changed by recrystallization of the solid from ethanol or petroleum ether.

Anal. Calcd. for $C_{18}H_{17}NO_3$: C, 73.20; H, 5.80; N, 4.74. Found: C, 73.00; H, 5.91; N, 4.86.

The picrate, m.p. 100–101°, was crystallized from ethanol.

Anal. Calcd. for $C_{24}H_{20}N_4O_{10}$: C, 54.96; H, 3.84; N, 10.68. Found: C, 54.77; H, 3.99; N, 10.45.

Acidification of the alkaline solution remaining from the ether extraction gave benzoic acid in quantitative yield.

When the benzoate XVI was mixed with an equal weight of veratraldehyde, then saponified, there was obtained a mixture of carbinol XVII and ketone XVIII, as indicated by the presence of absorption peaks at 3335 and 1680 cm.$^{-1}$ in the infrared spectrum.

Preparation of 1-(3,4-Dimethoxybenzyl)-isoquinoline (XIX).—When the lithium salt of 2-benzoyl-1,2-dihydroisoquinaldonitrile (XV) was treated with 3,4-dimethoxybenzyl chloride (X) and the reaction mixture worked up in the same manner as described for the preparation of papaverine (I), there was obtained crude 1-(3,4-dimethoxybenzyl)-isoquinoline (XIX), an oil, in 53% yield. The picrate melted at 165.0–165.5° after crystallization from ethanol.

Anal. Calcd. for $C_{24}H_{20}N_4O_9$: C, 56.69; H, 3.97; N, 11.02. Found: C, 56.92; H, 3.89; N, 10.93.

Xanthinin. II. The Structures of Xanthinin and Xanthatin

BY PETER G. DEUEL AND T. A. GEISSMAN

RECEIVED FEBRUARY 11, 1957

Xanthinin, $C_{17}H_{22}O_5$, and xanthatin, $C_{15}H_{18}O_3$, have been found to be α-methylenic lactones containing a single carbocyclic ring. Evidence is presented for the nature of all of the structural elements, and complete structures are proposed. The compounds are formulated as sesquiterpenoid lactones related to the known azulenogenic guaianolides.

In the first paper of this series[1] were described the isolation and characterization of xanthinin from *Xanthium pennsylvanicum*, and its conversion into xanthatin. Xanthinin is an acetoxy ketolactone which loses the elements of acetic acid with the formation of an α,β–γ,δ-dienone (xanthatin). The composition of xanthatin, $C_{15}H_{18}O_3$, indicated that the compound possessed, in addition to the keto and lactone carbonyl groups, the lactone ring, and the two carbon–carbon double bonds, a total of two additional rings or double bonds.

Hydrogenation and quantitative bromination studies indicated that of these two remaining structural elements, one was a double bond, and that xanthinin and xanthatin were monocarbocyclic compounds. Hydrogenation of xanthinin resulted in the uptake of amounts of hydrogen (about 3 moles) that suggested that both addition and hydrogenolysis were occurring. Hydrogenolysis could be accounted for, since the easily eliminated acetoxy group was probably in a position allylic to one of the double bonds; and indeed it was found that acetic acid is present in the solutions after hydrogenation. However, under conditions in which hydrogenation was allowed to proceed to completion no crystalline products could be isolated.

When hydrogenation was allowed to proceed to the uptake of one mole of hydrogen only, and then interrupted, crystalline dihydroxanthinin was isolated. The formation of dihydroxanthinin did not involve the saturation of the double bond that eventually becomes part of the dienone system of xanthatin, since by the removal of acetic acid from dihydroxanthinin, dihydroxanthatin, having an ultraviolet absorption spectrum nearly identical with that of xanthatin, was formed. It was thus apparent that a double bond hitherto unrecognized had been disclosed, and that xanthinin and xanthatin each contained but one carbocyclic ring.

That the double bond that is reduced in the formation of dihydroxanthinin is present in an exocyclic methylene group was shown by the presence in the dihydro compound of an additional carbon-linked methyl group (Table III, Experimental part) over those present in xanthinin itself. This was confirmed by the isolation of formaldehyde (as the dimedone derivative) by ozonization of xanthinin, and by other experiments described herein.

An examination of the infrared absorption spectrum of xanthinin failed to reveal the characteristic absorption of the aliphatic $>C=CH_2$ grouping at about 890 cm.$^{-1}$ [2] despite the clear indication, reinforced by subsequent observations, of the presence of this group. It seemed probable that the behavior of the methylene group was altered by its presence in a situation other than that of a simple 1,1-disubstituted olefin, and that it might exist in conjugation with the lactone carbonyl group. This expectation was borne out by an examination of the ultraviolet absorption spectra of xanthinin and the dihydro compound.

Xanthinin possesses no prominent ultraviolet absorption until the low wave length region is reached, when strong end absorption is observed in the 220–210 mμ region. This is characteristic of α-methylenic γ-lactones,[3,4] and distinguishes them from α,β-unsaturated γ-lactones in which the double bond is intracyclic. In the latter case, absorption maxima near 215–225 mμ are observed.[3,5] Dihydroxanthinin and dihydroxanthatin lack the pronounced end absorption of their unreduced counterparts, an indication that the reduction of an α-methylenic γ-lactone to an α-methyl lactone has occurred (Table I).

TABLE I

EXTINCTION COEFFICIENTS OF XANTHININ AND DERIVATIVES

Compound	Molar extinction coefficient, ϵ In 95% ethanol 220 mμ	In 95% ethanol 215 mμ	In water 220 mμ	In water 215 mμ
Xanthinin	5974	9037	8823	12193
Dihydroxanthinin	401	925	2031	3332
Xanthinin-pyrazoline	..	2500	..	...

The presence of the conjugated exocyclic methylene group was further established by the reaction of xanthinin with diazomethane, with the formation of a pyrazoline.[4,6] The pyrazoline showed the same loss of end absorption, compared with xanthinin, as did the dihydro compound, again showing that the α,β-ethylenic linkage had disappeared in its formation.

Diazomethane also added to xanthatin with the formation of a compound that still retained the characteristic ultraviolet absorption maximum (276 mμ) of xanthatin itself. This substance, therefore, is the pyrazoline analogous to that derived from xanthinin, and resulted from the addition of diazomethane to the methylene group of the lactone. When the reaction of diazomethane with xanthinin or xanthatin was carried out in methanol–ether, rather than in dry ether alone, two molecules of diazomethane were added with the formation from either xanthinin or xanthatin of the same compound. It is apparent that elimination of acetic acid took place in the reaction with xanthinin. The bis-pyrazoline possesses a markedly different ab-

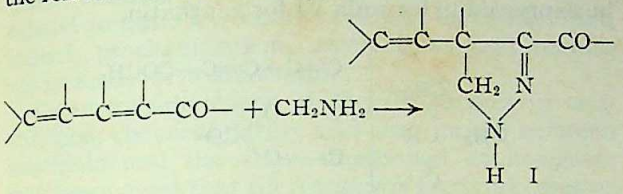
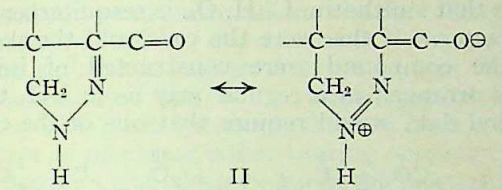
sorption spectrum from that of xanthatin, having a principal maximum at 314 mμ. This suggests that the relevant structural fragment (I) is formed



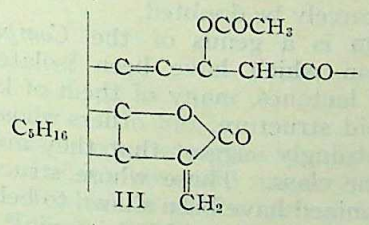
and that the 314 mμ absorption maximum is the result of participation of such contributing forms as II

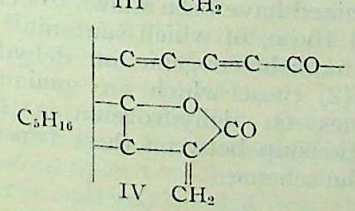


Dihydroxanthinin, as would be expected from these conclusions regarding the structure of the lactone moiety, was recovered unchanged after treatment with diazomethane in ether solution. In methanol, however, a monopyrazoline having the spectral characteristics (λ_{max} 314 mμ) of the bis-pyrazoline of xanthatin is formed.

The formulation of the lactone ring as 5-membered derives from a consideration of the infrared absorption spectra (Table II). The carbonyl absorption of the lactone, recurring in the spectra of xanthinin, xanthatin and their derivatives, is found at 1755–1765 cm.$^{-1}$, typical of γ-lactones and different from that (about 1740 cm.$^{-1}$) characteristic of 6-membered lactones. The observation that the lactone carbonyl frequency does not change materially or systematically upon removal of the α,β-unsaturation by hydrogenation or diazomethane addition is not unusual.[4,5]

The foregoing observations can be summarized in the following partial structures for xanthinin (III) and xanthatin (IV)





Evidence regarding the nature of the five carbon atoms not specified as to structure in III and IV is found in the results of oxidation procedures. These were of two kinds: hypoiodite oxidation and chromic acid oxidations under conditions that were essentially those of the Kuhn–Roth carbon-linked methyl group determination.

Both xanthinin and xanthatin, when treated with sodium hypoiodite, give iodoform and xanthatic acid, $C_{14}H_{16}O_4$. This confirms the presence of the grouping $-COCH_3$, and spectral data indicate that the conjugated system in xanthatin is C=C–C=C–$COCH_3$. The formation of xanthatic acid from xanthinin under these alkaline conditions is accompanied by the loss of acetic acid in a reaction analogous to that in which xanthatin is formed from xanthinin.

Table II

Infrared Spectral Data for Xanthinin and Derivatives

Compound	Absorption peaks in cm.$^{-1}$ Lactone CO	Other CO and C=C	$R_2C=CHR$[d]
Xanthinin[a]	1765	1720	814
Xanthatin[a]	1766	1660, 1609, 1590	812
Dihydroxanthinin[b]	1757	1720	807
Dihydroxanthatin[b]	1760	1653, 1606, 1587	820
Xanthatic acid[c]	1756	1670, 1608	827
Dihydroxanthatic acid[c]	1765	1677, 1613	815
Methyl xanthate-pyrazoline[b]	1770	1715sh, 1700, 1618	834

[a] Film. [b] Chloroform. [c] Potassium bromide disk. [d] For six olefins of the type $R_2C=CHR$, where the substituents are simple alkyl groups, Sheppard and Simpson[2] give 801, 812, 823, 824, 825 and 833 cm.$^{-1}$.

Xanthatic acid shows an absorption maximum at 252 mμ (ethanol) (ε 21,400), in good agreement with the value reported for sorbic acid (254 mμ, ε 24,800),[7] and indicates that xanthatic acid is an α,γ-dienoic acid whose derivation from xanthatin may be represented as

C=C–C=C–$COCH_3$ ⟶ C=C–C=C–COOH

That the lactone grouping of xanthatin is preserved in xanthatic acid is shown by the positive hydroxamic test and by titration experiments. Xanthatic acid can be titrated in ethanol solution to a sharp end-point with the consumption of exactly one equivalent of alkali. When excess alkali is added and the solution is heated, back-titration shows that two equivalents of base are consumed.

Dihydroxanthatic acid was prepared in two ways: by catalytic hydrogenation of xanthatic acid, or by hypoiodite oxidation of dihydroxanthinin. Dihydroxanthatic acid has an absorption maximum at 252 mμ (ε 22,400) and thus possesses the same conjugated system as xanthatic acid. The C-methyl values are in harmony with these observations: xanthatic acid shows 0.54 and dihydroxanthatic acid 1.39 C-methyl groups. Moreover, xanthatic acid shows a greater absorption in the short wave length region than does the dihydro acid, the values for Δε being 7304 (220 mμ) and 9080 (215 mμ).[8]

When xanthatic acid was treated with diazomethane in ether, a nitrogen-containing compound was formed. This substance is the pyrazoline formed by the addition of diazomethane to the α,β-unsaturated system of the lactone, with concomitant esterification of the carboxyl group; it displays an ultraviolet absorption maximum at 262 mμ (ε 25,700), in agreement with its formulation as the

(7) A. E. Gillam and R. E. Stearn, "An Introduction to Electronic Absorption Spectroscopy in Organic Chemistry," E. Arnold, London, 1955.

(8) The value Δε is the difference between the molar extinction coefficients of the unsaturated acid and the dihydro acid at the indicated wave length.

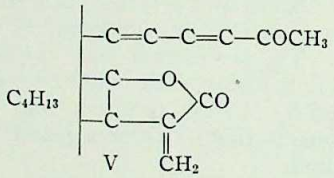
methyl α,γ-dienoate. The very low absorption of the pyrazoline in the 210–220 mμ region, like that of dihydroxanthinin, shows again that the addition of diazomethane is accompanied by the loss of the α,β-unsaturation in the lactone grouping.

Both xanthatic and dihydroxanthatic acids show infrared absorption curves that confirm the above conclusions. The lactone carbonyl bands of 1755 cm.$^{-1}$ for xanthatic acid and 1765 cm.$^{-1}$ for the dihydro acid are in agreement with their formulation as γ-lactones. Xanthatic acid shows a weak absorption at 1410 cm.$^{-1}$ which is assigned to in-plane $=CH_2$ deformations[9]; this band is absent from the spectrum of dihydroxanthatic acid.

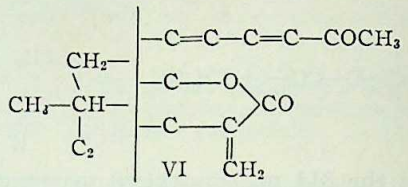
Since xanthatin can now be formulated as V, the remaining questions concern the nature of the residual four-carbon fragment and the manner in which the structural elements shown are assembled.



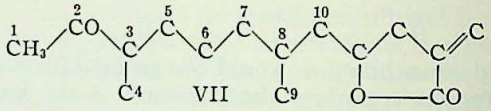
Since the C-methyl determination on xanthatin shows value of 1.44, the presence of two methyl groups is suggested. One of these is in the $-CO-CH_3$ grouping and would be expected to give nearly the theoretical amount of acetic acid. The other, from which only about 0.5 mole of acetic acid is formed, is probably present in a secondary, saturated location. In a very illuminating study of the Kuhn–Roth oxidation, Eisenbaum, McElvain and Aycock[10] have demonstrated that certain simple substances are remarkably resistant to the conditions of this method, and suggested that such acids as succinic, glutaric and adipic may be end-products of the degradation of more complex substances. Model studies were carried out in the course of the present investigation, and it was found that succinic, glutaric and adipic acids could be isolated from proline, cyclopentanone and cyclohexanone, respectively, after simulated C-methyl determinations on these compounds.

The oxidation of xanthinin with a chromic–sulfuric acid mixture gave a 29% yield of methylsuccinic acid. This compound was identified by analysis of it, its monoanilide and the *l*-quinine salt, and by mixed melting point determinations using the latter and an authentic sample. Melting point data on the acid and its anilide were inconclusive, probably because the "natural" acid was a mixture of racemic and active forms. Markownikov[11] reported the isolation of partially racemized (+)-methylsuccinic acid from oxidations of several terpene derivatives. Ladenburg[12] has stated that the *l*-quinine salt formed from *rac*-methylsuccinic acid is that of the dextrorotatory form. In the present experiments the *l*-quinine salt of the "natural" and synthetic samples of methylsuccinic acid were identical in melting point and behavior.

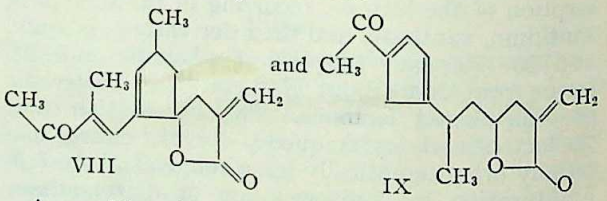
These data allow the structural information to be expressed in formula VI for xanthatin



The presence of the α-substituted lactone grouping and an additional methyl group strongly suggests that xanthatin, $C_{15}H_{18}O_3$, is sesquiterpenoid in character. If this were the case, and the skeleton of the compound were constructed of isoprene units arranged in a regular way as in VII, the C-methyl data would require that one of the carbon



atoms 4 and 9 be utilized in ring formation. Now the ultraviolet absorption maximum of xanthatin is 276 mμ, which corresponds best to a dienone system that is linear and bears two alkyl substituents, or that contains a ring of at least six members in which the γ,δ-double bond is found.[13] Such structures as VIII and IX for xanthatin fail on one or the other of these requirements.



A consideration of biogenetical relationships allows the proposal of a structure that not only accommodates all of the experimental evidence but relates these lactones to others to which their kinship can scarcely be doubted.

Xanthium is a genus of the *Compositae*, the family from which have been isolated a large number of lactones, many of them of known, sesquiterpenoid structure, and others whose empirical formulas strongly suggest that they are members of the same class. Those whose structures have been determined have been shown to belong to two groups: (1) those, of which santonin[14] is typical, which are naphthalenogenic on dehydrogenation (X); and (2) those which are guaianolides and give azulenes on dehydrogenation (XI). The formal relationship between these two classes can be seen in the scheme:

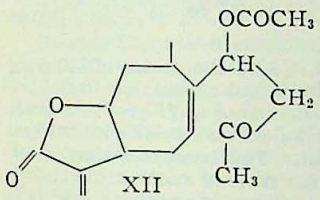
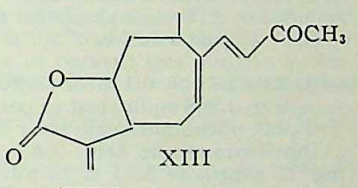
It is further to be noted that xanthinin, a C_{17}-compound, is related to xanthatin as prochamazulene,[15] tenulin,[16] pyrethrosin[17] and isotenulin[16] are related to basic C_{15}-sesquiterpenoid lactones; and, indeed, prochamazulene, pyrethrosin and tenulin are isomeric with xanthinin.

These considerations of the similarities in constitution, chemical nature and plant origin between xanthinin and the above-mentioned azulenogenic lactones suggest that the *Xanthium* lactone possesses a structure which, while not constructed on an azulene skeleton, is a monocarbocyclic congener of this type of compound. Structures XII and XIII are proposed for xanthinin and xanthatin. They accommodate all of the experimental evidence, possess the same basic carbon skeleton (except for the open 5-membered ring) as the known guaianolides, and may be regarded as being derived from a common type of precursor either by ring opening or by the failure of a ring-closing step in the biosynthesis.

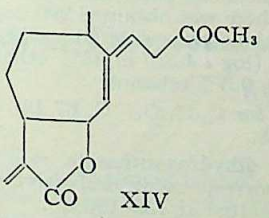


XII



XIII

An alternative structure (XIV, given for xanthatin) cannot be excluded from consideration, and indeed bears a closer analogy in respect to the position of oxygenation of the ring to the known guaianolides than do structures XII and XIII. However, the position of oxygenation of the ring in XII



XIV

and XIII finds its counterpart in tenulin and helenalin,[18] both of which bear two ring-oxygenated positions, one of which is at the carbon shown oxygenated in XII and XIII. Indeed, in the formula advanced for helenalin the lactone ring is constructed as it is in XII and XIII.

The present preference for structure XII for xanthinin rather than the corresponding derivative of XIV is based upon two observations: (1) while methylsuccinic acid was isolated from the oxidation of xanthinin and xanthatin, no α-methylglutaric acid could be found. Since α-methylglutaric acid appears to be nearly as stable as methylsuccinic acid to the oxidizing conditions used,[10] it would have been expected as a product from XIV, but not from XIII. (2) There was no evidence of the presence of an acidic compound, other than acetic acid, among the products of hydrogenation of xanthinin—a result that suggests that the lactone oxygen atom is not attached in the allylic position shown in XIV, in which it would be subject to hydrogenolysis.

With the structures XII and XIII for xanthinin and xanthatin in consideration, supporting evidence was found upon further scrutiny of the infrared spectral data. In the spectra of all of the compounds examined in this study is observed a prominent band in the neighborhood of 820 cm.$^{-1}$ (Table II). This band corresponds to the hydrogen-deformation frequency characteristic of trisubstituted olefins of the type $R_1R_2C{=}CHR_3$,[2] and is excellent confirmatory evidence for the presence in the compounds of a carbon–carbon double bond of the kind shown in XII and XIII (and XIV) as a part of the seven-membered ring.

The structures proposed for the xanthium lactones accommodate all the experimental evidence that is at hand, and in addition allow the reconciliation of some negative results. Numerous experiments aimed at the formation of naphthalene or azulene derivatives by dehydrogenation failed to yield any products of these types.

Further evidence will be required to establish structures XII and XIII, and studies of these and related lactones of the *Compositae* are continuing.

Experimental

Xanthinin was isolated from *Xanthium pennsylvanicum* in the manner described in the first paper in this series.[1]

Xanthatin was prepared by a method that is superior to that first used.[1] A solution of 1.24 g. of xanthinin and 2.3 g. of sodium acetate in 20 ml. of ethanol was refluxed for 40 minutes, 10 ml. of alcohol being allowed to distil from the solution during this period. The mixture was made slightly acid (litmus) with hydrochloric acid and water was added until the sodium chloride had dissolved. Xanthatin (0.96 g., 96%) crystallized on cooling, m.p. 114.5–115.5° after recrystallization from absolute ethanol.

Catalytic Hydrogenation of Xanthinin and Xanthatin.—In attempts to prepare reduction products of xanthinin, experiments were performed in which the extent of hydrogen uptake was determined. (a) Reduction of 55.2 mg. of xanthinin in glacial acetic acid with 8.8 mg. of platinum oxide resulted in the absorption of 2.95 moles of hydrogen per mole of xanthinin. In a repetition of this experiment, 3.17 moles was absorbed. (b) In ethanol, with platinum oxide, 2.90 moles of hydrogen was absorbed. (c) Xanthatin absorbed 3.14 moles of hydrogen in glacial acetic acid and 2.87 moles in ethanol. In none of these experiments could a crystalline hydrogenation product be obtained. The oily materials that resulted gave no indication of acidic character.

Dihydroxanthinin.—A solution of 1.50 g. of xanthinin in 35 ml. of absolute ethanol was hydrogenated at atmospheric pressure in the presence of 27 mg. of platinum oxide. The reaction was interrupted when the amount of hydrogen corresponding to 1.0 mole had been absorbed (about 2 hours), and after removal of the catalyst the filtrate was concentrated and cooled. The yield of dihydroxanthinin from a series of runs using a total of 15.03 g. of xanthinin was 8.02 g. (45%). Dihydroxanthinin forms colorless crystals (from ethanol), m.p. 117–118°.

Anal. Calcd. for $C_{17}H_{24}O_5$: C, 66.21; H, 7.85. Found: C, 66.13; H, 7.80.

The combined mother liquors from the first crystallizations of dihydroxanthinin were evaporated and the residue dissolved in ether. This solution was found to contain 2.64

meq. of titratable acid (compared to 49.05 millimoles of xanthinin reduced), and from it, by appropriate manipulations, 1.17 millimoles of *p*-bromophenacyl acetate was obtained, m.p. 83–85°.

Dihydroxanthatin.—To a solution of 0.53 g. of dihydroxanthinin in 15 ml. of boiling absolute ethanol was added 0.60 g. of sodium bicarbonate. The mixture was refluxed for one hour, filtered and acidified with dilute hydrochloric acid. Colorless crystals of dihydroxanthatin formed at once. Recrystallized from ethanol, the compound forms colorless leaflets, m.p. 138–140°.

Anal. Calcd. for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12. Found: C, 72.47; H, 8.14.

Ozonization of Xanthinin: Isolation of Formaldimedon.—A solution of 0.152 g. of xanthinin in 30 ml. of methylene chloride was ozonized at Dry Ice-acetone temperature for 105 minutes. The reaction solution was added to the contents of a water trap used on the outlet from the ozonization flask and the mixture was refluxed for 20 minutes. The water layer was separated and distilled into an ice-cooled receiver.

An aliquot of 60 ml. of the total 200 ml. of distillate was added to a hot solution of 300 mg. of dimedon in 30 ml. of water. The formaldimedon that separated weighed 11.0 mg. (0.254 mole CH_2O per mole xanthinin), and melted at 190–190.5°. There was no depression on mixing with an authentic sample, m.p. 189°.

Another 60-ml. aliquot of the distillate was analyzed for formic acid by Harper's method.[19] The result showed that 0.112 mole of formic acid was formed per mole of xanthinin.

Reaction of Xanthinin and Xanthatin with Diazomethane. (A).—The diazomethane generated from 3.9 g. of nitrosomethylurea was added to a solution of 1.24 g. of xanthinin in a total of 500 ml. of dry ether. The solution was kept at room temperature for an hour and at 3° for 25 hours, and then evaporated until the diazomethane had been removed and the solution was colorless. The crystalline product that separated on cooling weighed 1.26 g. (90%) and melted at 130–132° with gas evolution. The reaction also was carried out in dioxane–ether; the yield was 0.18 g. from 0.24 g. of xanthinin.

Anal. Calcd. for $C_{18}H_{24}O_5N_2$: C, 62.05; H, 6.94; N, 8.04. Found: C, 62.02; H, 6.94; N, 8.17.

(B).—When dihydroxanthinin was treated with diazomethane in dioxane–ether solution, no adduct could be isolated, and 84% of (recrystallized) starting material was recovered.

(C).—From 79 mg. of xanthatin and excess diazomethane in dioxane–ether was obtained the pyrazoline, m.p. 144.5–146° after recrystallization from methanol.

Anal. Calcd. for $C_{16}H_{20}O_3N_2$: C, 66.64; H, 6.99; N, 9.72. Found: C, 66.66; H, 6.90; N, 9.92.

The compound had a λ_{max} at 276 mμ, showing that the dienone chromophore of xanthatin was unaltered.

(D).—An ethereal solution of diazomethane was added to a solution of 0.30 g. of xanthinin in absolute methanol (10 ml.). After 20 hours at room temperature the solution was evaporated, affording 0.10 g. of product, yellow crystals, m.p. 170–73° with gas evolution. This compound no longer gives the purple-red color with hydrochloric acid that is characteristic of xanthinin and xanthatin; λ_{max} 314 mμ (95% ethanol).

Anal. Calcd. for $C_{17}H_{22}O_3N_4$: C, 61.80; H, 6.71; N, 16.96. Found: C, 61.52; H, 6.70; N, 16.77.

(E).—The same "dipyrazoline" was obtained from xanthatin and diazomethane in methanol–ether solution.

Anal. Found: C, 61.67; H, 7.06; N, 17.28.

(F).—Dihydroxanthinin (0.30 g.) in 10 ml. of methanol was treated with excess ethereal diazomethane. After 6 hours the ether was removed by distillation, and the product allowed to crystallize. The yield was 14.1 mg. of slightly yellowish needles, m.p. 139–142° dec., λ_{max} 314 mμ (95% ethanol).

Anal. Calcd. for $C_{16}H_{22}O_3N_2$: C, 66.18; H, 7.64. Found: C, 66.01; H, 7.48.

Xanthatic Acid.—To a solution of 12.5 g. of iodine in 125 ml. of 20% potassium iodide solution was added 10% aqueous sodium hydroxide until the color of the iodine was discharged. The resulting solution was added to 5.0 g. of xanthinin and, while stirring, sodium hydroxide was added until the solution of the xanthinin was complete. After 30 minutes the solution was acidified carefully until iodine reappeared, then made basic and the precipitated iodoform collected by filtration. The reaction required 24 hours to go to completion. Acidification yielded 3.82 g. of crude xanthatic acid; 4.0 g. of iodoform was obtained, and was identified by melting point and mixed melting point with authentic material.

After three recrystallizations from absolute ethanol, 1.36 g. of xanthatic acid, m.p. 300° dec., was obtained.

Anal. Calcd. for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50. Found: C, 67.37; H, 6.52.

Xanthatic acid gives a positive hydroxamic acid test, but does not give a red color with concentrated hydrochloric acid. It had λ_{max} 252 mμ (log ϵ 4.33) in 95% ethanol, 260 mμ (log ϵ 4.33) in 9.5% ethanol.

***p*-Nitrobenzyl Xanthatate.**—A solution of 105 mg. of xanthatic acid in 0.7 ml. of 4% sodium hydroxide solution was brought to slight acidity (litmus) with hydrochloric acid and added to a solution of 96 mg. of *p*-nitrobenzyl bromide in 3 ml. of ethanol. After one hour of refluxing, the volume of the solution was reduced by distillation and cooled. The product (59.5 mg.) formed colorless crystals from ethanol, m.p. 140–142°.

Anal. Calcd. for $C_{21}H_{21}O_6N$: C, 65.78; H, 5.52. Found: C, 65.74; H, 5.71.

Titration of Xanthatic Acid. (A).—A solution of 110.5 mg. of xanthatic acid in 5 ml. of ethanol containing 10.0 ml. of 0.118 *N* sodium hydroxide was heated at 75° for 20 minutes and titrated to the phenolphthalein end-point with 2.75 ml. of 0.102 *N* hydrochloric acid. The base consumed corresponded to 2.00 equivalents per mole of xanthatic acid.

(B).—A cold solution of 235.8 mg. of xanthatic acid in 50 ml. of ethanol was titrated to a phenolphthalein end-point with 8.24 ml. of 0.115 *N* sodium hydroxide. This corresponds to 0.998 equivalent of base per mole of xanthatic acid. The pink phenolphthalein color faded after about 5 minutes.

Dihydroxanthatic Acid. (A).—The hydrogenation of 167 mg. of xanthatic acid in 15 ml. of ethanol (with platinum oxide, 7.6 mg.) was stopped after 20.0 ml. (0.81 mole) of hydrogen had been taken up. The solution was filtered and concentrated, and yielded on cooling 21.4 mg. of dihydroxanthatic acid, m.p. 232–239° (crude product).

(B).—The oxidation of 0.89 g. of dihydroxanthinin with an alkaline solution of 2.21 g. of iodine was carried out as described for the preparation of xanthatic acid. The crude dihydroxanthatic acid weighed 450 mg. After several recrystallizations there was obtained 296 mg., m.p. 240–243°; iodoform (0.51 g.) also was isolated. Dihydroxanthatic acid had λ_{max} 252 mμ (log ϵ 4.35) in 95% ethanol, and λ_{max} 260 mμ (log ϵ 4.35) in 9.5% ethanol.

Anal. Calcd. for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25. Found: C, 67.06; H, 7.53.

***p*-Nitrobenzyl dihydroxanthatate** was prepared as described for the corresponding derivative of xanthatic acid. The compound melted at 135–136.5°.

Anal. Calcd. for $C_{21}H_{23}O_6N$: C, 65.44; H, 6.02. Found: C, 65.61; H, 6.09.

Chromic Acid Oxidations.—An oxidizing solution was prepared by dissolving 33.6 g. of chromium trioxide in 200 ml. of water and 20 ml. of concentrated sulfuric acid. When 600 mg. of succinic acid was refluxed with 100 ml. of this solution for 1.5 hours, 47% of the succinic acid was recovered. From 1.5 g. of cyclohexanone and 150 ml. of the oxidizing solution (2 hours), 1.21 g. (73%) of adipic acid was isolated; from 1.0 g. of cyclopentanone and 100 ml. of the oxidizing solution (2 hours), 1.14 (73%) of glutaric acid was isolated; and from 1.53 g. of proline and 100 ml. of oxidizing solution, 0.11 g. (8%) of succinic acid was isolated.

Methylsuccinic Acid. (A).—A solution of 1.95 g. of xanthinin in 140 ml. of the oxidizing solution was refluxed for 2.25 hours. The excess chromic acid was reduced with 40% formaldehyde and the aqueous solution extracted continuously with ether. After evaporation of the ether, the residual oily material was dissolved in hot benzene and allowed to cool. The product weighed 0.25 g., melted at 109–111° (reported[19] m.p. 111°), and after recrystallization from water melted at 115–117°. Mixed with *dl*-methylsuccinic acid (m.p. 115–117°) the m.p. was 103–113°. The variation in melting point (recrystallized from carbon tetrachlo-

(19) S. H. Harper, *J. Chem. Soc.*, 595 (1942).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

ride the sample melted at 104–106°) appears to be due to the fact that the compound is a mixture of the active and racemic acids.[11]

Anal. Calcd. for $C_5H_8O_4$: C, 45.45; H, 6.10. Found: C, 45.30; H, 6.26.

(B).—Oxidation of xanthatin under the above conditions gave an 18% yield of methylsuccinic acid, m.p. 112–114°; mixed with *dl*-methylsuccinic acid the m.p. was 105–114°.

Monoanilide of Methylsuccinic Acid (from Xanthinin).—A solution of 85 mg. of methylsuccinic acid in 0.75 ml. of thionyl chloride was refluxed for 45 minutes. The excess thionyl chloride was removed and to the residue was added a solution of 0.5 g. of aniline in 5 ml. of benzene. After 5 minutes refluxing a precipitate appeared. This was collected, washed with dilute hydrochloric acid, dissolved in 5% sodium hydroxide solution, and reprecipitated with dilute acid. Recrystallized from ethanol–benzene, the anilide melted at 150–151.5°.

Anal. Calcd. for $C_{11}H_{13}O_3N$: C, 63.75; H, 6.32; N, 6.76. Found: C, 63.85; H, 6.59; N, 6.74.

Authentic *dl*-methylsuccinanilic acid was prepared, and had m.p. 147–149° (reported 148–149°,[20] 147°[21]), and a mixture of the two melted at 140–144°. Again, the presence of a mixture of active and racemic forms in the product derived from xanthinin is probably responsible for the differences in melting point.

Quinine Salt of *d*-Methylsuccinic Acid (from Xanthinin).—To a hot aqueous solution of 0.114 g. of the methylsuccinic acid from the oxidation of xanthinin was added an equivalent amount of *l*-quinine. On cooling, the solution deposited the crystalline salt, m.p. 168–169.5°. The quinine salt derived from authentic *dl*-methylsuccinic acid was made in the same way, and melted at 168–169.5° (reported[12,22] 169–171°). The two samples showed no depression in melting point on mixing.

The quinine salt crystallizes with water and after drying at room temperature over phosphorus pentoxide (16 hours) melted at 184–186° and analyzed for the monohydrate.

Anal. Calcd. for $C_{20}H_{24}N_2O_2 \cdot C_5H_8O_4 \cdot H_2O$: C, 67.65; H, 7.32. Found: C, 67.63; H, 7.30.

After drying at 138° (P_2O_5, 27 hours) the salt melted at 188–190° and was anhydrous.

Anal. Calcd. for $C_{20}H_{24}N_2O_2 \cdot C_5H_8O_4$: C, 69.20; H, 7.23. Found: C, 68.97; H, 7.27.

The salt from the synthetic acid, treated in the same way, formed the monohydrate (m.p. 182–184°; found: C, 67.64; H, 7.48) and the anhydrous form (m.p. 188–189°; found: C, 69.11; H, 7.36).

Carbon-linked methyl groups were determined by the use of the procedure of Barthel and LaForge.[23] In Table III are collected the C-methyl values for the compounds analyzed.

TABLE III

Compound	C-Methyl groups
Xanthinin	2.45
Xanthatin	1.44
Dihydroxanthinin	2.96
Dihydroxanthatin	1.95
Xanthinin-pyrazoline	2.55
Xanthatin-pyrazoline	1.47
Xanthatin-dipyrazoline	1.42
Xanthatic acid	0.53
Dihydroxanthatic acid	1.39
Methyl xanthatate pyrazoline	0.64

Ultraviolet absorption spectra were determined with a Beckman model DU spectrophotometer.

Infrared absorption spectra were determined with a Perkin–Elmer model 21 recording spectrophotometer equipped with a sodium chloride prism. Samples were in chloroform solution, as a film, or in a potassium bromide disk as noted in Table II.

The Reaction of Thiopseudoureas with 1,3-Diamino-2,2-bis-(hydroxymethyl)-propane[1]

BY L. S. HAFNER AND ROBERT EVANS

RECEIVED DECEMBER 14, 1956

The reaction of 1,3-diamino-2,2-bis-(hydroxymethyl)-propane with the salts of 2-methyl-2-thiopseudourea or with 1-nitro-2-alkyl-2-thiopseudourea formed the following products: the salt of 1,3-bis-(guanidino)-2,2-bis-(hydroxymethyl)-propane, the salt of 1-guanidino-3-amino-2,2-bis-(hydroxymethyl)-propane, 1,3-bis-(nitroguanidino)-2,2-bis-(hydroxymethyl)-propane, 2-nitrimino-5,5-bis-(hydroxymethyl)-1,3-diazacyclohexane and 2-imino-5,5-bis-(hydroxymethyl)-1,3-diazacyclohexane, which may have formed from the nitrimino compound by a secondary reaction involving the addition of ammonia and the elimination of nitramide. These compounds when nitrated yielded 1,3-bis-(nitroguanidino)-2,2-bis-(nitroxymethyl)-propane and 2-nitrimino-5,5-bis-(nitroxymethyl)-1,3-diazacyclohexane. The 1,3-diamino-2,2-bis-(hydroxymethyl)-propane was prepared from the diacetate of 1,3-dibromo-2,2-bis-(hydroxymethyl)-propane by the Gabriel synthesis.

Both straight chain and cyclic guanidine and nitroguanidine derivatives of 2,2-bis-(hydroxymethyl)-1,3-propanediol have been prepared by the reaction between 1,3-diamino-2,2-bis-(hydroxymethyl)-propane and 1-nitro-2-alkyl-2-thiopseudoureas[2] or the salts of 2-methyl-2-thiopseudoureas.[3–5] The 1,3-diamino-2,2-bis-(hydroxymethyl)-propane used in the synthesis of these compounds was prepared from the diacetate of 1,3-dibromo-2,2-bis-(hydroxymethyl)-propane by the Gabriel synthesis. 1,3-Bis-(phthalimido)-2,2-bis-(hydroxymethyl)-propane could not be prepared from 1,3-dibromo-2,2-bis-(hydroxymethyl)-propane. The recovery of over 50% of the potassium phthalimide used in this reaction as phthalimide indicated that hydrogen bromide had split from the 1,3-dibromo-2,2-bis-(hydroxymethyl)-propane with the probable formation of an oxacyclobutane ring. Phthalimide would then be formed by the reaction between hydrogen bromide and potassium phthal-

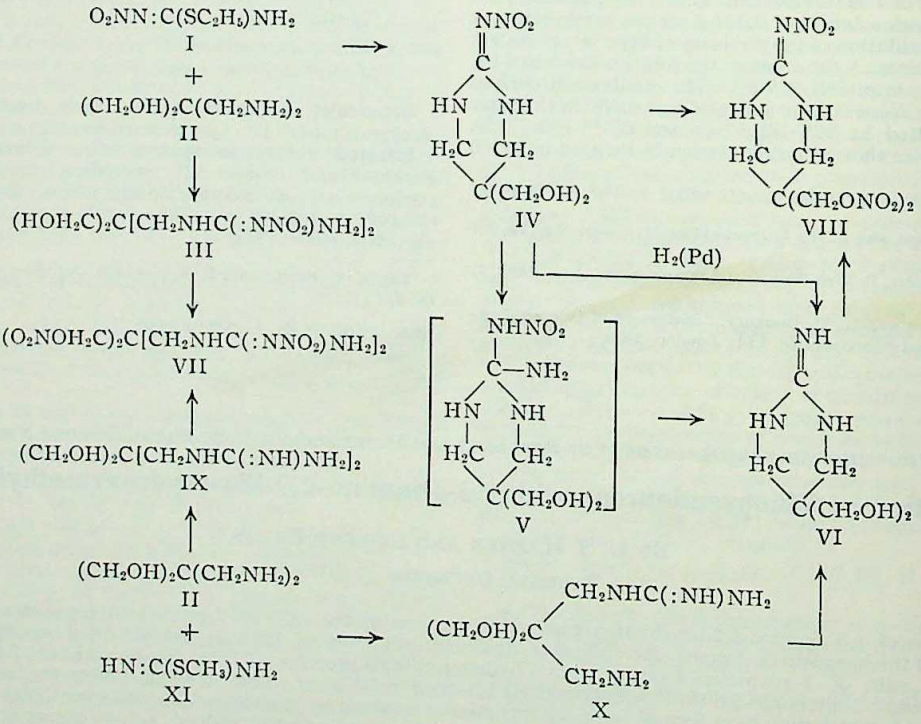
imide. Phthalimide formation was greatly reduced by the acetylation of the hydroxyl groups of the 1,3-dibromo-2,2-bis-(hydroxymethyl)-propane, and by this method a 60% yield of the phthalimido compound was obtained. The hydrolysis of the phthalimido compound with hydrogen bromide was unsatisfactory due to a partial bromination of the hydroxyl groups. However, with aqueous hydrazine,[6] 1,3-diamino-2,2-(hydroxymethyl)-propane was obtained in 45% yield. Slight variations in the hydrazinolysis procedure led to the formation of alcohol-soluble sirups that were difficult to process. Under the conditions used, however, the hydrochloride and nitrate salts of the amine were obtained readily in the crystalline state and were not hygroscopic. Govaert and Beyert,[7] who prepared the amine by the ammonolysis of 1,3-dibromo-2,2-bis-(hydroxymethyl)-propane, stated that these salts were deliquescent and difficult to obtain in a pure state, and elemental analyses were not reported.

uct VI also was prepared by the hydrogenolysis of the cyclic nitrimino compound in the presence of a palladium catalyst.

The reaction between 55% of the molar quantity of 1-nitro-2-methyl-2-thiopseudourea and II produced 26% of the cyclic imino compound VI, 20% of the cyclic nitrimino compound IV and none of the bis-(nitroguanidino) compound III. 2-Nitrimino-5,5-bis-(nitroxymethyl)-1,3-diazacyclohexane (VIII) was prepared from either the cyclic nitrimino compound IV or the nitrate salt of the cyclic imino compound VI by the selection of the proper nitrating conditions.

The free base II reacted with 60% of the molar quantity of the nitrate salt of 2-methyl-2-thiopseudourea (XI) to form the dinitrate salts of both 1,3-bis-(guanidino)-2,2-bis-(hydroxymethyl)-propane (IX, 13%) and 1-amino-3-guanidino-2,2-bis-(hydroxymethyl)-propane (X, 21.5%). The reaction between II and a 20% molar excess of XI gave a 52% yield of the bis-(guanidino) compound



Three compounds were isolated from the reaction between 1-nitro-2-ethyl-2-thiopseudourea (I) (20% molar excess) and 1,3-diamino-2,2-bis-(hydroxymethyl)-propane (II). The principal product was 1,3-bis-(nitroguanidino)-2,2-bis-(hydroxymethyl)-propane (III, 26% yield). The other two products were 2-nitrimino-5,5-bis-(hydroxymethyl)-1,3-diazacyclohexane (IV) (6.3%) and 2-imino-5,5-bis-(hydroxymethyl)-1,3-diazacyclohexane (VI, 20%). The cyclic imino compound VI probably was not an initial reaction product. Possibly it resulted from the elimination of nitramide from an addition compound V formed when the ammonia liberated as IV was produced added to IV.[8] Product IX. By selecting the proper conditions, either the bis-(nitroguanidino) compound III or the nitrate salt of the bis-(guanidino) compound IX could be nitrated to form 1,3-bis-(nitroguanidino)-2,2-bis-(nitroxymethyl)-propane (VII). The free base 1-amino-3-guanidino-2,2-bis-(hydroxymethyl)-propane (X) was converted to the cyclic imino compound VI (20% yield) in refluxing methanol.

Experimental[9]

1,3-Bis-(phthalimido)-2,2-bis-(hydroxymethyl)-propane Diacetate.—The conditions employed for this preparation were a modification of those used by Sheehan and Bolhofer[10] to prepare dimethyl α,δ-diphthalimidoadipate. A solution

of 1,3-dibromo-2,2-bis-(hydroxymethyl)-propane diacetate (194 g., 0.561 mole) in 675 ml. of dimethylformamide was placed in a 2-liter flask equipped with a stirrer, condenser and thermometer. The temperature was maintained at 152° with stirring, while seven portions (24.4 g. each) of potassium phthalimide were added at 10-minute intervals. The temperature was then lowered to 144°, and two more portions of potassium phthalimide were added at 20-minute intervals. The mixture was heated for an additional 4.3 hr. at 144°. The reaction was then cooled to approximately 100° and the sodium bromide removed by filtration. The filtrate was allowed to stand at room temperature overnight, and the precipitate that formed was removed and washed in turn with dimethylformamide, ethanol, water and hot ether. The crude product, 164 g. (62%), was used for the preparation of 1,3-diamino-2,2-bis-(hydroxymethyl)-propane. A pure sample prepared by recrystallizing three times from benzene melted at 199.5–200.5°.

Anal. Calcd. for $C_{25}H_{22}O_8N_2$: C, 62.75; H, 4.64; N, 5.86. Found: C, 62.78; H, 4.64; N, 5.82.

1,3-Diamino-2,2-bis-(hydroxymethyl)-propane Dihydrochloride.—The phthalimido compound was converted to the diamine by the method of Child and co-workers.[6] 1,3-Bis-(phthalimido)-2,2-bis-(hydroxymethyl)-propane diacetate, 153.8 g. (0.324 mole), and 358 ml. of ethanol were placed in a flask equipped with a condenser, stirrer and dropping funnel. The mixture was heated to the reflux temperature, with stirring, and 38.9 g. of aqueous hydrazine (61%, 0.741 mole) was added over a period of 10 minutes. After stirring at the reflux temperature for 15 minutes, the heat was removed, and the mixture was stirred for an additional 50 minutes. At the end of this interval, 55 ml. of concentrated hydrochloric acid was added and the solution stirred for an additional 35 minutes. Concentrated hydrochloric acid (18 ml.) was added to the reaction mixture which was then heated and the ethanol–ethyl acetate azeotrope removed by distillation. Four hundred ml. of additional alcohol was put in as required. The alcoholysis was complete in about 2 hr. The phthalyl hydrazide and undissolved reaction products were then filtered, washed with ethanol and with water and the combined filtrates and wash solutions concentrated under vacuum to a sirup. This sirup was washed twice with absolute ethanol and once with ether, dissolved in water (60 ml.) and filtered. The filtrate was agitated for 1 hr. with salicylaldehyde to remove excess hydrazine. The insoluble material was removed, and the filtrate, after extracting with ether to remove excess salicylaldehyde, was concentrated under vacuum to a sirup. The sirup was washed twice in a Waring blender with absolute ethanol. Recrystallization from ethanol gave 30.8 g. (45.8%) of product with a melting point of 246–247°.

Anal. Calcd. for $C_5H_{16}O_2N_2Cl_2$: C, 28.99; H, 7.79; N, 13.53; Cl, 34.24. Found: C, 29.25; H, 8.02; N, 13.55; Cl, 34.58.

1,3-Diamino-2,2-bis-(hydroxymethyl)-propane Dinitrate Salt.—This compound was prepared from the dipicrate salt of the diamine and after recrystallization from ethanol melted at 117–118°.

Anal. Calcd. for $C_5H_{16}O_8N_4$: C, 23.08; H, 6.20; N, 21.53. Found: C, 23.19; H, 5.99; N, 21.46.

1,3-Bis-(phthalimido)-2,2-bis-(hydroxymethyl)-propane Monoacetate.—A solid sometimes separated from the alcoholic solution remaining after the insoluble phthalyl hydrazide was removed. After purification by crystallizing from methanol, dissolving in chloroform and precipitating with *n*-heptane and crystallizing again from methanol, the compound melted at 142–143°.

Anal. Calcd. for $C_{23}H_{20}O_7N_2$: C, 63.29; H, 4.62; N, 6.42. Found: C, 63.30; H, 4.77; N, 6.58.

1,3-Bis-(phthalimido)-2,2-bis-(hydroxymethyl)-propane.—The attempt to hydrolyze the diacetyldiphthalimido compound to the diamino compound with dilute hydrochloric acid was unsuccessful. The product after crystallization from benzene melted at 220.5–222.0°.

Anal. Calcd. for $C_{21}H_{18}O_6N_2$: C, 63.95; H, 4.60; N, 7.11. Found: C, 64.09; H, 4.44; N, 7.37.

Reaction of 1-Nitro-2-methyl-2-thiopseudourea with an Excess of 1,3-Diamino-2,2-bis-(hydroxymethyl)-propane.—The free base of the diamine was prepared by the reaction between the dihydrochloride and sodium ethoxide. To 3.743 g. (0.0279 mole) of the free base in a 50-ml. flask was added 3.957 g. (0.0293 mole) of the thiopseudourea in small portions over a period of about 15 minutes. The well stirred reaction mixture became warm, and ammonia and methyl mercaptan were evolved. At the end of the addition period, the flask was evacuated with a water aspirator (about 30 mm.) for 15 minutes. Fourteen ml. of absolute ethanol was added, and the flask was evacuated for an additional 15 minutes. The reaction product was filtered and washed with absolute ethanol. The precipitate, which weighed 1.4 g. and melted at 185–193° dec., was set aside. The filtrate was treated with a picric acid–methanol solution. The precipitate that formed (7.3 g.) was dissolved in 500 ml. of ethanol, and, by taking off successive fractions, two products were obtained. The first, consisting of 2.8 g. (17%), was determined to be the dipicrate of the original diamine. The second picrate, 3.9 g. (36.2%), after two crystallizations from ethanol melted at 179–180° and by proof outlined in the discussion was determined to be the picrate of 2-imino-5,5-bis-(hydroxymethyl)-1,3-diazacyclohexane VI.

Anal. Calcd. for $C_{12}H_{16}O_9N_6$: C, 37.12; H, 4.15; N, 21.64. Found: C, 37.10; H, 4.46; N, 21.64.

This picrate was converted to the nitrate salt which, after two crystallizations from absolute ethanol, melted at 114–115°.

Anal. Calcd. for $C_6H_{14}O_6N_4$: C, 32.46; H, 6.36; N, 25.24. Found: C, 32.64; H, 6.22; N, 25.40.

The crude alcohol-insoluble reaction product was dissolved in water and fractionated by slow evaporation. The fractions which melted at 203–207° dec. and weighed 1.01 g. (18.8%) were combined. Crystallization from alcohol and then from water raised the melting point to 207.5–208.5° dec. This product was 2-nitrimino-5,5-bis-(hydroxymethyl)-1,3-diazacyclohexane (IV).

Anal. Calcd. for $C_6H_{12}O_4N_4$: C, 35.29; H, 5.93; N, 27.46. Found: C, 35.43; H, 6.05; N, 27.02.

The nitrimino compound IV was converted to the imino compound VI by hydrogenolysis in the presence of palladium black by the following procedure. The nitrimino compound IV (0.469 g., 0.00296 mole) was added to 50 ml. of 15% acetic acid solution containing 0.06 g. of palladium black in a modified Skita[11] hydrogenation apparatus and agitated, slightly above atmospheric pressure, for 20 hr. The catalyst was removed, the filtrate treated with picric acid and the picrate (57% yield) after crystallization from methanol melted at 179–180°. A mixed melting point with the picrate of compound VI was not depressed.

Reaction of an Excess of 1-Nitro-2-ethyl-2-thiopseudourea with 1,3-Diamino-2,2-bis-(hydroxymethyl)-propane.—A solution of 3.214 g. (0.02175 mole) of the thiopseudourea in 11 ml. of tetrahydrofuran was added to 1.2075 g. (0.009 mole) of the diamine. The mixture was stirred for 25 minutes, the tetrahydrofuran removed under a vacuum, 10 ml. of absolute ethanol added and the stirring continued for 2.5 hr. The solid material was removed and washed with absolute ethanol and then with ether. The filtrate was treated with picric acid. The only product isolated was the picrate of 2-imino-5,5-bis-(hydroxymethyl)-1,3-diazacyclohexane (VI, 20.1%). The insoluble reaction product weighed 1.14 g. and melted at 158–160° dec. Washing with water, alcohol and finally ether reduced the weight to 0.83 g. and increased the melting point to 164–168° dec. This material was dissolved in concentrated hydrochloric acid, filtered and precipitated by dilution with water. The product, compound III (26%), melted at 200–201° dec.

Anal. Calcd. for $C_7H_{16}O_6N_8$: C, 27.23; H, 5.23; N, 36.35. Found: C, 27.43; H, 5.28; N, 36.24.

The material recovered by the evaporation of the diluted hydrochloric acid solvent and by the evaporation of the water wash of the crude material was crystallized from ethanol. The product was the nitrimino compound IV (6.3%). A mixed melting point with an authentic sample of IV was not depressed.

Reaction of 1,3-Diamino-2,2-bis-(hydroxymethyl)-propane with an Excess of the Nitrate Salt of 2-Methyl-2-thiopseudourea.—To a stirred solution of 2.459 g. (0.0183 mole) of the diamine in 2 ml. of water was added a 10% excess of the nitrate salt of 2-methyl-2-thiopseudourea, 6.184 g.

(11) A. Skita and W. A. Meyer, *Ber.*, **45**, 3589 (1912).

(0.0403 mole), dissolved in 8 ml. of water. The reaction was stirred for 5.5 hr. at room temperature, allowed to stand overnight and then stirred for an additional 5 hr. with a current of air blowing over the surface of the liquid to remove methyl mercaptan and ammonia. The reaction mixture was filtered, the precipitate washed with absolute ethanol and all the filtrates combined and treated with picric acid. The reaction precipitate was dissolved in warm water (60°) and successive fractions of crystals collected by slow evaporation of the water. A total of 3.27 g. (51.8%) of material was recovered. After recrystallizing twice from water, the product, the dinitrate salt of compound IX, melted at 196–198° dec.

Anal. Calcd. for $C_7H_{20}O_8N_8$: C, 24.41; H, 5.86; N, 32.55. Found: C, 24.59; H, 5.98; N, 32.33.

The dipicrate was prepared from the nitrate salt and after crystallization from methanol melted at 257–259° dec.

Anal. Calcd. for $C_{19}H_{24}O_{16}N_{12}$: C, 33.74; H, 3.58; N, 24.85. Found: C, 33.81; H, 3.68; N, 24.85.

The picrates from the filtrate could not be separated. Conversion to the nitrate salts and extraction with acetone gave a small amount of the nitrate salt of the starting material, 2-methyl-2-thiopseudourea (XI).

Reaction of the Nitrate Salt of 2-Methyl-2-thiopseudourea with an Excess of 1,3-Diamino-2,2-bis-(hydroxymethyl)-propane.—To the diamine (2.951 g., 0.022 mole) dissolved in 2 ml. of water was added 3.719 g. (0.0275 mole) of the thiopseudourea salt in 2 ml. of water. The mixture was stirred for 5.5 hr., absolute ethanol added and the insoluble material removed and washed with absolute ethanol. This product was crystallized from water, and its properties indicated that it was the dinitrate salt of compound IX (13% yield).

The filtrate was heated with picric acid, and the picrates were collected and converted to the nitrate salts. Fractional crystallization from ethanol gave 1.43 g. (21.4%) of product X which melted at 128–129°.

Anal. Calcd. for $C_6H_{18}O_8N_6$: C, 23.84; H, 6.00; N, 27.80. Found: C, 24.50; H, 5.63; N, 27.49.

The dipicrate was prepared from the purified nitrate and after crystallization from methanol melted at 209.5–211.5° dec.

Anal. Calcd. for $C_{18}H_{12}O_{16}N_{10}$: C, 34.20; H, 3.51; N, 22.10. Found: C, 34.18; H, 3.42; N, 21.93.

It was found that 1-amino-2-guanidino-2,2-bis-(hydroxymethyl)-propane (X) could be cyclized to VI by the following procedure. The salt (0.365 g.) was converted to the free base with sodium ethoxide, dissolved in methanol and refluxed for 1.2 hr. The product was neutralized with dilute nitric acid and concentrated in a current of air. Absolute ethanol was then added and 0.163 g. of sodium nitrate removed. The filtrate was treated with picric acid and the picrate removed. After crystallization from water the product weighed 0.093 g. (20%) and melted at 179–180°. A mixed melting point with an authentic sample of the picrate of VI was not depressed.

2-Nitrimino-5,5-bis-(nitroxymethyl)-1,3-diazacyclohexane (VIII).—The nitrate salt of the imino compound VI (0.7 g., 0.0032 mole) was added to a nitration mixture consisting of 1.29 g. of 99% nitric acid and 2 ml. of 98% sulfuric acid at −15°. The mixture was kept below 10° for 12 minutes and then allowed to warm and stand at room temperature (21°) for 1.7 hr. It was then poured over 30 g. of crushed ice and the precipitate collected on a medium sintered-glass funnel. The product VIII (0.61 g., 65.9%) after crystallization from ethanol melted at 214–215° dec.

The nitrimino compound IV (0.465 g., 0.0023 mole) was added to 5 g. of 99% nitric acid at −10°. The solution was held at 10–15° for 30 minutes, poured over 30 g. of crushed ice, filtered and the precipitate washed with cold water. The product VIII (0.601 g., 89%) after crystallization from water melted at 214–215° dec.

Anal. Calcd. for $C_5H_{10}O_8N_6$: C, 24.49; H, 3.43; N, 28.57. Found: C, 24.56; H, 3.28; N, 28.63.

1,3-Bis-(nitroguanidino)-2,2-bis-(nitroxymethyl)-propane (VII).—The dinitrate salt of IX (1.008 g., 0.0029 mole) was nitrated by the procedure used to produce the nitrate salt of VI except that the holding time at room temperature was increased to 2.7 hr. The product VII (0.613 g., 53%) after crystallization from water melted at 158.5–160° dec.

The nitroguanidino compound III (0.39 g., 0.00129 mole) was nitrated in 4 ml. of 99% nitric acid using the same procedure as for the cyclic nitrimino compound IV. The product VII weighed 0.4393 g. (85.5%) and melted at 158–160° dec.

Anal. Calcd. for $C_7H_{14}O_{10}N_{10}$: C, 21.11; H, 3.54; N, 35.17. Found: C, 21.37; H, 3.66; N, 34.82.

Acknowledgment.—We wish to thank Mrs. P. P. Wheeler for the microanalyses and Dr. J. A. Gallaghan for his helpful suggestions.

2,2-Disubstituted-1,3-propanediamines and Related Diurethans, Diureides and Hexahydropyrimidin-2-ones

BY GLENN S. SKINNER, RICHARD H. HALL AND PETER V. SUSI

RECEIVED FEBRUARY 20, 1957

2,2-Disubstituted-1,3-propanediamines have been prepared and converted to diurethans, diureides and hexahydropyrimidin-2-ones. A practical synthesis of 5-alkyl-5-phenylhexahydropyrimidin-2-ones has been the major achievement. As a cyclization reagent diphenyl carbonate was superior to diethyl carbonate.

Since the replacement of carbonyl by methylene at position 2 in 5-ethyl-5-phenylbarbituric acid gave a compound[1] which still possessed anticonvulsant properties, it seemed of interest to prepare analogs with methylene groups at positions 4 and 6 in the ring. Our experimental work was practically complete when there appeared a paper[2] describing the preparation of one of these compounds (Table III) by reduction of the corresponding barbituric acid derivative.

Our syntheses depend upon the preparation of the 2,2-disubstituted-1,3-propanediamines. The method involving the condensation of ketones[3] with nitromethane generally gave poor yields when both radicals were larger than ethyl. In the case of propiophenone none of the intermediate dinitro compound was obtained.

The 2-alkyl-2-phenyl-1,3-propanediamines were therefore prepared from phenylcyanoacetamide[4] which was alkylated[5] and then reduced to the di-

amine. The use of lithium aluminum hydride gave incomplete reduction, partial cleavage to 2-phenylbutylamine and a poor yield of the diamine when tested in the case of ethylphenylcyanoacetamide. The 2-phenylbutylamine was identical with that from 2-phenylbutyronitrile. Equimolar quantities of aluminum chloride[6] and the hydride afforded a good yield of the diamine and almost completely eliminated cleavage to the monoamine. The yields of VII, VIII, IX and X (Table I) all refer to this improved procedure.

2,2-Dimethyl-1,3-propanediamine (I) when refluxed 4 days with 5 moles of diethyl carbonate until the theoretical amount of alcohol had distilled gave almost twice as many moles of diurethan XI as the hexahydropyrimidin-2-one XX (Table II). The identical diurethan prepared from ethyl chloroformate, when heated at 240–245°, gave diethyl carbonate and XX. In contrast to the action of diethyl carbonate on the diamine, diphenyl carbonate gave good yields of the hexahydropyrimidin-2-one (Table III) in 8 hr. XI was also converted to the diamine I by acid hydrolysis. The diureide XVI was thermally decomposed to the hexahydropyrimidin-2-one XXVIII. Finally, the hexahydropyrimidin-2-one XX was hydrolyzed to I by refluxing with sulfuric acid.

Preliminary pharmacological tests[7] indicate that the diurethans and hexahydropyrimidin-2-ones possess hypnotic and anticonvulsant activity while the diureides have little or no activity.

Experimental

2,2-Dialkyl-1,3-dinitropropanes.—These compounds were prepared by condensation of nitromethane[8] with the corresponding ketone. 2,2-Diisobutyl-1,3-dinitropropane is new. Diisobutyl ketone (427 g.), diethylamine (880 g.), nitromethane (735 g.) and Drierite (200 g.), allowed to react one week at ice temperature, gave 86.5 g. (11.7%) of the desired product, b.p. 153° (3.4 mm.).

Anal. Calcd. for $C_{11}H_{22}O_4N_2$; N, 11.34. Found: N, 11.24.

Reduction of 2,2-Dialkyl-1,3-dinitropropanes to Diamines.—2,2-Diethyl-1,3-dinitropropane (0.20 mole) in 100 cc. of alcohol with 15 g. of Raney nickel[8] at an initial pressure of 1000 p.s.i. of hydrogen was allowed to react in a rocking bomb at 50–65° until there was no further drop in pressure (2 hr.). In addition to the desired product (20 g., 77%), diethylmalonamide (1.5 g., m.p. 219–219.5°) and low boiling cleavage products were formed.

[a] This compound (m.p. 195–197°) has been made by the reduction of phenobarbital and was reported after our product had been prepared; ref. 2.

The remaining dialkyldinitropropanes were reduced to II, III, V and VI, respectively, by iron and hydrochloric acid. The reduction procedure of Senkus[9] was followed except that alcohol was added to the reaction mixture to aid in the separation of the diamine from the voluminous precipitate of iron hydroxide. Thus the reaction mixture from 20.4 g. (0.100 mole) of 2-isobutyl-2-methyl-1,3-dinitropropane, 44.8 g. (0.800 mole) of iron turnings, 21 cc. of hydrochloric acid (sp. gr. 1.19), 100 cc. of water and 150 cc. of alcohol required 20 g. of sodium hydroxide to cause separation of the iron hydroxide so that the clear supernatant liquid could be decanted. The iron hydroxide was washed by decantation with small portions of alcohol. Sodium hydroxide was dissolved in the combined decantate and washings until two layers separated. The upper alcohol layer was removed and the lower aqueous layer was extracted with three 30-cc. portions of alcohol. The com-

bined alcohol layer and extracts were dried over sodium sulfate. The alcohol was distilled and enough water was added to dissolve the residual sodium hydroxide. The supernatant liquid was removed and the water layer was extracted with four 20-cc. portions of ether. The combined liquid and extract were dried over sodium sulfate. II was obtained by distillation (Table I).

2-Alkyl-2-phenylcyanoacetamides.—Phenylcyanoacetamide was prepared by the action of aqua ammonia on phenylcyanoacetic ester[4] in yields of 75–80%. This was alkylated according to the method of Thompson, *et al.*[5] The methyl derivative does not appear to have been reported. In this case the temperature of the reaction mixture was lowered to 50° before the methyl iodide was added; yield 70%, m.p. 113–114°.

Anal. Calcd. for $C_{10}H_{10}ON_2$: N, 16.08. Found: N, 15.82.

2-Alkyl-2-phenyl-1,3-propanediamines.—To a well-stirred mixture of 20.0 g. (0.528 mole) of lithium aluminum hydride and 150 cc. of absolute ether was added rapidly through the dropping funnel a solution of 70.5 g. (0.528 mole) of aluminum chloride[6] in 350 cc. of ether. Five minutes later a solution of 0.100 mole of the 2-alkyl-2-phenylcyanoacetamide in 150 cc. of absolute ether and 60 cc. of anhydrous tetrahydrous tetrahydrofuran was added dropwise to the stirred refluxing mixture. Refluxing was continued 18–24 hr. during which the color changed from light tan to dark gray.

The excess hydride was decomposed by the dropwise addition of 20 cc. of water to the cooled mixture. After careful addition of 700 cc. of 6 *N* hydrochloric acid and 500 cc. of water, the mixture was allowed to stand overnight. The ether layer was separated and the aqueous layer was extracted with four 100-cc. portions of ether. Potassium tartrate (380 g.) was dissolved in the aqueous layer and sodium hydroxide (scales) was carefully added until no solid remained. The alkaline solution was extracted with six 200-cc. portions of ether. The extract was dried over sodium sulfate and distilled (Table I). The amount of monoamine produced under these conditions was negligible in all cases.

Reduction to a Monoamine with $LiAlH_4$.—A mixture of 20 g. (0.528 mole) of the hydride and 300 cc. of dry ether (or tetrahydrofuran) was refluxed for 6 hr. To this was added dropwise a solution of 18.8 g. (0.100 mole) of 2-ethyl-2-phenylcyanoacetamide in 100 cc. of tetrahydrofuran. The mixture was refluxed 14 hr. and after cooling was decomposed with 20 cc. of water followed by 430 cc. of 9 *N* hydrochloric acid. Most of the solvent was distilled and the aqueous layer was extracted with ether. The aqueous layer was treated carefully with 300 g. of sodium hydroxide and then extracted with six 100-cc. portions of ether. The ether extract was dried over sodium sulfate and distilled: (1) b.p. 108–112° (20 mm.), 2.6 g. (18%); (2) b.p. 159–163° (20 mm.), 3.7 g. (21%). The combined products from three preparations were redistilled. Fraction 1: b.p. 109–109.5° (20 mm.)[10]; $n^{25}D$ 1.5162, d^{25} 0.9317. Calcd. for $C_{10}H_{15}N$: *MR*, 48.21; neut. equiv., 149. Found: *MR*, 48.39; neut. equiv., 151.

The hydrochloride was precipitated from a dry ether solution of the monoamine, m.p. 168–169° (lit.[10] 156°). An authentic sample of 2-phenylbutylamine (b.p. 108–110° (20 mm.), $n^{25}D$ 1.5163) prepared by reduction of 2-phenylbutyronitrile with $AlCl_3$ and $LiAlH_4$ (see above) gave a hydrochloride which, after crystallization from ligroin (b.p. 90°) containing enough alcohol to dissolve it at the boiling point, had m.p. and mixed m.p. 168–169°.

Anal. Calcd. for $C_{10}H_{16}NCl$: Cl, 19.09. Found: Cl, 19.10.

Redistilled fraction 2 had b.p. 162–164° (18 mm.). *Anal.* Calcd. for $C_{11}H_{14}(NH_2)_2$: neut. equiv., 89. Found: neut. equiv., 95.

Reaction of Diethyl Carbonate with 2,2-Dimethyl-1,3-propanediamine (I).—A mixture of 20.4 g. (0.200 mole) of I and 118 g. (1.00 mole) of diethyl carbonate was refluxed four days in a flask fitted with a small condenser (protected from air by Ascarite) and a small fractionating column. From time to time the alcohol from the reaction was distilled while the condenser was closed; yield of alcohol 17.7 g. (96%). The solid in the cooled residue was filtered with suction. One crystallization from alcohol gave XX, m.p. 255–257°, soluble in hot water and insoluble in ether. The filtrate was distilled to give 19.9 g. (41%) of the diurethan XI, b.p. 138–141° (0.6–0.7 mm.). The product crystallized on standing and was purified by crystallization from ligroin, m.p. 62–64°, identical with XI from the action of ethyl chloroformate on the diamine.

A mixture of 1.6 g. of XI, 6.6 g. of hydrochloric acid (37%) and 1.6 g. of glacial acetic acid was refluxed two days to yield 1.0 g. of the dihydrochloride[11] which had m.p. 256–257° (from alcohol). The m.p. of this salt varies greatly with the rate of heating. It was identical with an authentic sample prepared from the diamine.

Preparation of the Diurethans.—In a typical adaptation of a well known procedure,[12] 5.1 g. (0.050 mole) of I and 10.9 g. (0.100 mole) of ethyl chloroformate gave 10.7 g. (87%) of product which crystallized from ligroin to yield pure XI.

Conversion of the Diurethan to the Hexahydropyrimidin-2-one.—XI (2.5 g., 0.10 mole) was heated 1 hr. at 240–245° and 1 hr. at 265–275° during which 0.90 g. (76%) of diethyl carbonate (b.p. 124–126°) distilled. The cooled solid residue, after washing with ether, weighed 0.70 g. (55%). Crystallization from alcohol gave XX, m.p. 255–257°, identical with that obtained from the action of diethyl carbonate on I.

2-Alkyl-2-phenyl-1,3-propanediureides.—In a typical experiment 6.6 g. (0.040 mole) of VII was dissolved in 13 cc. of water and 6.6 cc. (0.080 mole) of hydrochloric acid (sp. gr. 1.19). To this solution was added rapidly with stirring a solution of 6.8 g. (0.084 mole) of potassium cyanate in 12 cc. of water. The mixture was heated on the steam-bath for 15 min. (5 for the isopropyl derivative) with occasional stirring. After standing at room temperature the mixture was cooled in ice. The crystalline XVI was filtered, crystallized from hot water and dried *in vacuo*.

Conversion of the Diureide to the Hexahydropyrimidin-2-one.—XVI (1.0 g.) was heated 30 min. at 210–215° and then 15 min. at 255–260°. The cooled material was dissolved in hot alcohol and filtered from a small amount of insoluble matter. The filtrate was evaporated to a small volume, mixed with two volumes of hot water and cooled. The crystals were recrystallized twice from 2:1 water–alcohol; yield of XXVIII, 0.32 g. (42%), m.p. 217–219°, identical with the product from the diamine (mixed m.p.).

Preparation of 5,5-Disubstituted Hexahydropyrimidin-2-ones.—In a typical case 13.5 g. (0.063 mole) of diphenyl carbonate was mixed portionwise with 9.8 g. (0.060 mole) of VII. The mixture was then heated in a bath at 160–170° for 8 hr. in an apparatus protected by a tube filled with Ascarite. After distillation of the phenol under diminished pressure, the cooled residue was triturated with ether. The crystalline material was filtered and crystallized from a 2:1 mixture of alcohol and water to give XXVIII (Table III).

Hydrolysis of 5,5-Dimethylhexylhydropyrimidin-2-one (XX).—XX (2.6 g., 0.020 mole) was refluxed in 20 cc. of sulfuric acid (40%) with the addition of 2.2-cc. portions of sulfuric acid (sp. gr. 1.84) at intervals until carbon dioxide was detected at the outlet. The resulting 60% solution was refluxed for 4 days. The deliquescent salt of the diamine was precipitated by 14 volumes of acetone. The solution of the salt in 40 cc. of water was treated with an excess of sodium hydroxide and extracted with six 10-cc. portions of ether. The organic base was identified as I by conversion to the diurethan XI (yield 53%, m.p. and mixed m.p. 62–64°).

The Structure of Novobiocin[1,2]

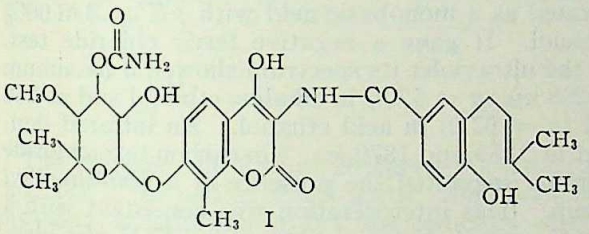
BY J. W. HINMAN, E. LOUIS CARON AND HERMAN HOEKSEMA

RECEIVED JANUARY 24, 1957

The antibiotic novobiocin[2] has been shown to be 7-[4-(carbamoyloxy)-tetrahydro-3-hydroxy-5-methoxy-6,6-dimethyl-pyran-2-yloxy]-4-hydroxy-3-[4-hydroxy-3-(3-methyl-2-butenyl)-benzamido]-8-methylcoumarin (I).

Novobiocin, elaborated by *Streptomyces niveus*, is a crystalline, acidic antibiotic of the composition $C_{31}H_{36}N_2O_{11}$. Studies on the fermentation,[3-4] extraction, purification and properties,[5,6] biological activity[7] and clinical usefulness[8] have been reported.

Because of its interesting antibacterial action and its clinical efficacy, the structure of novobiocin is of particular significance. Evidence is presented in this paper to show that novobiocin possesses structure I.



I

General Characteristics.—Novobiocin crystallized in two polymorphic modifications, one melting at 174–178° and the other at 152–156°.[5-6] The dibasic acid properties of the compound were indicated by the preparation of both acid and neutral salts. Potentiometric titrations and ultraviolet spectral shifts confirmed these observations and showed novobiocin to be a dibasic acid with pK'_a values of 4.3 and 9.1 in aqueous solution. The ultraviolet spectra in acid, neutral and alkaline solutions are given in Fig. 1. The ultraviolet spectra showed a characteristic hypsochromic shift of the phenolindophenol type in going from acid to alkaline solution. Isosbestic points linked the curves for acid to acid salt and acid salt to neutral salt transitions. Infrared spectra indicated the presence of a monosubstituted amide, hydroxyl groups, ether linkages, conjugate C=C unsaturation and possible isopropylidene and urethan groups. One methoxyl and at least two C-methyl groups were detected by analytical group determinations.

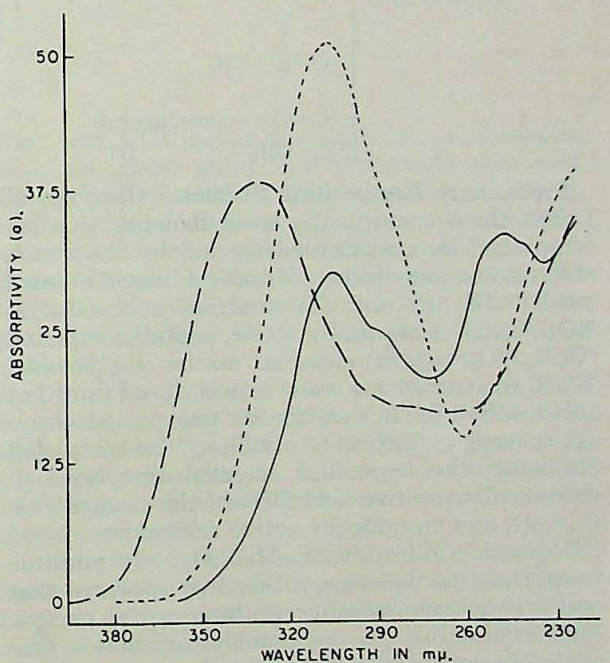


Fig. 1.—Ultraviolet spectra of novobiocin, solvents: ———, 70% ethanolic 0.01 *N* phosphate buffer, *p*H 7.5; - - - - - -, alkaline ethanol; – – – – –, acid ethanol.

Investigation of the polarographic behavior of novobiocin revealed no groups reducible below −1.5 v. *vs.* S.C.E. in acid solution or below −2.0 v. *vs.* S.C.E. in neutral on alkaline solution. These findings virtually eliminated the possible presence of nitro groups, aromatic aldehyde or keto groups, conjugate unsaturation other than an aromatic system and conjugated aliphatic acid groups.

On reaction with one mole of diazomethane the stronger acid group was neutralized with the formation of a methyl derivative whose ultraviolet spectrum closely resembled the alkaline curve of novobiocin and which did not alter appreciably with change of *p*H. This observation, considered with the absence of carboxylate absorption in the infrared, indicated that the pK'_a 4.1 function was enolic. The pK'_a value of the other acid function was in the range for a phenol, although novobiocin failed to

(1) Novobiocin. IV. The investigations upon which this paper is based were first reported in a series of preliminary communications. (a) (THIS JOURNAL, **77**, 6710 (1955); (b) **78**, 1072; (c) **78**, 2019 (1956)). These findings are in agreement with those reported independently by the Merck group (d) (*ibid.*, **78**, 1770 (1956)).

(2) The Upjohn Co. Registered Trademark for novobiocin is Albamycin. Our former generic name, streptonivicin, has been abandoned.

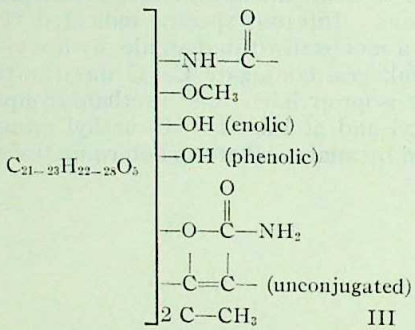
give a typical ferric chloride reaction for an unhindered phenol. Elemental analyses and molecular weight determinations on the intact molecule gave variable results because of solvation. For this reason only an approximate formula of $C_{30-31}H_{38-42}N_2O_{11}$ was established prior to degradation studies. Mild catalytic hydrogenation of I yielded a dihydro-derivative (II) whose ultraviolet and infrared spectra were almost identical with those of I indicating saturation of an unconjugated double bond. Dihydronovobiocin was found to be fully as active as novobiocin both *in vitro* and *in vivo*. The tentative findings on the intact molecule may be summarized by III.

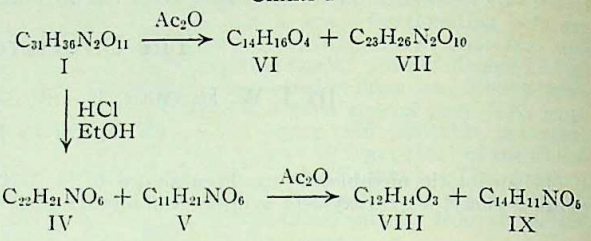


III

Preliminary Degradation Studies.—Cleavage of I into three conveniently sized moieties was accomplished by acid alcoholysis and by the action of hot acetic anhydride. Heating I in acid ethanol yielded IV, an optically inactive acid ($C_{22}H_{21}NO_6$),[9] and V, an optically active, neutral compound ($C_{11}H_{21}NO_6$) which appeared to be a glycoside. When an attempt was made to acetylate I using hot acetic anhydride in pyridine, an unexpected cleavage occurred. Instead of obtaining the acetylated antibiotic, two crystalline acetates were isolated: an optically inactive acid (VI) of the composition $C_{14}H_{16}O_4$ and an optically active neutral compound (VII) with the formula $C_{23}H_{26}N_2O_{10}$. In addition to splitting the molecule, it therefore appeared that acetic anhydride introduced three acetyl groups. Further study of the reaction showed that it proceeded in acetic anhydride alone but not with pyridine alone or with pyridine in combination with water, hydrochloric acid or glacial acetic acid. Carbon dioxide was not a product of the reaction. When the acid alcoholysis product, IV, was heated with acetic anhydride and pyridine, a similar cleavage and acetylation reaction took place to yield VIII ($C_{12}H_{14}O_3$), an optically inactive acid, and neutral IX ($C_{14}H_{11}NO_5$). These findings are summarized in Chart I.

Considering the composition of the various degradation products, VI through IX, and the methods by which they were obtained, the $C_{31}H_{36}N_2O_{11}$ formula for I was indicated. It also seemed likely that there were three main moieties in the molecule. Thus if I were represented by ABC, acetic anhydride cleaved the A–B linkage, and acid–ethanol the B–C linkage. The general properties of the degradation products indicated that those related to the A moiety were substitued benzoic acids, those related to B, an aromatic heterocyclic compound, and those related to C, some type of sugar.

CHART I



The Substituted Benzoic Acid.—Because of their apparent simplicity, the acetic anhydride degradation products VI and VIII were investigated first. The latter, a $C_{12}H_{14}O_3$ compound, m.p. 181–183°, titrated as a monobasic acid with pK'_a 6.3 in 66% ethanol. It gave a negative ferric chloride test. In the ultraviolet its spectrum showed a maximum at 258 mμ (a = 57.9) in alkaline ethanol and at 269 mμ (a = 67.2) in acid ethanol. An infrared doublet at 1385 and 1370 cm.$^{-1}$ in carbon tetrachloride solution suggested the presence of a *gem*-dimethyl group. This interpretation was consistent with a low C-methyl analysis. Compound VIII was identified as 2,2-dimethyl-6-carboxychroman[12] by comparison with an authentic sample.

Compound VI, the $C_{14}H_{16}O_4$ acid obtained directly from I by the action of hot acetic anhydride, titrated as a monobasic acid with pK'_a 5.67 in 50% ethanol. The infrared spectrum, similar to that of acetylsalicylic acid, contained bands which could be accounted for by carbonyl, ester, ethylenic and C–O linkages. The ferric chloride test was negative, but hydrolysis with 0.5 *N* sodium hydroxide deacetylated it to a dibasic acid (XI) with pK'_a values of 6.2 and 11.0 in 66% ethanol. In the ultraviolet XI exhibited maxima at 260 mμ (a = 68.2) in acid ethanol and 288 mμ (a = 76.2) in alkaline ethanol characteristic of *p*-hydroxybenzoic acids (see Fig. 2). An infrared band at 842 cm.$^{-1}$ indicated the presence of an isopropylidene group. With ferric chloride XI gave a red-brown color suggesting steric hindrance of the phenolic hydroxyl. Successive oxidations of VI with osmium tetroxide and sodium periodate yielded acetone as a major product. The side-chain was shown therefore to be the pentenyl group. Its position on the aromatic ring was determined when XI was heated in 4 *N* hydrochloric acid in 70% ethanol and cyclized to 2,2-dimethyl-6-carboxychromane (VIII) *via* the ethyl ester.

Under mild hydrogenation conditions VI consumed one mole of hydrogen to yield X, $C_{14}H_{18}O_4$. This compound, with absorption spectra very similar to those of VI, was also obtained by the action of acetic anhydride on dihydronovobiocin (II). This conveniently established the site of hydrogenation in novobiocin. Thus, the structure 4-acetoxy 3-(3-methyl-2-butenyl)-benzoic acid was assigned

(9) Although first described by this Laboratory,[1a] this compound was named *cyclonovobiocic acid* and synthesized later by the Merck group.[10,11]

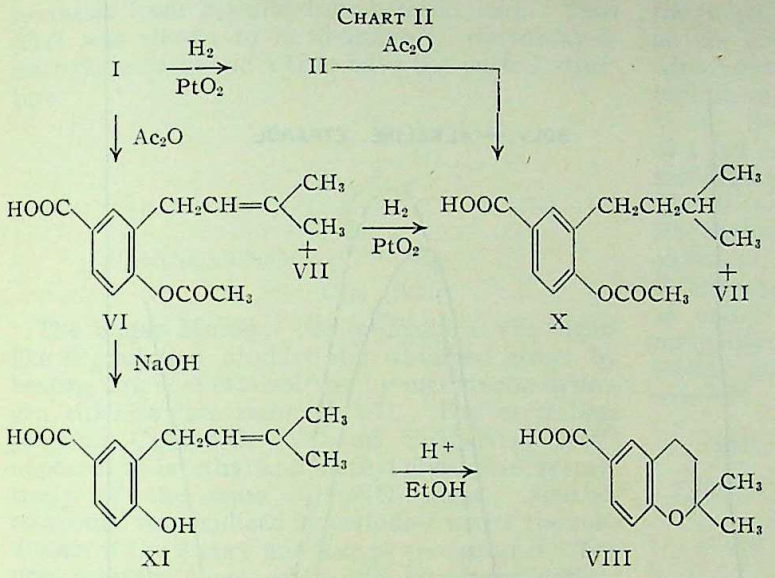
to VI, 4-acetoxy-3-(3-methylbutyl)-benzoic acid to X and 4-hydroxy-3-(3-methyl-2-butenyl)-benzoic acid to XI (see Chart II).

CHART II



The Heterocyclic Center Moiety.—As indicated in Chart I, the action of hot acetic anhydride on I provided, in addition to VI, an optically active, neutral compound, VII. This compound, m.p. 168–172°, solvated readily, especially when crystallized from acetone, but its composition was determined finally as $C_{23}H_{26}N_2O_{10}$. Its ultraviolet spectra showed characteristic fine structure between 280 and 340 mμ in neutral and acid solution and gave evidence of irreversible degradation in alkaline solution. Sodium methoxide in boiling methanol caused removal of one acetyl group with formation of another neutral compound, $C_{21}H_{24}N_2O_9$ (XII), m.p. 276–280°. The ultraviolet absorption was essentially the same as that of VII. Hot methanolic hydrogen chloride cleaved both VII and XII to optically inactive, amphoteric XIII and neutral, optically active XIV. These reactions are summarized in Chart III. The two methanolysis products were separated by fractional crystallization, XIII being the less soluble.

Compound XIII was isolated as the hydrochloride, but recrystallization from water or aqueous ethanol gave a halogen-free zwitterion-like material which decomposed above 200°. Both the hydrochloride and the free base gave a pink color with ferric chloride, a positive Benedict test, and an intense blue color with ninhydrin in pyridine. The ultraviolet spectra showed maxima at 238 mμ (a = 57.8) and 301 mμ (a = 34.5) and 347 mμ (a = 104.5) in alkaline ethanol. This same amphoteric material was obtained from IX (see Chart I) by acid hydrolysis (see Chart IV).

CHART III

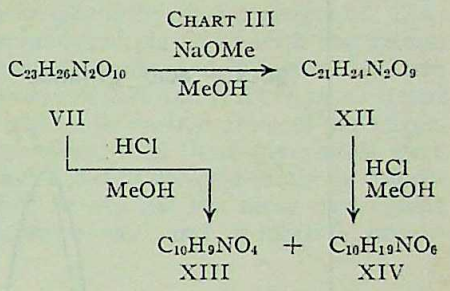


CHART IV

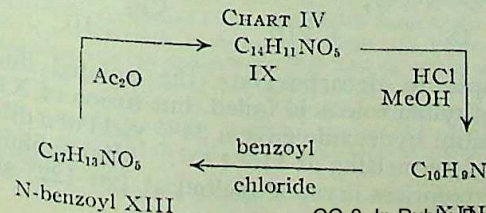

Benzoylation of XIII under Schotten–Baumann conditions gave an acidic monobenzoyl derivative of the composition $C_{17}H_{13}NO_5$. It appeared, therefore, that XIII had an aromatic nucleus substituted with an amino group and a strongly acid enol. Group analyses indicated the presence of one C-methyl group. Elemental analyses and ultraviolet absorption spectra indicated the presence of a neutral or phenolic hydroxyl group. On reaction with nitrous acid, XIII formed a yellowish diazo compound, $C_{10}H_7N_2O_4$ (XV). The diazo group was detected by intense infrared absorption at 2165 cm.$^{-1}$. The properties and reactions of XIII suggested a close resemblance to 3-amino-4-hydroxycoumarin[13] (XVI). The latter, generously supplied by Professor K. P. Link and also prepared according to his procedure,[13] served as a useful model compound.

Benzoylation of XVI provided 3-benzamido-4-hydroxycoumarin (XVII) whose ultraviolet spectra and other properties were similar to those of the unknown benzoyl derivative of XIII. Actually the spectra of 3-benzamido-4-hydroxycoumarin, which has no phenolic hydroxyl, exhibited the same unusual hypsochromic shift in going from acid to alkaline solution as did novobiocin itself. With the model compound the maxima occurred at 305 mμ in alkaline ethanol and at 320 mμ in acid ethanol *vs.* 308 and 333 mμ, respectively, for novobiocin. On heating with acetic anhydride, the model benzamido compound XVII yielded benzoic acid and a cyclized derivative whose properties and reactions

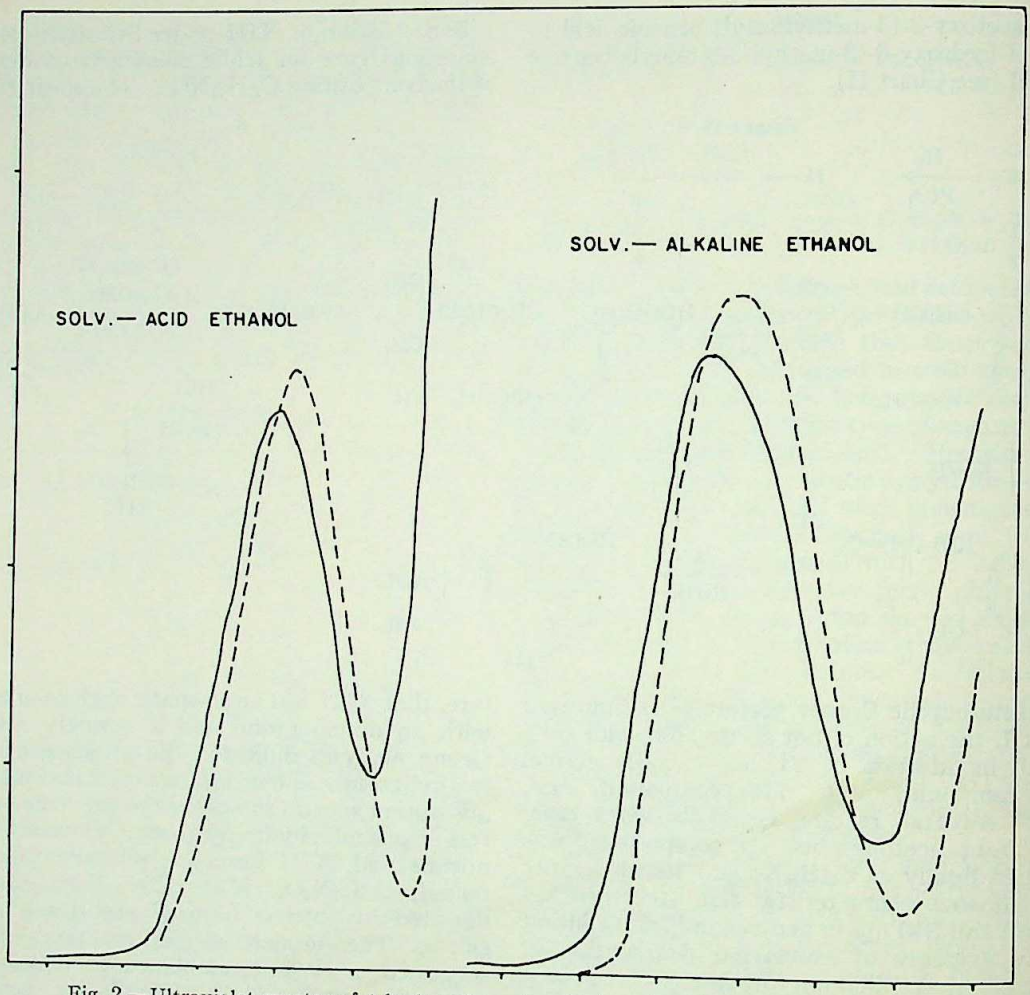

Fig. 2.—Ultraviolet spectra of *p*-hydroxybenzoic acid (- - - -) and compound XI (———).

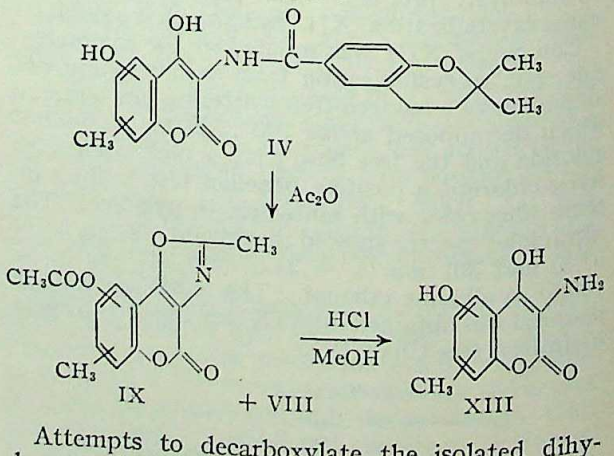
showed it to be 2-methyl-4H[1]benzopyrano[3,4-d]oxazol-4-one (XVIII). The ultraviolet spectrum of XVIII in neutral and acid solution exhibited the same characteristic fine structure and irreversible destruction by alkali as did the spectra of the acetic anhydride products VII and IX (Fig. 3). Furthermore, treatment of N-benzoyl XIII with acetic anhydride caused elimination of benzoic acid and reformation of IX. This ready replacement of the benzoyl group by acetyl and cyclization to the oxazole derivative provided an explanation for the somewhat unexpected course of the acetic anhydride cleavage of I. It was concluded, therefore, that XIII was a hydroxyl- and methyl-substituted 3-amino-4-hydroxycoumarin and that IX was the acetoxy- and methyl-substituted analog of XVIII. Accepting these structures, the conversion of cyclonovobiocic acid (IV) to XIII was explained readily (Chart V).

The assignment of the positions of the hydroxyl and methyl groups to the coumarin ring was made by converting XIII to a dihydroxymethylbenzoic acid. Hydrolysis of XIII with 1 *N* sodium hydroxide at room temperature or heating XIII in Benedict reagent gave complex colored mixtures which were separated by chromatography and the desired component purified by sublimation. The crystalline acid, obtained in 15–20% yields, melted with sublimation at 210–225°, gave a bluish-purple ferric chloride test and analyses indicated a formula of $C_8H_8O_4$ with one C–CH_3 group. Ultraviolet absorption studies indicated the presence of two phenolic hydroxyl groups.

CHART V



Attempts to decarboxylate the isolated dihydroxymethylbenzoic acid failed, but fusion of XIII in potassium hydroxide gave a 34% yield of a dihydroxytoluene melting at 115–120°. After sublimation, the colorless crystals melted at 120–122° and

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

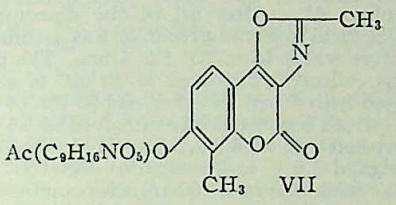
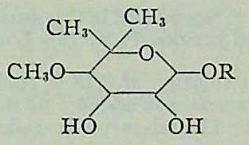
were identified as 2-methylresorcinol.[14] The identity of the isolated acid was confirmed as 2,4-dihydroxy-*m*-toluic acid by melting point and infrared comparison with an authentic sample[15] obtained by synthesis from 2,4-dihydroxybenzoic acid. Thus XIII was shown to be 3-amino-4,7-dihydroxy-8-methylcoumarin and VII to have the partial structure.



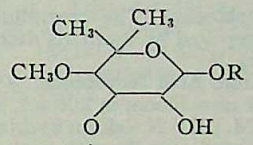
VII

The Sugar Moiety.—An optically active sugar-like degradation product was obtained either by heating I in acid ethanol[16] or by methanolic hydrogen chloride treatment of VII. The crystalline products $C_{11}H_{21}NO_6$ (V) and $C_{10}H_{19}NO_6$ (XIV) appeared to be ethyl and methyl glycosides, respectively, of the same $C_9H_{16}NO_6$ sugar. Neither compound was oxidized by periodate under the conditions of the Fleury and Lange procedure.[17] The preparation of monoacetate and monomesyl derivatives indicated the presence of one free hydroxyl group in V and XIV. The presence of one methoxyl in addition to the glycosidic alkoxyl was shown by analysis. A low C-methyl analysis (about 30% of the value calculated for one C-methyl) suggested the possibility of a *gem*-dimethyl group. A doublet at 1382 and 1366 cm.$^{-1}$ in the infrared spectra of these compounds supported this contention. Hydrolysis of XIV with hot aqueous acid caused loss of the nitrogen as ammonium chloride. This eliminated an acylamino group as a possibility for the nitrogen-containing function. When heated under reflux in methanolic hydrogen chloride, XIV yielded (in addition to ammonium chloride) a crystalline sugar derivative, $C_{10}H_{16}O_6$ (XIX), whose infrared spectrum showed a complete absence of OH/NH absorption and a strong band at 1785 cm.$^{-1}$ suggestive of a carbonate ester carbonyl. Upon treatment with barium hydroxide at room temperature, XIX gave nearly the theoretical yield of barium carbonate and a new glycoside, $C_9H_{18}O_5$ (XX). Repetition of this reaction with XIV and extending the reaction time somewhat gave ammonia, barium carbonate and a $C_9H_{18}O_5$ glycoside (XXI) as the products. These reactions and the physical-chemical data provided conclusive evidence for the presence of a carbamate group and further indicated the carbamate to be located on a carbon atom adjacent to the free hydroxyl group.

The isomeric methyl glycosides XX and XXI were shown to be anomers by hydrolysis to the same sugar aldehyde XXII. Both XX and XXI consumed one mole of periodate[17] cleanly and on oxidation with chromic acid gave acetone in 46% yield as the dinitrophenylhydrazone. This latter finding furnished confirmatory chemical evidence for the presence of the *gem*-dimethyl group. Analyses on the crystalline sugar aldehyde XXII were in agreement for the formula $C_8H_{16}O_5$ indicating retention of one methoxyl group under acid conditions. Positive reactions were obtained with Benedict and 2,4-dinitrophenylhydrazine reagents. Consumption of two moles of periodate with the formation of two moles of formic acid indicated the two free hydroxyl groups of XX and XXI to be adjacent to the no. 1 or glycosidic carbon atom of the sugar. It appeared, therefore, that these glycosides were α- and β-methyl 2,3-dihydroxy-4-methoxy-5,5-dimethylpyranoside or—to use the more convenient trivial nomenclature—α- and β-methyl novioside.[1c,18]

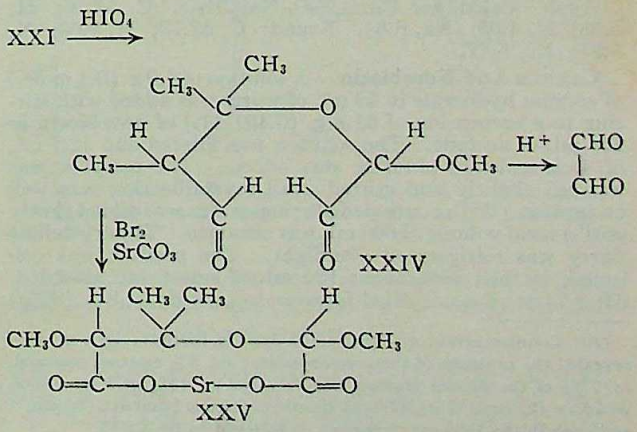


XX, XXI, R = Me
XXII, R = H



V, R = Et
XIV, R = Me
XXIII, R = H

Additional support for this structure was obtained by studying the oxidation products of XXI. Mild acid hydrolysis of the periodate oxidation product of XXI yielded glyoxal which was isolated as the 2,4-dinitrophenylosazone. Oxidation of the dialdehyde XXIV with bromine in the presence of strontium carbonate according to the method of Jackson and Hudson[19] gave the expected crystalline strontium salt XXV.



Hydrolysis of methyl 3-*O*-carbamylnovioside (XIV) with 0.5 *N* sulfuric acid removed the glyco-

(14) E. T. Jones and A. Robertson, *J. Chem. Soc.*, 1690 (1932).
(15) R. C. Shah and M. C. Laiwalla, *ibid.*, 1828 (1938).
(16) When Compound I was heated under reflux in alcohol with one mole of acetyl chloride or hydrogen chloride, the major products of the reaction were the glycoside (*i.e.*, V or XIV depending on the alcohol used) and 4,7-dihydroxy-3-[4-hydroxy-3-(3-methyl-2-butenyl)-benzamido]-8-methylcoumarin. For the latter we propose the trivial name *novobiocic acid*. Its structure was established by acetic anhydride cleavage to IX and 4-acetoxy-3-(3-methyl-2-butenyl)-benzoic acid (VI).
(17) P. F. Fleury and J. Lange, *J. pharm. chim.*, **17**, 107, 196 (1933).
(18) According to the Merck nomenclature,[1d] which evolved independently, these compounds would be called α- and β-methyl 4-methylnovobioside. This name seems undesirable because (1) the *biose* ending erroneously indicates the sugar to be a disaccharide and (2) precedent favors overwhelmingly the inclusion of the stable methoxyl group in the trivial name. This point has been discussed with the Merck group and they agree that the trivial name *novobiose* should be abandoned in favor of *noviose*. Recently the configuration of L-lyxose has been assigned to this sugar (E. Walton, J. O. Rodin, C. H. Stammer, F. W. Holly and K. Folkers, THIS JOURNAL, **78**, 5454 (1956)). Therefore, the glycosides in question may be named α- and β-methyl 4-*O*-methyl-5,5-dimethyl-L-lyxoside.
(19) E. L. Jackson and C. J. Hudson, *ibid.*, **59**, 994 (1937).

Digitized by Arya Samaj Foundation Chennai and eGangotri

sidic methyl group to give 3-*O*-carbamylnoviose (XXIII) in 77% yield.[20] The carbamate group was assigned to the 3-position of the sugar because XXIII consumed one mole of periodate with the formation of one mole of formic acid. Since the type and position of the linkages between the three major moieties were established in cyclonovobiocic acid (IV) and degradation product VII, structure I could be assigned to novobiocin.

Acknowledgments.—The authors are indebted to Drs. J. L. Johnson, E. C. Olson, Mrs. G. S. Fonken and Mr. J. E. Stafford for certain physico-chemical determinations, and to Mr. W. A. Struck and his associates for micro-analytical work. Appreciation is expressed to Drs. M. Calvin, H. E. Carter, D. J. Cram, W. G. Jackson, M. S. Newman and D. I. Weisblat for their interest and assistance.

Experimental[21]

Novobiocin.—The crystalline novobiocin used in this study was prepared by methods described previously by this Laboratory.[3,5]

Sodium Acid Novobiocin.—To a solution of 6.18 g. (0.01 M.) of novobiocin in 200 ml. of acetone was added 1.67 ml. (0.01 M.) of 6 *N* sodium hydroxide. The mixture was seeded and stirred rapidly with a magnetic stirrer for 16–18 hr. at 30–40°. During this time the suspended alkali dissolved and crystalline sodium acid novobiocin separated. The crystals were collected, washed with acetone and dried to yield 5.9 g. (90%), m.p. 210–215° dec., $[\alpha]_D^{25}$ −34° (*c* 1.081 in water). The crystalline salt had a potency of approximately 1000 mcg./mg. by the *K. pneumoniae* novobiocin bioassay.[3]

Anal. Calcd. for $C_{31}H_{35}N_2O_{11}Na \cdot H_2O$: C, 57.05; H, 5.72; N, 4.29. Found: C, 57.04; H, 5.93; N, 4.06.

Disodium Novobiocin.—To a suspension of 10 g. (0.0162 M.) of novobiocin in 100 ml. of water was added slowly 32.4 ml. (0.0324 M.) of 1.0 *N* sodium hydroxide. The novobiocin dissolved during this treatment and the resulting solution was dried by evaporation from the frozen state. This white amorphous salt had a potency of about 960 mcg./mg. by the *K. pneumoniae* novobiocin assay.[3]

Anal. Calcd. for $C_{31}H_{34}N_2O_{11}Na_2 \cdot 2H_2O$: C, 53.76; H, 5.53; N, 4.05; Na, 6.64. Found: C, 53.73; H, 5.63; N, 3.97; Na, 6.77.

Calcium Acid Novobiocin.—A solution of 4.0 g. (0.1 mole.) of sodium hydroxide in 50 ml. of water was added with stirring to a suspension of 61.8 g. (0.101 M.) of novobiocin in 250 ml. of acetone. The solution was filtered and 12.7 ml. of 4 *M* calcium chloride was added. The solution was warmed slightly and stirred until crystallization was well underway. With continued stirring, water was added slowly until a total volume of 600 ml. was obtained. The crystalline slurry was refrigerated overnight. The product was collected, washed with about 100 ml. of water and air-dried. After 24 hr. the salt dried *in vacuo* to provide 54.8 g. (86%) of nearly white microcrystalline powder. On the Kofler micro-hot-stage the crystals lost birefringence above 240° but did not melt up to 325°.

Anal. Calcd. for $C_{31}H_{35}N_2O_{11}Ca/2 \cdot H_2O$: C, 57.31; H, 5.74; N, 4.31. Found: C, 57.12; H, 5.88; N, 4.21.

Diazomethane Methylation of Novobiocin.—The diazomethane from 6.9 g. (0.032 M.) of N-methyl-N-nitroso-*p*-toluenesulfonamide was distilled into a stirred suspension of 10 g. (0.016 M.) of novobiocin in 40 ml. of ether and 10 ml. of methanol at 4°. After all of the diazomethane was added (a 60% yield from the precursor was assumed), the reaction mixture was held at 25° for 4 hr. The precipitated product was collected, dissolved in 30 ml. of acetone then reprecipitated with 30 ml. of ether and 60 ml. of Skellysolve B. The oil which separated was dissolved in 35 ml. of acetone and precipitated with 6 volumes of Skellysolve B. The product weighed 2.6 g. and melted at 158–160° dec. This material was subjected to a 200-transfer countercurrent distribution analysis using the solvent system 20% water, 30% ethanol, 32.5% ethyl acetate and 17.5% cyclohexane. It was found to contain 5% unchanged novobiocin, but the remainder was homogeneous by this method. The peak fraction was isolated for analysis and physical constants. Its ultraviolet spectra showed maxima in basic ethanol at 314 mμ (a = 58.6) and in acid ethanol at 310 mμ (a = 27.2) and 290 mμ (a = 27.5).

Anal. Calcd. for $C_{32}H_{38}N_2O_{11}$: N, 4.47; OCH_3, 9.90. Found: N, 4.39; OCH_3, 9.61.

Dihydronovobiocin.—A solution of 40 g. (0.0654 M.) of novobiocin in 400 ml. of warm absolute ethanol was hydrogenated using 10 g. of Adams catalyst and 40 p.s.i.g. of hydrogen pressure for 1 hr. at 25–40°. The mixture was filtered through Celite, and 1400 ml. of water was added to the vigorously stirred filtrate. Addition of 20 ml. of 1 *N* hydrochloric acid to the resulting emulsion caused a white precipitate to form. This was collected and dried *in vacuo* to yield 36 g. (90%), m.p. 163–165° dec.

Anal. Calcd. for $C_{31}H_{40}N_2O_{11}$: C, 60.38, H, 6.54; N, 4.54. Found: C, 59.96; H, 6.44; N, 4.49.

Sodium Acid Dihydronovobiocin.—A solution of 4.0 g. (6.45 mM.) of dihydronovobiocin in 90 ml. of acetone was dried 30 minutes over magnesium sulfate. To the filtered solution was added 350 mg. (6.4 mM.) of sodium methoxide. The mixture was stirred 24 hr. at 25°. As the sodium methoxide dissolved, sodium acid dihydronovobiocin crystallized. The product was collected, washed with 90 ml. of dried acetone and dried at 25° *in vacuo* to yield 3.35 g. (81%), m.p. 225–235° dec.

Anal. Calcd. for $C_{31}H_{37}N_2O_{11}Na \cdot H_2O$: C, 56.87; H, 6.01; N, 4.28. Found: C, 56.98; H, 5.95; N, 4.47.

Calcium Acid Dihydronovobiocin.—To a solution of 250 g. (0.47 M.) of dihydronovobiocin in 1 l. of acetone was added 1200 ml. (0.47 M.) of a 0.00039 *N* sodium hydroxide solution. The solution was treated with 29.7 g. (0.20 M.) of calcium chloride dihydrate in 50 ml. of water and stirred 3 hr. The crystalline precipitate was washed with acetone and dried *in vacuo* at 25° to yield 190 g. (75%) of white crystals, m.p. 225–250° dec.

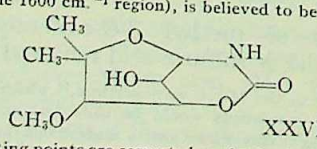
Anal. Calcd. for $(C_{31}H_{37}N_2O_{11})_2Ca \cdot 6H_2O$: C, 54.14; H, 6.30; N, 4.07; Ca, 2.91. Found: C, 54.57; H, 6.49; N, 4.24; Ca, 3.14.

Hydrolysis of Novobiocin in Acid Ethanol. A. Preparation of Cyclonovobiocic Acid (IV).—A solution of 10 g. (16.2 mM.) of novobiocin in 100 ml. of ethanol was heated to boiling. Concentrated hydrochloric acid (50 ml.) was added over a period of 7 minutes. The mixture was heated under reflux for about 30 minutes, then cooled. The solid (6.1 g., 95%) was collected, washed with water and recrystallized from 400 ml. of 1-butanol to yield 5.4 g. of IV. After a second recrystallization from ethanol the pale yellow crystals melted at 288–291°. In 75% DMF the compound titrated as a monobasic acid with pK'_a 6.3. Absorption maxima were observed at 252 mμ (a = 84.7) and 328 mμ (a = 68.2) in alkaline ethanol. In acid ethanol the intensity of the 252 mμ maximum was greatly diminished and the 328 mμ peak shifted to 331 mμ (a = 61.0).

Anal. Calcd. for $C_{22}H_{21}NO_6$: C, 66.82; H, 5.35; N, 3.54; 2 C-CH_3, 7.60. Found: C, 67.18; H, 5.40; N, 3.70; C-CH_3, 3.67.

B. Preparation of 3-*O*-Carbamyl-4-*O*-methyl-5,5-di-

(20) Countercurrent distribution analysis of the hydrolysis mixture revealed the presence of three components: *ca.* 8% starting material, *ca.* 77% of the desired product (XXIII) and *ca.* 15% of a substance, which on the basis of its infrared spectrum (strong band at 1695 cm.$^{-1}$ and none in the 1600 cm.$^{-1}$ region), is believed to be XXVI.



XXVI

(21) All melting points are corrected as obtained with a Kofler micro-hot-stage. Specific rotation values were determined using a 2-decimeter tube. All ultraviolet spectra were obtained using Cary model 11 recording spectrophotometers; infrared measurements, with Perkin–Elmer recording spectrophotometers. With reference to solvents used for ultraviolet measurements, the term *acid ethanol* means 70% ethanol 0.01 *N* with respect to its sulfuric acid content, and *alkaline ethanol* means 70% ethanol 0.01 *N* with respect to its potassium hydroxide content. The abbreviation *a* (absorptivity) is the density of a 1-g./l. solution. The abbreviations M. and mM. are used for mole and millimole, respectively.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

methyl-L-lyxoside (V).—The acid mother liquor from the above experiment was neutralized with 6 *N* sodium hydroxide and concentrated at reduced pressure to a small volume. The precipitated sodium chloride was removed and the filtrate was taken to dryness. The residue was extracted with acetone and the extract diluted with Skellysolve B to yield 316 mg. of ethyl 3-*O*-carbamyl-4-*O*-methyl-5,5-dimethyl-L-lyxoside (V), m.p. 172–176°. Recrystallization from acetone–Skellysolve B gave a 72% recovery of material melting at 173–175°, $[\alpha]_D^{25}$ −36° (*c* 1.0 in ethanol).

Anal. Calcd. for $C_{11}H_{21}NO_6$: C, 50.18; H, 8.04; N, 5.32; OCH_3, 11.79; OEt, 17.11. Found: C, 50.68; H, 8.16; N, 5.25; OCH_3, 11.71; OEt, 17.01.

Cleavage of Novobiocin to Novobiocic Acid and Ethyl 3-*O*-Carbamyl-4-*O*-methyl-5,5-dimethyl-L-lyxoside (V).—To a solution of 10 g. (0.0162 M.) of novobiocin in 100 ml. of boiling absolute ethanol was added slowly 1.1 g. (0.014 M.) of acetyl chloride. After 2 hr. of heating under reflux the solution was cooled, then treated with 300 ml. of water to precipitate 6.0 g. (94% yield) of crystalline 4,7-dihydroxy-3-[4-hydroxy-3-(3-methyl-2-butenyl)-benzamido]-8-methylcoumarin (novobiocic acid). This product was recrystallized from acetone, then purified in a 424-transfer countercurrent distribution in a solvent system containing ethyl acetate, ethanol, water and cyclohexane. The main peak fraction, representing 63% of the reaction product, was recovered and analyzed. Prolonged heating *in vacuo* at 100° was necessary to remove solvent of crystallization.

Anal. Calcd. for $C_{22}H_{21}NO_6$: C, 66.82; H, 5.35; N, 3.50. Found (average of three analyses): C, 66.47; H, 5.66; N, 3.50.

The filtrate from the reaction mixture was distilled *in vacuo* to a volume of 100 ml., then neutralized with 1*N* sodium hydroxide. The distillation was continued until the volume was 25 ml. This was then chilled to precipitate 3.0 g. of crude crystalline V, which was recrystallized from a acetone–Skellysolve B solution to yield 1.14 g. (27%) of ethyl glycoside identical with that described above.

Cleavage of Novobiocic Acid with Acetic Anhydride to VI and IX.—A solution containing 2 g. (0.005 M.) of novobiocic acid, 20 ml. of pyridine and 4 g. (0.039 M.) of acetic anhydride was heated under reflux 4 hr. It was cooled to 4°, diluted with 25 ml. of water and acidified to *p*H 2 with 22 ml. of concentrated hydrochloric acid. The resulting precipitate was filtered and dried to yield 2.6 g. of material. This was leached three times with 30 ml. of ether. The residue (1.5 g.) was crystallized from ethanol and water and the crystalline product dried *in vacuo* to yield 0.75 g. (55%). Its melting point, ultraviolet and infrared spectra were identical with those of IX.

The ether leachings were combined and evaporated to dryness to yield 0.9 g. of solid. This was crystallized from ethanol and water to yield 0.72 g. (57%) of white crystalline product which was identified as VI by its ultraviolet spectra and melting point.

Reaction of Novobiocin with Acetic Anhydride: Preparation of VI and VII.—A solution of 100 g. (0.162 M.) of novobiocin in 1 l. of pyridine and 216 g. (2.14 M.) of acetic anhydride was heated under reflux 4 hr. The solution was cooled to 5°, 1500 ml. of water and 1030 ml. of 12 *N* hydrochloric acid were added. The precipitate which formed was collected, washed with water and dried to yield 110 g. of partially crystalline solid. This was extracted with ether and the extract was evaporated to yield crude VI. After recrystallization from 400 ml. of ethanol and 600 ml. of water, 26 g. (60%) of VI, m.p. 100–113°, was obtained. The ether-insoluble fraction (51 g.) was recrystallized from 750 ml. of ethanol and 200 ml. of water to yield 46.5 g. (65%) of VII, m.p. 167–172°. Recrystallization from boiling acetone gave solvated crystals which melted at 150–170°. Another recrystallization from ethanol and water gave material which melted at 169–172°.

Compound VI, an optically inactive acid (pK_a' 5.67 in 50% ethanol), exhibited absorption maxima at 235 mμ (a = 51.6), 275 mμ (a = 5.35) and at 285 mμ (a = 4.65) in acid ethanol. In ethanolic base an irreversible shift of the maximum to 288 mμ (a = 63.2) occurred.

Optically active, $[\alpha]_D^{25}$ −94.4 (*c* 2% in DMF), VII titrated as a neutral compound which appeared to be unstable in alkali. Its ultraviolet absorption spectrum in neutral or acid ethanol showed characteristic peaks at 292 mμ (a = 25.3), 315 mμ (a = 39.7), 238 mμ (a = 33.6), 321 mμ (a = 35.0) and 329 mμ (a = 32.3). In alkaline ethanol the spectrum was irreversibly changed to end absorption with inflection points at about 240, 290 and 340 mμ.

Anal. Calcd. for $C_{14}H_{16}O_4$ (VI): C, 67.72; H, 6.50; acetyl, 17.3; 2 C–CH_3, 12.08; equiv. wt., 248.27. Found: C, 67.75; H, 6.56; acetyl, 16.3; C–CH_3, 8.84; equiv. wt., 254. Calcd. for $C_{23}H_{26}N_2O_{10}$ (VII): C, 56.33; H, 5.35; N, 5.71. Found: C, 56.65; H, 5.44; N, 5.74.

Subsequent experiments showed that this cleavage does not occur in pyridine, aqueous pyridine, pyridine with hydrochloric acid or with pyridine and glacial acetic acid. No carbon dioxide was formed during the reaction.

Reaction of Cyclonovobiocic Acid (IV) with Acetic Anhydride: Formation of VIII and IX.—A solution of 10 g. (0.025 M.) of IV in 80 ml. of pyridine and 10 ml. (0.10 M.) of acetic anhydride was heated under reflux for 3 hr. After addition of 2 ml. of water to the hot solution, it was cooled to 5° and acidified to *p*H 2 with 80 ml. of 12 *N* hydrochloric acid. The precipitate was dissolved in 400 ml. of hot 97% ethanol. On cooling, 4.3 g. of crude IX separated. The filtrate was diluted with 800 ml. of water to precipitate VIII (4.6 g.). Both compounds were recrystallized twice from ethanol. Compound VIII, m.p. 184°, was obtained in 90% yield and was identified as 2,2-dimethyl-6-carboxychromane by comparison with an authentic sample.[12] Compound IX, m.p. 203–206°, obtained in 62% yield, was neutral, optically inactive and unstable in alkali. Its ultraviolet spectrum is given in Fig. 3.

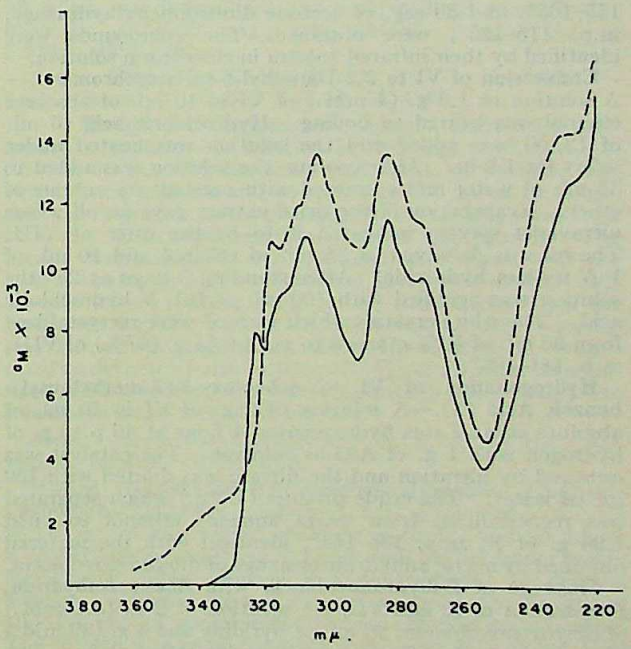


Fig. 3.—Ultraviolet spectra of 2-methyl-4H-[1]benzopyrano [3,4-d]oxazol-4-one (XVIII) (———) and compound IX (- - - - -); solvent and acid ethanol.

Anal. Calcd. for $C_{12}H_{14}O_3$ (VIII): C, 69.88; H, 6.84. Found: C, 69.80; H, 6.71. Calcd. for $C_{14}H_{11}NO_5$ (IX): C, 61.54; H, 4.06; N, 5.13. Found: C, 61.59; H, 3.77; N, 5.06.

Deacetylation of VI; Preparation of 4-Hydroxy-3-(3-methyl-2-butenyl)-benzoic Acid (XI).—A solution of 0.5 g. (2 mM.) of VI, 20 ml. of 1 *N* sodium hydroxide and 50 ml. of ethanol was allowed to stand at 25° for 3 hr. After acidification to *p*H 2 with 6 *N* hydrochloric acid, the solution was distilled at reduced pressure to an aqueous concentrate. This was extracted with ether, the extract dried and evaporated. The residue was crystallized from acetone and water by rapid evaporation of the acetone to yield 350 mg. (85%) of XI, m.p. 103–106°; ultraviolet spectra are given in Fig. 2.

Anal. Calcd. for $C_{12}H_{14}O_3$: C, 69.88; H, 6.84; 2 C–CH_3, 14.6; equiv. wt., 206.23. Found: C, 69.89; H, 6.94; C–CH_3, 6.94; equiv. wt., 208.

Osmium Tetroxide–Sodium Periodate Oxidation of VI.—To a solution of 3 g. (12.1 mM.) of VI in 60 ml. of ether (dried by distillation from methylmagnesium iodide) was

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

added 3 g. (11.8 mM.) of osmium tetroxide in 20 ml. of dry ether at 0°. A heavy green precipitate formed immediately. The mixture was allowed to warm slowly to 24° and was stored for 3 days at this temperature. The precipitate was separated, the ethereal solution evaporated and the residue and precipitate combined. The solid was added to 100 ml. of ethanol, 80 ml. of water and 18 g. of sodium sulfite and the mixture heated under reflux for 30 minutes. The mixture was filtered, the precipitate washed with 200 ml. of hot ethanol and the washings added to the filtrate. The latter was evaporated to 25 ml. of aqueous solution, acidified with hydrochloric acid to *p*H 2 and extracted with ether. The dried ether extract was evaporated to yield 1.82 g. of hygroscopic solid. The ultraviolet spectra were similar to those of the unsaturated starting material, but the infrared absorption showed greatly increased hydroxyl content. A 1.72-g. quantity of this solid was dissolved in 17.2 ml. of methanol, and 1.5 g. of sodium metaperiodate in 30 ml. of water was added. After 1.5 hr. at 25° the solution was neutralized to *p*H 6.0 with sodium hydroxide and distilled as rapidly as possible into ethanolic 2,4-dinitrophenylhydrazine to yield 200 mg. of a mixture of products. This material (90 mg.) was chromatographed using a 1″ × 40″ silicic acid column (dry-packed) which was developed with a Skellysolve B–ether mixture (the ether content progressively increased from 2 to 6%). The column was dried, extracted, cut into fractions and the products isolated by elution with chloroform. After recrystallization from ethanol and water 40 mg. of formaldehyde 2,4-dinitrophenylhydrazone, m.p. 155–165°, and 30 mg. of acetone dinitrophenylhydrazone, m.p. 115–125°, were obtained. The compounds were identified by their infrared spectra in chloroform solution.

Conversion of VI to 2,2-Dimethyl-6-carboxychromane.—A solution of 1.0 g. (4 mM.) of VI in 10 ml. of absolute ethanol was heated to boiling. Hydrochloric acid (5 ml. of 12 *N*) was added and the solution was heated under reflux for 1.5 hr. After cooling, the solution was added to 35 ml. of water and extracted with one-half its volume of ether. Evaporation of the dried extract gave an oil whose ultraviolet spectra indicated it to be the ester of VIII. The oil was dissolved in 35 ml. of ethanol and 10 ml. of 1 *N* sodium hydroxide. After standing 3 days at 25° the solution was acidified with 100 ml. of 0.1 *N* hydrochloric acid. The white crystals which formed were recrystallized from 20 ml. of 50% ethanol to yield 0.55 g. (67%) of VIII, m.p. 181–183°.

Hydrogenation of VI to 4-Acetoxy-3-(3-methylbutyl)-benzoic Acid (X).—A solution of 2 g. of VI in 50 ml. of absolute ethanol was hydrogenated 1 hour at 40 p.s.i.g. of hydrogen with 1 g. of Adams catalyst. The catalyst was removed by filtration and the filtrate was diluted with 150 ml. of water. The crude product (1.3 g.) which separated was recrystallized from warm aqueous ethanol to yield 1.06 g. of X, m.p. 136–144°, identical with the material obtained by acetic anhydride cleavage of dihydronovobiocin.

Cleavage of Dihydronovobiocin with Acetic Anhydride; Preparation of X and VII.—A solution of 2 g. (3.2 mM.) of dihydronovobiocin, 20 ml. of pyridine and 4 g. (39 mM.) of acetic anhydride was heated under reflux 3 hr. The solution was diluted with 25 ml. of water, chilled to 5°, brought to *p*H 1 with 20 ml. of 12 *N* hydrochloric acid and extracted with three 50-ml. portions of ether. The combined extracts were washed with 150 ml. of water, dried and evaporated to a residue. Crystallization from 150 ml. of 30% ethanol yielded 0.32 g. of X, m.p. 135–144°. The ultraviolet spectra were similar to those of VI.

Anal. Calcd. for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25. Found: C, 67.45; H, 6.93.

The material which was not extracted with ether was separated by filtration, crystallized and recrystallized from ethanol to yield 0.68 g. of VII identical with that obtained from novobiocin.

Deacetylation of VII.—A suspension of 2.0 g. (4 mM.) of VII in 50 ml. of commercial anhydrous methanol and 1 *N* sodium methoxide in methanol was heated under reflux for 30 minutes. During this time all of the original solid dissolved and the product separated as white crystals (1.43 g.), m.p. 268–272°. For analysis a portion of the material was recrystallized from a large volume of boiling acetone. This material (XII) was neutral, non-reducing, ferric chloride and ninhydrin negative and exhibited ultraviolet spectra qualitatively identical with those of VII.

Anal. Calcd. for $C_{21}H_{24}N_2O_9$: C, 56.34; H, 5.40; N, 6.25. Found: C, 56.07; H, 5.54; N, 6.25.

Methanolysis of XII; Preparation of 3-Amino-4,7-dihydroxy-8-methylcoumarin (XIII) and Methyl 3-*O*-Carbamyl-4-*O*-methyl-5,5-dimethyl-L-lyxoside (XIV).—A suspension of 2.0 g. (4.45 mM.) of XII (VII could also be used) in 400 ml. of methanol and 100 ml. of 3.15 *N* methanolic hydrogen chloride was heated under reflux with frequent swirling. After about 2 hr. all of the crystals dissolved and the colorless solution was cooled, filtered and concentrated *in vacuo*. The two products, XIII and XIV, crystallized and were separated by fractional crystallization from methanol and ether to yield 1.9 g. of XIII as the hydrochloride and 435 mg. of XIV. The former, less soluble in methanol, decomposed above 200°, gave a pink color with ferric chloride and a strong positive reaction with ninhydrin in pyridine in the cold.

Anal. Calcd. for $C_{10}H_{10}NO_4Cl$: C, 49.49; H, 4.15; N, 5.77; Cl, 14.61. Found: C, 48.52; H, 4.79; N, 5.44; Cl, 12.06.

Recrystallization of XIII hydrochloride from water or aqueous ethanol yielded the free-base or zwitterion compound.

Anal. Calcd. for $C_{10}H_9NO_4$: C, 57.99; H, 4.38; N, 6.77. Found: C, 57.69; H, 4.32; N, 6.25.

Final purification of XIV was accomplished by recrystallization from acetone and Skellysolve B. The colorless platelets were neutral, ninhydrin-negative, showed only end absorption in the ultraviolet and melted at 194–195°, $[\alpha]_D^{25}$ − 24.7° (*c* 1 in 95% ethanol).

Anal. Calcd. for $C_{10}H_{19}NO_6$: C, 48.19; H, 7.68; N, 5.62. Found: C, 48.11; H, 7.71; N, 5.61.

Reaction of IX with Methanolic Hydrogen Chloride. Preparation of 3-Amino-4-hydroxy-8-methylcoumarin Hydrochloride (XIII).—A solution of 2 g. (7.3 mM.) of IX in 100 ml. of 3.5 *N* methanolic hydrogen chloride and 400 ml. of methanol was heated under reflux 3 hr., then stored at 24° 16 hr. Concentration of the solution to 100 ml. by distillation *in vacuo* and chilling to −10° yielded 1.5 g. of white precipitate. Recrystallization from 100 ml. of absolute ethanol and 200 ml. of ether gave 1.15 g. which decomposed over the range 240–310°. This material was ninhydrin-positive in the cold and gave a transient pink color with ferric chloride.

Anal. Calcd. for $C_{10}H_{10}NO_4Cl$: C, 49.49; H, 4.15; N, 5.77. Found: C, 49.88; H, 5.30; N, 5.18.

Recrystallization of this hydrochloride from hot 30% ethanol gave XIII free base identical with that obtained from XII.

3-Benzamido-4,7-dihydroxy 8-methylcoumarin (N-Benzoyl XIII).—Benzoyl chloride (0.6 ml.) was added portionwise and with vigorous shaking to a solution of 0.46 g. of XIII in 30 ml. of 1 *N* sodium hydroxide at 0–5°. After 2 hr., the solution was filtered free of a trace of insoluble material and acidified with 2 *N* hydrochloric acid. The orange precipitate which formed was filtered off, washed with water and dried. The crude product was extracted with four 30–40-ml. portions of boiling Skellysolve B to remove benzoic acid then recrystallized from 95% ethanol using Darco G-60 for decolorization. The yield of pale yellow product was 0.39 g., m.p. 309–310°. For analysis, a sample was recrystallized again from ethanol.

Anal. Calcd. for $C_{17}H_{13}NO_5$: C, 65.59; H, 4.21; N, 4.50. Found: C, 65.63; H, 4.19; N, 4.42.

Conversion of N-Benzoyl-XIII to IX by the Action of Acetic Anhydride.—A solution of 515 mg. of 3-benzamido-4,7-dihydroxy-8-methylcoumarin in 45 ml. of pyridine and 15 ml. of acetic anhydride was held at 25° for 1 hr. and heated under reflux for 2 hr. After cooling, water and solid potassium bicarbonate were added and the solution taken to dryness *in vacuo*. The residue was taken up in water and chloroform. After shaking, the layers were separated and the aqueous phase extracted several times with chloroform. The combined, dried extracts were evaporated and the residue crystallized from aqueous ethanol to yield 100 mg. of nearly colorless crystals, m.p. 201–203°. Comparison with IX obtained by the other route by means of ultraviolet and infrared spectra and mixed melting point established the identity.

Anal. Calcd. for $C_{14}H_{11}NO_6$: C, 61.54; H, 4.06; N, 5.13. Found: C, 61.84; H, 3.80; N, 5.12.

3-Benzamido-4-hydroxycoumarin (XVII).—Using the same procedure as employed for the benzoylation of XIII, 1.0 g. of 3-amino-4-hydroxycoumarin[13] was benzoylated with benzoyl chloride in 1 *N* sodium hydroxide at 5°. The benzoic acid-free product was recrystallized from ethanol to yield 700 mg. of benzamide, m.p. 207–208° dec.

Anal. Calcd. for $C_{16}H_{11}NO_4$: C, 68.48; H, 3.94; N, 4.98. Found: C, 68.31; H, 4.04; N, 4.88.

2-Methyl-4H-[1] benzopyrano[3,4-d]oxazol-4-one (XVIII).—A solution of 200 mg. (0.14 mM.) of 3-benzamido-4-hydroxycoumarin in 2 ml. of pyridine was heated under reflux for 3 hr. with 5.0 g. (50 mM.) of acetic anhydride. After addition of 0.4 ml. of water and cooling, the solution was diluted with one volume of water and acidified to *p*H 2 with hydrochloric acid. The precipitate was filtered, washed with water and dried. The crude product was washed with ether and recrystallized from absolute ethanol to yield 80 mg. of white crystals, m.p. 195° dec. The ultraviolet spectrum was almost identical with that of IX (see Fig. 3).

Anal. Calcd. for $C_{11}H_7NO_3$: C, 65.67; H, 3.51; N, 6.96. Found: C, 65.83; H, 3.55; N, 6.94.

3-Diazo-7-hydroxy-8-methyl-2,4-chromandione (XV).—To an ice-cold solution of 200 mg. of XIII in 20 ml. of glacial acetic acid and 15 ml. of water was added 200 mg. of sodium nitrite. The solution was stirred until the nitrite crystals dissolved. After 1.5 hr. the solution was allowed to warm to room temperature and was taken to dryness *in vacuo*. The oily yellow residue was triturated with water and the product crystallized. The crude crystals (80 mg.) were recrystallized from ethanol and water using Darco G-60 to yield 60 mg. of peach-colored crystals which melted at 195–197° with explosive decomposition. The infrared spectrum showed a prominent band at 2165 cm.$^{-1}$ for the diazo group. Ultraviolet maxima occurred at 250 mμ (a = 46.2) and 312 mμ (a = 69.9) in acid ethanol and at 260 mμ (shoulder) (a = 37.8) and 366 mμ (a = 95.0) in alkaline ethanol.

Anal. Calcd. for $C_{10}H_7N_2O_4$: C, 54.79; H, 3.22; N, 12.78. Found: C, 55.28; H, 3.19; N, 12.91.

2,4 Dihydroxy-*m*-toluic Acid from 3-Amino-4,7-dihydroxy-8-methylcoumarin (XIII).—A solution of 0.50 g. (2.05 mM.) of XIII hydrochloride in 30 ml. of 1 *N* sodium hydroxide was allowed to stand at 25° for 4 days. The dark solution, which smelled of ammonia, was acidified with 2 *N* hydrochloric acid. Following the vigorous evolution of carbon dioxide, the solution was extracted several times with ether. The combined, dried extract was evaporated to yield 0.21 g. of red-brown solid. This material was dissolved in ethanol, stirred with Darco G-60 and the filtered solution evaporated to dryness. Most of the residue dissolved in saturated aqueous bicarbonate. The solution was filtered, acidified and extracted with ether. After drying, the ether extract was concentrated to a volume of about 10 ml. and passed through a $^3/_8'' \times 10''$ column of Florisil (Upjohn 6565a) previously dry-packed and wet-down with ether. As the column was developed with ether, most of the colored impurities were held near the top. The ferric chloride-positive material passed through with little or no adsorption. Fractions of 15–20 ml. were collected and evaporated. The residues from the first two fractions were crystallized from ether and Skellysolve B to provide 65.8 mg. (20%) of pale yellow acid which melted with sublimation at 210–215°. Final purification by sublimation at 200–220° and atmospheric pressure gave 50.4 mg. of colorless plates, m.p., with sublimation, 210–215°. In ethanol solution the spectrum showed maxima at 262.5 mμ (a_M = 12,950) and 298 mμ (a_M = 4,175); in acid ethanol, 264 mμ (a_M = 14,300) and 298 mμ (a_M = 4,250); and in alkaline ethanol, 237 mμ (a_M = 12,350) and 282 mμ (a_M = 14,375). This substance was identified as 2,4-dihydroxy-*m*-toluic acid by direct comparison with a synthetic sample.[15]

Anal. Calcd. for $C_8H_8O_4$: C, 57.14; H, 4.80; C–CH_3, 8.93. Found: C, 57.28; H, 5.24; C–CH_3, 8.16.

2-Methylresorcinol from 3-Amino-4,7-dihydroxy-8-methylcoumarin (XIII).—Three grams (12.3 mM.) of XIII hydrochloride was added to 20 g. of molten potassium hydroxide with stirring and continued heating on the hot-plate. The mixture became very dark and bubbled vigorously as ammonia evolved. After 30 minutes the reaction mixture was cooled to room temperature. Water (35 ml.) was added to the dark solid and the mixture was stirred until a uniform gelatinous slurry was obtained. The coal-black slurry was acidified with concentrated hydrochloric acid and extracted several times with ether. After drying over magnesium sulfate, the solvent was evaporated and the residue crystallized from benzene. Two crops totaling 0.52 g. (34%) of yellow crystals, m.p. 115–120°, were obtained. Part of this material was sublimed at *ca.* 125° and atmospheric pressure to yield colorless crystals which melted at 120–122°. When dissolved in ethanol and treated with 1% aqueous ferric chloride, little or no color change was noted. In aqueous solution alone (*i.e.*, no ethanol) a fleeting purple color was observed. This is in agreement with the properties recorded by Jones and Robertson,[14] for 2-methylresorcinol. When mixed with tolu-*p*-quinol, the m.p. was depressed to 100–105°.

Anal. Calcd. for $C_7H_8O_2$: C, 67.73; H, 6.49; C–CH_3, 12.1. Found: C, 67.89; H, 6.21; C–CH_3, 9.18.

Methyl 2-*O*-Acetyl-3-*O*-carbamyl-4-*O*-methyl-5,5-dimethyl-L-lyxoside.—A solution of 201 mg. (0.8 mM.) of XIV in 2.0 ml. of pyridine and 0.5 ml. of acetic anhydride was allowed to stand at 25° for 48 hr. The solution was cooled in an iced bath and diluted with 10 ml. of water. After 10–15 minutes the reaction mixture was extracted twice with an equal volume of chloroform. The dried, pooled extracts were evaporated to yield 230 mg. of colorless oil which was crystallized and recrystallized from Skellysolve B; yield 202 mg., m.p. 44–48°, $[\alpha]_D^{24}$ −14.0 (c 1.136 in 95% ethanol).

Anal. Calcd. for $C_{12}H_{21}NO_7$: C, 49.47; H, 7.27; N, 4.81. Found: C, 49.67; H, 7.49; N, 4.96.

Methyl 3-*O*-Carbamyl-2-*O*-mesyl-4-*O*-methyl-5,5-dimethyl-L-lyxoside.—A solution of 916 mg. (3.67 mM.) of XIV in 15 ml. of chloroform and 3 ml. of pyridine was chilled in an ice-bath and swirled with 0.3 ml. of methanesulfonyl chloride. After standing in a glass-stoppered flask at 4° for 22 hr., the reaction mixture was filtered. The filtrate was cooled to 0–5°, shaken with water and the layers separated. The chloroform layer was washed with ice-cold 0.5 *N* sulfuric acid, water, saturated sodium bicarbonate solution and finally with water. After drying over anhydrous magnesium sulfate, the solution was evaporated to dryness to yield 610 mg. (61%) of oil which crystallized quite readily. On recrystallization from water, the colorless crystals melted at 149–151°.

Anal. Calcd. for $C_{11}H_{21}NO_8S$: S, 9.79; OCH_3, 19.0. Found: S, 9.82; OCH_3, 18.5.

Methyl 4-*O*-Methyl-5,5-dimethyl-L-lyxoside 2,3-Cyclic Carbonate (XIX).—A solution of 1.03 g. (4 mM.) of XIV in 175 ml. of commercial absolute methanol and 40 ml. of 3 *N* methanolic hydrogen chloride was heated under reflux for 3.5 hr. The solution was concentrated to dryness *in vacuo*. The residue was slurried in 10–12 ml. of acetone, and 98.4 mg. of insoluble ammonium chloride was removed. The filtrate was evaporated to 5 ml. and 245 mg. of XIV recovered. The filtrate was concentrated to dryness under nitrogen and the remaining hydrogen chloride dispelled by vacuum drying. The residue was extracted with 15 ml. of hot water. As the solution cooled colorless crystals formed, 109 mg., m.p. 122–128°. After sublimation at 120° and 20–25 mm. the carbonate ester melted at 132–132.5°, $[\alpha]^{25}D$ +117.7° (c 0.998 in 95% ethanol).

Anal. Calcd. for $C_{10}H_{16}O_6$: C, 51.72; H, 6.95; OCH_3, 26.7. Found: C, 51.97; H, 6.91; OCH_3, 27.6.

Methyl 4-*O*-Methyl-5,5-dimethyl-L-lyxoside (XX).—Three ml. of saturated aqueous barium hydroxide solution was added to a solution of 76 mg. (0.328 mM.) of XIX in 12 ml. of carbon dioxide-free water. A white precipitate of barium carbonate separated immediately. After 2 hr. the precipitate (58.25 mg., 90%) was removed and the filtrate was neutralized with solid carbon dioxide. Again the barium carbonate was removed and the filtrate was concentrated *in vacuo* to a colorless sirup (48.26 mg., 71%). Crystallization and recrystallization from Skellysolve B gave colorless platelets, m.p. 61–68°, $[\alpha]^{25}D$ +113.8° (c 1.0 in water).

Anal. Calcd. for $C_9H_{18}O_5$: C, 52.41; H, 8.80. Found: C, 52.42; H, 8.57.

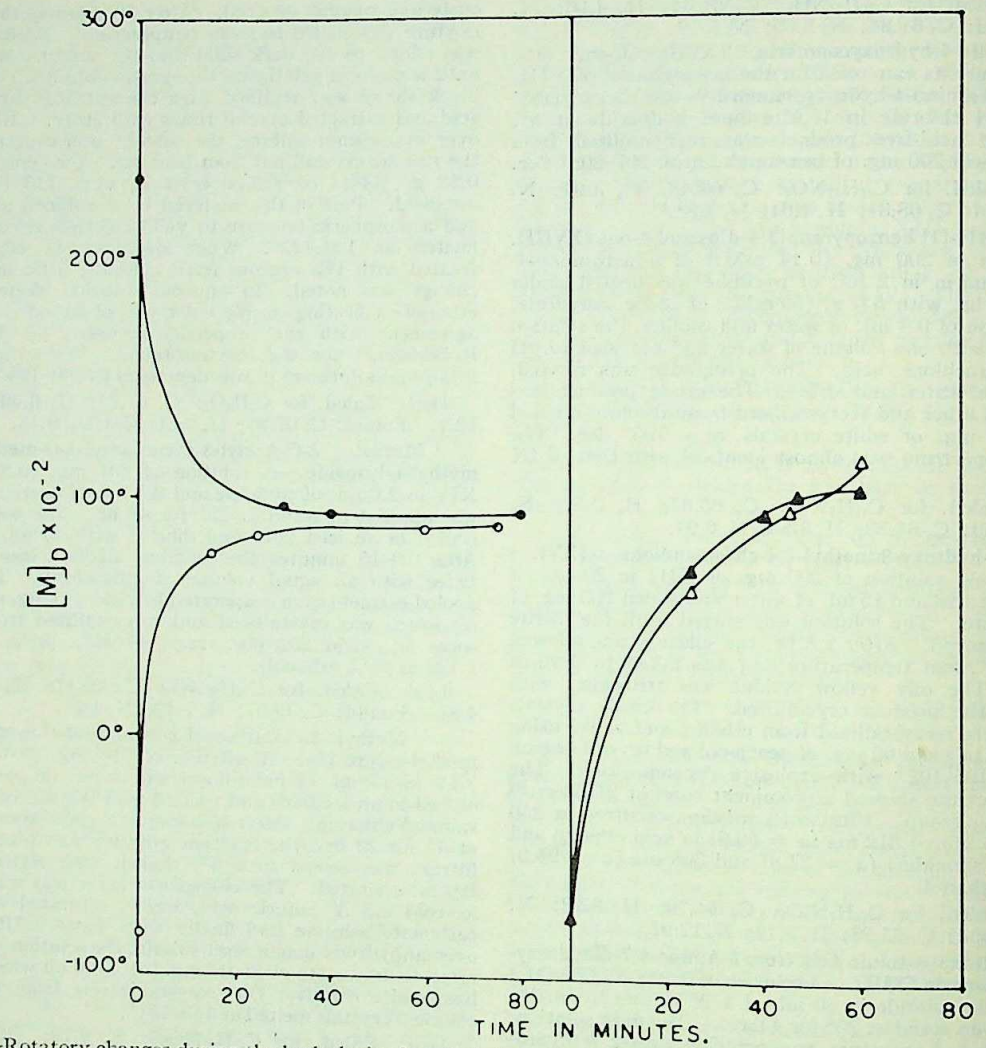

Fig. 4.—Rotatory changes during the hydrolysis of methyl glycosides in 0.5 *N* sulfuric acid at *ca.* 80°: ●, methyl novioside, anomer XXI; ○, methyl novioside, anomer XX; ▲, methyl 3-*O*-carbamylnovioside, 30 ml. of solution; ○, methyl 3-*O*-carbamylnovioside, 250 ml. of solution.

methyl-L-lyxoside (XXI) from XIV.—A solution of 2.0 g. (8 mM.) of XIV in 75 ml. of water was treated with 55 ml. of a saturated solution of barium hydroxide and allowed to react at 25° for 16 hr. The precipitate of barium carbonate was removed by filtration through a pad of Celite, and the filtrate (which smelled strongly of ammonia) was neutralized with carbon dioxide. The second precipitate was removed in the same fashion and the filtrate was taken to dryness *in vacuo*. The residue was dissolved in ether, filtered free of the last traces of barium carbonate and the solution evaporated to yield 1.6079 g. of a clear oil, which crystallized on standing. After recrystallization from Skellysolve B the dense, colorless rods melted at 65–70° and depressed the m.p. of XX. The infrared spectrum of XXI was very similar to that of XX but not identical, $[\alpha]^{24}D$ −63.6° (*c* 0.621 in 95% ethanol), −63.6° (*c* 1.0 in water).

Anal. Calcd. for $C_9H_{18}O_5$. C, 52.41; H, 8.80; OCH_3, 30.0; C–CH_3, 14.7. Found: C, 52.67; H, 8.88; OCH_3, 29.9; C–CH_3, 2.17.

Methyl 2,3-Di-*O*-acetyl-4-*O*-methyl-5,5-dimethyl-L-lyxoside.—Using the procedure described for the acetylation of XIV, 201.58 mg. (0.975 mM.) of XXI was acetylated using 3 ml. of pyridine and 1 ml. of acetic anhydride. The product was crystallized and recrystallized from Skellysolve B to yield 217 mg. of dense rods, m.p. 62–64°, $[\alpha]^{24}D$ −20.4° (*c* 0.973 in 95% ethanol).

Anal. Calcd. for $C_{13}H_{22}O_7$: C, 53.78; H, 7.64; OAc, 29.66. Found: C, 54.16; H, 7.59; OAc, 28.07.

4-*O*-Methyl-5,5-dimethyl-L-lyxose (XXII).—A solution of 840 mg. (4.07 mM.) of methyl novioside (XXI) in 84 ml. of 0.5 *N* sulfuric acid was heated on the steam-bath at 80–85° for 1.25 hr. Previous studies had shown that this was sufficient time for completion of the reaction as indicated by the change in rotation (see Fig. 4). The solution was cooled and stirred with an excess of barium carbonate. The neutralized mixture was filtered free of insoluble salts and concentrated *in vacuo* to dryness. The residue was dissolved in absolute ethanol and the solution filtered to remove traces of salts. Evaporation of the filtrate gave a nearly quantitative yield of noviose as a colorless sirup which crystallized on standing. After recrystallization from ethanol–ether, acetone–Skellysolve B and finally from ethyl acetate, the fine colorless needles melted at 128–130°, $[\alpha]^{24}D$ +19.9° (*c* 0.950 in 50% ethanol).

Anal. Calcd. for $C_8H_{16}O_5$: C, 49.99; H, 8.39; OCH_3, 16.15. Found: C, 49.71; H, 8.50; OCH_3, 16.23.

Noviose, identical with the above, was obtained by similar treatment of XX. This proved the α-, β-methyl glycoside relationship between XX and XXI.

Chromic Acid Oxidation of Methyl 4-*O*-Methyl-5,5-dimethyl-L-lyxoside (Methyl Novioside).—To 300 mg. (1.45 mM.) of XXI was added 10 ml. of a solution containing 7.5 ml. of 5 *N* chromic acid and 2.5 ml. of concd. sulfuric acid. The solution was distilled rapidly into ethanolic 2,4-dinitrophenylhydrazine. Two additional 5-ml. portions of the oxidizing mixture and 15 ml. of water were added during the distillation. The yield of re-

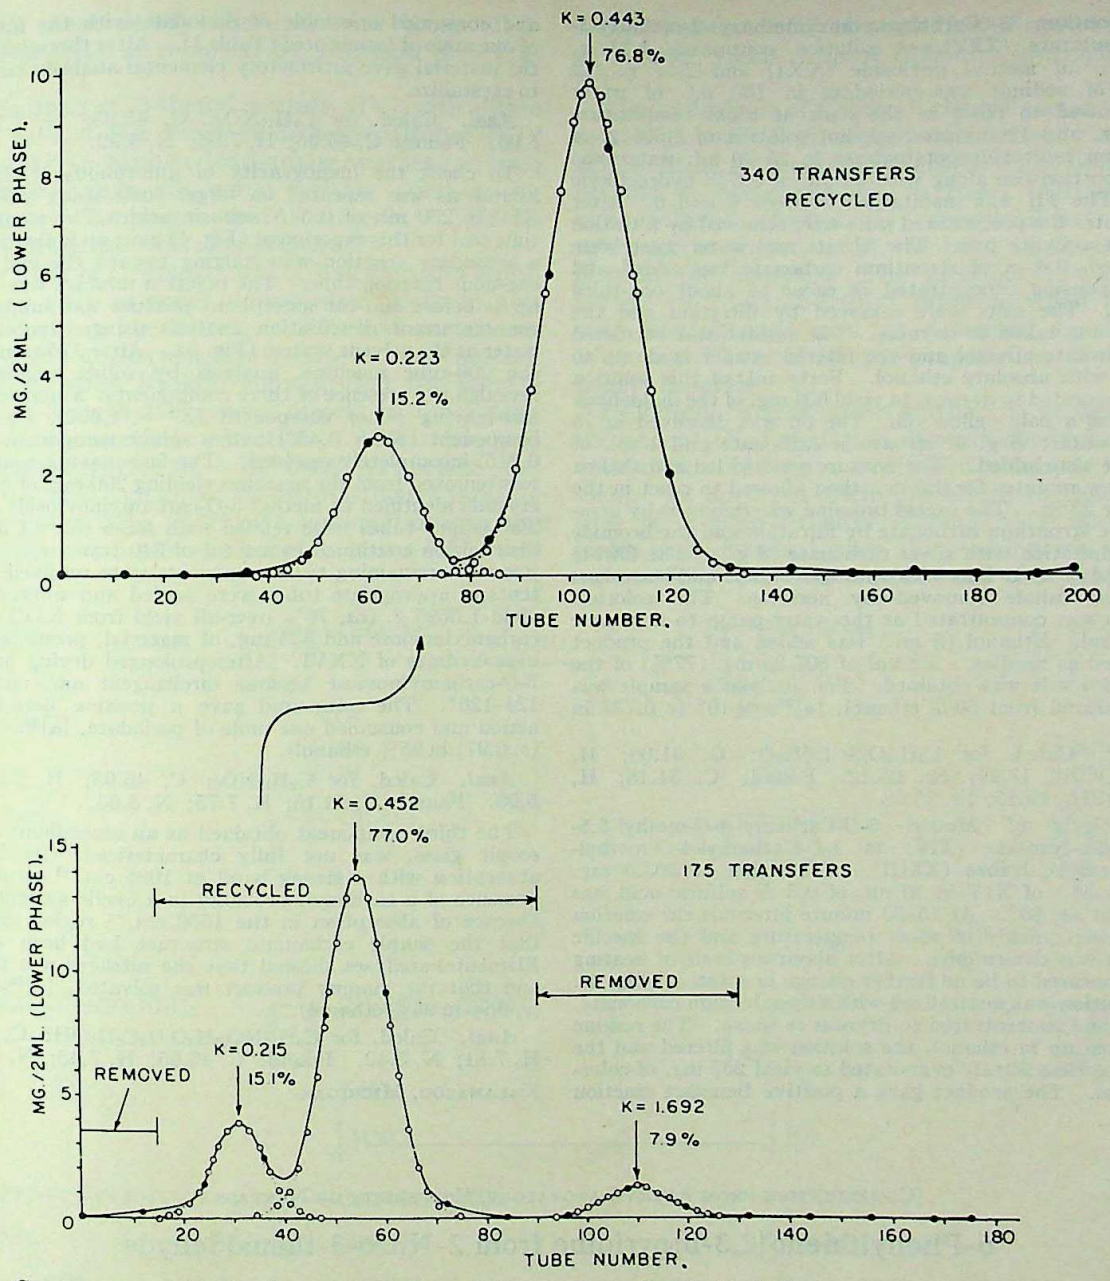

Fig. 5.—Countercurrent distribution analysis of methyl 3-*O*-carbamylnovioside hydrolysate; ●, observed; O, calculated.

crystallized acetone 2,4-dinitrophenylhydrazone was 160 mg. (46%), m.p. 125–127°. The sample was further identified by infrared comparison with authentic acetone 2,4-dinitrophenylhydrazone.

Quantitative Periodate Oxidation Studies.—Using the procedure of Fleury and Lange,[17] 0.1-mM. quantities of each compound were oxidized with sodium metaperiodate in aqueous solution in the dark at room temperature. Formic acid was determined by potentiometric titration, conversion of mercuric chloride to calomel[22] or by isolation as the water-soluble but alcohol-insoluble strontium formate. Results for pertinent compounds are given in Table I.

Glyoxal from Periodate Oxidation of Methyl Novioside (XXI).—To 249 mg. of XXI in 50 ml. of water was added 25 ml. of a 50 mg./ml. solution of sodium metaperiodate. After 2 hr. in the dark at 25°, the iodate and excess periodate were precipitated with barium hydroxide (*p*H 7). The neutral solution was evaporated *in vacuo* to 25 ml. and sodium bicarbonate added to precipitate the remaining barium ions. The filtrate was evaporated to dryness at reduced pressure and the residue extracted with ethanol. Removal of the solvent left a residue of 225 mg. which was dissolved in 10 ml. of 0.5 *N* hydrochloric acid. The solution was heated at 80° for 15 minutes then added to a hot solution of 730 mg. of 2,4-dinitrophenylhydrazine, 1 ml. of concd. hydrochloric acid and 100 ml. of ethanol. This mixture was boiled 5 minutes and an additional 5 ml. of 2 *N* hydrochloric acid was added. On cooling, 400 mg. of glyoxal dinitrophenylosazone (m.p. 345°) separated. Its identity was confirmed by infrared comparison with an authentic

Strontium 3-(Carboxymethoxymethoxy)-2-methoxy-3-methylbutyrate (XXV).—A solution containing 1.24 g. (6 mM.) of methyl novioside (XXI) and 2.57 g. (12 mM.) of sodium metaperiodate in 150 ml. of water was allowed to react in the dark at room temperature for 1 hr. and 10 minutes. A hot solution of 1.595 g. of strontium hydroxide octahydrate in 25–30 ml. water was added portionwise along with 24 ml. of 0.5 *N* hydrochloric acid. The *p*H was maintained between 5 and 6. After 30 minutes the precipitated salts were removed by filtration through a Celite pad. The filtrate and water wash were combined, 0.4 g. of strontium carbonate was added and the suspension concentrated *in vacuo* to about one-third volume. The salts were removed by filtration and the filtrate was taken to dryness. The residue was extracted with absolute ethanol and the filtered extract made up to 50 ml. with absolute ethanol. Forty ml. of this solution was evaporated to dryness to yield 694 mg. of the dialdehyde XXIV as a pale yellow oil. The oil was dissolved in 75 ml. of water; 8 g. of strontium carbonate and 1 ml. of bromine were added. The mixture was swirled and shaken every few minutes for 0.5 hr., then allowed to react in the dark for 23 hr. The excess bromine was removed by aeration, the strontium carbonate by filtration and the bromide by precipitation with silver carbonate (8 g.). The filtrate was freed of silver ions with hydrogen sulfide and the excess hydrogen sulfide removed by aeration. The colorless solution was concentrated at the water-pump to a volume of 3–4 ml. Ethanol (5 ml.) was added and the product separated as needles. A total of 807.23 mg. (77%) of the crystalline salt was obtained. For analysis a sample was recrystallized from 50% ethanol, $[\alpha]^{24}D$ +10° (*c* 0.734 in water).

Anal. Calcd. for $C_9H_{14}O_7Sr \cdot 1.5H_2O$: C, 31.00; H, 4.91; OCH_3, 17.39; Sr, 25.12. Found: C, 31.18; H, 5.07; OCH_3, 19.65; Sr, 25.68.

Hydrolysis of Methyl 3-*O*-Carbamyl-4-*O*-methyl-5,5-dimethyl-L-lyxoside (XIV) to 3-*O*-Carbamyl-4-*O*-methyl-5,5-dimethyl-L-lyxose (XXIII).—A solution of 303.5 mg. (0.928 mM.) of XIV in 30 ml. of 0.5 *N* sulfuric acid was heated at *ca.* 80°. At 15–30 minute intervals the solution was cooled quickly to room temperature and the specific rotation was determined. After about an hour of heating there appeared to be no further change in rotation (Fig. 4). The solution was neutralized with excess barium carbonate, filtered and concentrated to dryness *in vacuo*. The residue was taken up in ethanol, the solution was filtered and the clear, colorless filtrate evaporated to yield 257 mg. of colorless glass. The product gave a positive Benedict reaction and consumed one mole of periodate with the formation of one mole of formic acid (Table I). After thorough drying the material gave satisfactory elemental analyses but failed to crystallize.

Anal. Calcd. for $C_9H_{17}NO_6$: C, 45.95; H, 7.29; N, 5.96. Found: C, 45.95; H, 7.66; N, 5.92.

To check the homogeneity of amorphous XXIII, the hydrolysis was repeated on larger scale using 2.50 g. of XIV in 250 ml. of 0.5 *N* sulfuric acid. The rotation *vs.* time plot for this experiment (Fig. 4) gave an indication that a secondary reaction was starting toward the end of the one-hour reaction time. The reaction mixture was worked up as before and the amorphous product was subjected to countercurrent distribution analysis using 1-butanol and water as the solvent system (Fig. 5). After 175 transfers in the 200-tube machine, analysis by solids measurement revealed the presence of three components: a well-resolved, fast-moving minor component (K = 1.692), the major component (K = 0.452) and a minor component (K = 0.215) incompletely resolved. The fast-moving component was removed from the machine yielding 200 mg. of colorless crystals identified as methyl 3-*O*-carbamylnovioside (XIV). The empty tubes were refilled with fresh solvent and the distribution continued to a total of 340 transfers. At this point the remaining two components were resolved. Contents of appropriate tubes were pooled and worked up to yield 1.5595 g. (*ca.* 76% over-all yield from XIV) of 3-*O*-carbamylnoviose and 336 mg. of material, presumably the monohydrate of XXVI. After prolonged drying *in vacuo*, 3-*O*-carbamylnoviose became birefringent and melted at 124–126°. The compound gave a positive Benedict reaction and consumed one mole of periodate, $[\alpha]^{26}D$ +45.3° (*c*, 0.971 in 95% ethanol).

Anal. Calcd. for $C_9H_{17}NO_6$: C, 45.95; H, 7.29; N, 5.96. Found: C, 46.15; H, 7.75; N, 5.63.

The third component obtained as an amorphous, hygroscopic glass, was not fully characterized. Its infrared absorption with a strong band at 1695 cm.$^{-1}$ assured the presence of a carbonyl, probably in a cyclic system. The absence of absorption in the 1600 cm.$^{-1}$ region indicated that the simple carbamate structure had been altered. Elemental analyses showed that the nitrogen was retained and that the gummy product was solvated, $[\alpha]^{26}D$ +63° (*c*, 0.96 in 95% ethanol).

Anal. Calcd. for $C_9H_{15}NO_5 \cdot H_2O \cdot {}^1/_2C_2H_5OH$: C, 46.50; H, 7.81; N, 5.42. Found: C, 46.95; H, 7.45; N, 5.61.

6-Phenylthieno[2,3-b]pyridine from 2-Nitro-3-thenaldehyde

BY WILLIAM J. RAICH[1] AND CLIFF S. HAMILTON

RECEIVED JANUARY 17, 1957

3-Methylthiophene was converted to 3-thenyl acetate which on nitration gave a mixture of 2- and 5-nitro-3-thenyl acetates. The readily isolated 2-isomer was hydrolyzed to the alcohol, nitric acid oxidation of which gave 2-nitro-3-thenaldehyde. The aldehyde condensed readily with malonic acid and with acetophenone. The product from the latter reaction was reduced and cyclized to 6-phenylthieno[2,3-b]pyridine.

Recently, an interest developed in the synthesis of compounds containing fused thiophene rings of the C_4N–C_4S or C_4S–C_5N systems in which the sulfur and nitrogen atoms are in the peri position. Of particular interest as an intermediate was 2-nitro-3-thenaldehyde (I) which by analogy to *o*-nitrobenzaldehyde would be a satisfactory starting material for the preparation of a number of the desired type compounds. Using commercially available 3-methylthiophene (VI), 2-nitro-3-thenaldehyde (I) was prepared in an over-all yield of 5%. The aldehyde was converted *via* the condensation product with acetophenone to 6-phenylthieno[2,3-b]-pyridine (XII), the thiophene analog of 2-phenylquinoline.

3-Methylthiophene (VI) was treated with N-bromosuccinimide as described by Campaigne and Tuller[2] to give 3-thenyl bromide which without isolation was converted immediately to 3-thenyl acetate (IV) in 58% over-all yield. The small amount of 2-bromo-3-methylthiophene formed in the bromination step was removed readily from the ester by distillation. The physical properties of the ace-

tate IV were nearly identical with those of 2-thenyl acetate as reported by Emerson and Patrick.[3]

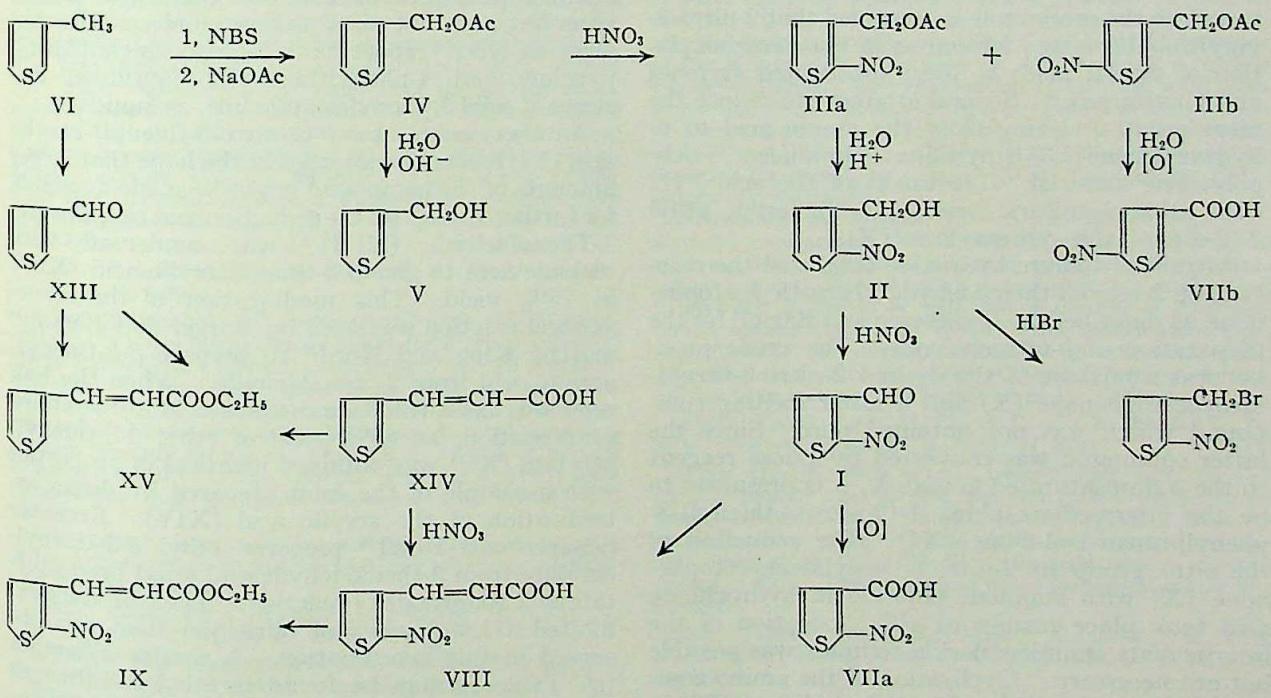
Hydrolysis of 3-thenyl acetate (IV) with dilute alkali gave a fair yield of 3-thenyl alcohol (V).[4] 3-Thenyl N-α-naphthylcarbamate synthesized from the alcohol gave the same melting point as reported by Campaigne and Bourgeois.[4] The N-phenylcarbamate was also prepared.

The work of Grimaux[5] and of Beilstein and Kuhlberg[6] as well as some unpublished work in this Laboratory on the nitration of benzyl acetate indicated the acetoxymethyl group to be *ortho-para* directing, while Rinkes[7] showed that the methyl group in 3-methylthiophene directs to the 2-position predominantly in nitration. With nitric acid in acetic anhydride at −10° 3-thenyl acetate (IV) gave a 30% yield of 2-nitro-3-thenyl acetate (IIIa) plus a 53% yield of a low-melting mixture of 2-nitro-and 5-nitro-3-thenyl acetates (IIIa and IIIb).

3-thenyl acetate (IV) to a solution of acetyl nitrate gave lower yields of more difficultly purified product.

The hydrolysis of 2-nitro-3-thenyl acetate (IIIa) to the alcohol II proceeded satisfactorily only in acid solution because of the sensitivity of both compounds to decomposition in base. Although 2-nitro-3-thenyl alcohol (II) recrystallized easily, sublimation proved to be the best means of purification for analysis. The alcohol II was converted to 2-nitro-3-thenyl bromide when treated with hydrobromic acid as described by Norris, Watt and Thomas[8] for the preparation of *o*-nitrobenzyl bromide.

Helferich, Streeck and Gunther[9] have described the uncontrolled oxidation of *o*-nitrobenzyl alcohol with nitric acid to give *o*-nitrobenzaldehyde in 85% yield. In applying their procedure to the oxidation of 2-nitro-3-thenyl alcohol (II) maximum yields were obtained when the reaction was carried out at 35°. At this temperature the yield of 2-



Attempts to obtain the 5-nitro isomer pure by fractional crystallization failed. Chromatography of the isomer mixture on alumina gave a small amount of pure 5-nitro-3-thenyl acetate (IIIb) due mainly to decomposition of the 2-isomer in the process. By projecting the results of the chromatographic experiment it was estimated that nitration of 3-thenyl acetate (IV) in the 2-position is favored 4:3 over nitration in the 5-position. No evidence of the existence of the third possible isomer, 4-nitro-3-thenyl acetate, was found although small amounts may have been present. The addition of nitro-3-thenaldehyde (I) remained nearly constant at 54% over a 15 to 30 minute reaction time. With shorter reaction periods larger amounts of 2-nitro-3-thenyl alcohol (II) were recovered while reactions of longer duration yielded increasing amounts of 2-nitro-3-thenoic acid (VIIa). The aldehyde I was isolated from the crude reaction mixture by steam distillation and further purified by sublimation in the dark. The phenylhydrazone and thiosemicarbazone of 2-nitro-3-thenaldehyde (I) were prepared most conveniently by appropriate treatment of the filtrate from the steam distillate.

The structure of 2-nitro-3-thenoic acid (VIIa) had been established earlier by Rinkes.[7] The iso-

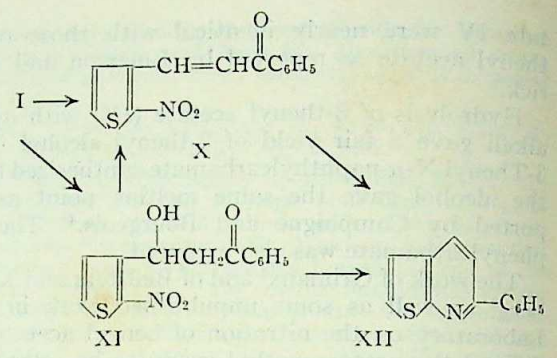
lation of this acid from the oxidation reaction substantiated the structures of the 2-nitro aldehyde I, alcohol II and acetate IIIa. The acid VIIa was converted to the previously unreported 2-nitro-3-thenamide without isolation of the intermediate acid chloride. The structure of 5-nitro-3-thenyl acetate (IIIb) was proved by hydrolysis and oxidation to the known 5-nitro-3-thenoic acid[4,7] (VIIb). Although the yield in the oxidation step was poor, only one acid was isolated. As a further check the acid VIIb was converted to 5-nitro-3-thenamide identical in melting point with that reported by Campaigne and Bourgeois.[4]

Besides forming the usual derivatives of the carbonyl group 2-nitro-3-thenaldehyde (I) underwent typical condensations with active methyl or methylene groups. With malonic acid in pyridine it reacted to form β-(2-nitro-3-thienyl)-acrylic acid (VIII). On heating the acrylic acid decomposed with the evolution of carbon dioxide; a reproducible melting point was obtained only when approached rapidly. Although no attempt was made to isolate the product, it is presumed that 2-nitro-3-vinylthiophene was formed as in the decarboxylation of similar acids to form substituted styrenes and vinylfurans.[10] Several attempts to reduce the nitro group and ring close the amino acid to 6-hydroxythieno[2,3,-b]pyridine produced only polymeric material. Treatment of the acid VIII with ethanol–sulfuric acid gave the ester, ethyl β-(2-nitro-3-thienyl)-acrylate (IX).

A trace of sodium hydroxide catalyzed the reaction of 2-nitro-3-thenaldehyde (I) with acetophenone as described by Tanesescu and Bacic[11] for the preparation of *o*-nitrochalcone. The crude product was a mixture of the desired 2-nitro-3-thenylideneacetophenone (X) and a lower melting compound which was not obtained pure. Since the latter compound was converted by Lucas reagent to the α,β-unsaturated ketone X, it is presumed to be the intermediate aldol, 1-(2-nitro-3-thienyl)-3-phenylpropan-1-ol-3-one (XI). The reduction of the nitro group in 2-nitro-3-thenylideneacetophenone (X) with stannous chloride in hydrochloric acid took place readily at 40°. Isolation of the intermediate stannic chloride complex was possible but not necessary. Cyclization of the amino compound to 6-phenylthieno[2,3,-b]pyridine (XII) in 66% yield occurred spontaneously when the crude reduction mixture was added to an excess of cold potassium hydroxide solution. It was found that both the impure aldol XI and the crude acetophenone condensation product gave only slightly lower yields of the fused ring compound under the same conditions.

Only four other thieno[2,3-b]pyridines have been reported in the literature. Two of these, the parent compound[12] and the 4,6-dimethyl derivative,[13] were prepared from 2-aminothiophene while the other two were synthesized from pyridine derivatives.



6-Phenylthieno[2,3-b]pyridine (X) is a solid quite similar in odor and appearance to 2-phenylquinoline. Of the compounds prepared in this work only the thienopyridine (XII) and β-(2-nitro-3-thienyl)-acrylic acid (VIII) exhibit melting points below those of the analogous benzene compounds. The similarity in physical properties between corresponding thiophene and benzene compounds is quite evident with the simple derivatives but may not exist among more complex analogs as Herz[14] reports both 7-phenylthieno[2,3-c]-pyridine and 4-phenylthieno[3,2-c]pyridine, isosteres of solid 1-phenylisoquinoline, as liquids.

Another route to β-(2-nitro-3-thienyl)-acrylic acid (VIII) was investigated in the hope that larger amounts of the compound might be made available for further studies on the reduction and ring closure. 3-Thenaldehyde (XIII)[15] was condensed with malonic acid to give β-3-thienylacrylic acid (XIV) in 78% yield. This modification of the Knoevenagel reaction was used by Barger and Easson[16] and by King and Nord[17] to prepare β-2-thienylacrylic acid from 2-thenaldehyde. When the half ester was substituted for malonic acid in the above condensation, an 86% yield of ethyl β-3-thienylacrylate (XV) was obtained identical in properties with a sample of the ester prepared by direct esterification of the acrylic acid (XIV). Recently Schuetz and Houff[18] prepared ethyl β-3-thienylacrylate from 3-thenaldehyde and ethyl bromoacetate in a Reformatsky reaction. Their product exhibited a lower index of refraction than was observed in this investigation. A similar difference (*cf.* Table I) may be found in ethyl β-2-thienylacrylate prepared by the Claisen and the Reformatsky methods.

TABLE I

REFRACTIVE INDICES OF ETHYL THIENYLACRYLATES

ported[19] to yield predominantly *o*- and *p*-nitrocinnamic acids, it was hoped that the nitration of β-3-thienylacrylic acid (XIV) would yield useful quantities of the desired 2-nitro isomer VIII. In practice the separation of the isomers formed proved formidable. However, a small amount of the desired isomer was obtained by repeated crystallizations. The work was hampered by the low solubility of the acids and the difficulty in reproducing the melting or decomposition points. The 5-nitro derivative presumably present could not be obtained pure enough for characterization.

Experimental[20]

3-Thenyl Acetate (IV).—3-Methylthiophene (VI) (109 g. 1.1 moles) was brominated with N-bromosuccinimide (178 g., 1.0 mole) as described by Campaigne and Tuller.[2] The benzene solution of crude 3-thenyl bromide remaining after removal of succinimide was added to a flask containing 90 g. (1.1 moles) of freshly fused sodium acetate. While stirring to prevent bumping the benzene was removed by distillation and replaced simultaneously with acetic anhydride until the temperature of the mixture reached 120°. Heating and stirring at this temperature continued for 8 hours. The salt removed from the mixture by filtration was dissolved in water and extracted twice with chloroform. The combined extracts and organic filtrate were washed with water and dried before removal of the solvent under reduced pressure. The dark residue was distilled through a six-inch Vigreux column to give a small forerun containing 2-bromo-3-methylthiophene and 90.1 g. (58%) of colorless 3-thenyl acetate (IV), b.p. 98–107° (17 mm.), $n^{25}D$ 1.5169. Two fractionations through a Podbielniak column[21] gave analytical material, b.p. 105.5° (16 mm.), $n^{25}D$ 1.5138, d^{20}_4 1.174.

Anal. Calcd. for $C_7H_8O_2S$: C, 53.83; H, 5.17. Found: C, 53.93; H, 5.39.

3-Thenyl Alcohol (V).—One-tenth mole of 3-thenyl acetate (IV) was heated under reflux for 3 hours with 200 ml. of 2 *N* sodium hydroxide containing a trace of synthetic detergent. After cooling the organic layer was separated with the aid of benzene, washed and dried. Following removal of the benzene, the material was distilled through a six-inch Vigreux column to give 6.6 g. (58%) of impure 3-thenyl alcohol (V), b.p. 106–115° (20 mm.), $n^{25}D$ 1.5609 (Campaigne and Bourgeois[4] reported b.p. 88–90° (10 mm.))

With phenyl isocyanate the alcohol V formed 3-thenyl N-phenylcarbamate, m.p. 73.5–74.0° (c), after recrystallization from cyclohexane.

Anal. Calcd. for $C_{12}H_{11}NO_2S$: C, 61.78; H, 4.75; N, 6.01. Found: C, 61.68; H, 4.88; N, 6.02.

3-Thenyl N-α-naphthylcarbamate was found to melt at 132–133° as reported by Campaigne and Bourgeois.[4]

2-Nitro-3-thenyl Acetate (IIIa).—Fuming nitric acid (10 ml., 0.24 mole, sp. gr. 1.51) was added *cautiously* drop by drop to a stirred solution of 31.2 g. (0.2 mole) of 3-thenyl acetate (IV) in 60 ml. of acetic anhydride cooled to below −10° with a Dry Ice–acetone bath. Stirring was continued for 3 hours while the temperature was allowed to rise slowly to 10°. The mixture was poured into about 1 liter of ice-water and stirred until crystallization of the oil was complete. The solid was washed twice with cold water by decantation, then was collected on a büchner funnel with the aid of 100 ml. of cold 50% methanol. Three rapid recrystallizations from minimum amounts of boiling 95% ethanol gave 12.0 g. (30%) of 2-nitro-3-thenyl acetate (IIIa) as yellow platelets, m.p. 88–91°.

Anal. Calcd. for $C_7H_7NO_4S$: C, 41.78; H, 3.51; N, 6.96. Found: C, 41.95; H, 3.56; N, 6.86.

The combined ethanolic filtrates from the above recrystallizations were cooled and diluted slowly with water until crystallization was complete. After drying in a vacuum desiccator over phosphorus pentoxide, the collected solid mixture of 2- and 5-nitro-3-thenyl acetates weighed 21.4 g. (53%) and melted below 55°.

5-Nitro-3-thenyl Acetate (IIIb).—Three grams of the low melting isomer mixture obtained above was dissolved in ether and placed on a chromatographic column prepared from 300 g. of alumina (Merck). Development and elution were carried out with ether. A light yellow band moved rapidly down the column and was collected to give 2.2 g., m.p. 59–61°. After recrystallization from ethyl acetate–petroleum solvent (b.p. 89–98°) and from isopropyl ether the material melted at 65.0–65.5° (c). This was shown below to be 5-nitro-3-thenyl acetate (IIIb).

Anal. Calcd. for $C_7H_7NO_4S$: C, 41.78; H, 3.51; N, 6.96. Found: C, 41.59; H, 3.39; N, 6.94.

A dark red band had formed and moved slowly down the column in a diffuse manner. When fractions containing this material were evaporated, only a brown oil was obtained. An ether solution of 2-nitro-3-thenyl acetate (IIIa) placed on a similar column could not be eluted as such but produced a similar dark oil.

A 2.0-g. sample of 2-nitro-3-thenyl acetate (IIIb) was heated with 35 ml. of 10% sulfuric acid for 1.5 hours, then filtered with an acetic acid wash to remove some carbonaceous material present. A saturated solution of 3 g. (1.5 oxidation equivalents) of sodium dichromate dihydrate in water was added slowly over an hour at 30–35°. After an additional hour at 50°, the mixture was thoroughly cooled and the dark green solid, wt. 0.3 g., collected. Extraction of the filtrate with ether gave an additional 0.2 g. of less colored material. Recrystallization of the first solid from water and from benzene (charcoal) gave colorless prisms of 5-nitro-3-thenoic acid (VIIb), m.p. 147° (reported[4,7] as 147° and 145–146°). The acid VIIb was converted to 5-nitro-3-thenamide, m.p. 162–163° as reported by Campaigne and Bourgeois.[4]

2-Nitro-3-thenyl Alcohol (II).—A mixture of 10 g. of 2-nitro-3-thenyl acetate (IIIa) and 150 ml. of 10% sulfuric acid was heated under reflux until solution was complete (about 2 hours), filtered with charcoal while hot, and cooled to give 6.8 g. (86%) of pale yellow needles of 2-nitro-3-thenyl alcohol (II), m.p. 88–91°. An additional 0.6 g., m.p. 65–72°, was extracted from the filtrate with ether. The colorless alcohol II melted at 90–91.5° after recrystallization from water and sublimation at 55° (300 μ).

Anal. Calcd. for $C_5H_5NO_3S$: C, 37.73; H, 3.17; N, 8.80. Found: C, 37.88; H, 3.16; N, 8.85.

When treated with concd. hydrobromic acid at 75° for 1.5 hours,[8] the alcohol was converted to 2-nitro-3-thenyl bromide, m.p. 58–61°, in 71% yield. After recrystallizations from ethanol–water and from benzene–petroleum ether (b.p. 30–60°) the pale yellow crystals melted at 62°. The compound was a lachrymator and skin irritant.

Anal. Calcd. for $C_5H_4NO_2SBr$: C, 27.04; H, 1.81; N, 6.31; Br, 35.99. Found: C, 27.32; H, 1.78; N, 6.19; Br, 35.96.[22]

2-Nitro-3-thenaldehyde (I).—A stirred solution of 4 g. of 2-nitro-3-thenyl alcohol (II) in 8 ml. of concd. nitric acid was warmed to 30° until an exothermic reaction and the evolution of nitrogen oxides began. Cooling was applied as necessary to keep the temperature at 35° until no further heat effects were noted (about 20 min.). The green mixture was poured onto 20 g. of ice and the yellow solid which formed collected by filtration. The material was distilled with steam, and from 500 ml. of cold distillate there was obtained 1.5 g. (37%) of yellow needles of 2-nitro-3-thenaldehyde (I), m.p. 52–54°. For analysis the aldehyde I was recrystallized from ether–petroleum ether (b.p. 30–60°) and then sublimed at 30–35° (150 μ); m.p. 54–55°.

Anal. Calcd. for $C_5H_3NO_3S$: C, 38.21; H, 1.92; N, 8.92. Found: C, 38.28; H, 1.83; N, 8.77.

By treatment of the filtrate from the steam distillate with phenylhydrazine–acetic acid solution, 2-nitro-3-thenaldehyde phenylhydrazone was obtained in amount corresponding to an additional 0.6 g. (17%) of the aldehyde. The phenylhydrazone crystallized from absolute ethanol as dark red platelets, m.p. 213–215° dec.

Anal. Calcd. for $C_{11}H_9N_3O_2S$: N, 16.99. Found: N, 17.08.

Similar treatment of the filtrate with an aqueous solution of thiosemicarbazide gave 2-nitro-3-thenaldehyde thiosemicarbazone, m.p. 243–244° dec., which could not be crystallized without decomposition.

Anal. Calcd. for $C_6H_6N_4O_2S_2$: N, 24.33. Found: N, 24.26.

Evaporation of the ether extract of the filtrate from the diluted reaction mixture gave 1.1 g. of yellow solid which after two recrystallizations from benzene proved to be 2-nitro-3-thenoic acid (VIIa), m.p. 156–157° (Rinkes[7] reported 155–156°). The acid was converted through the acid chloride to 2-nitro-3-thenamide, m.p. 184–185°, as yellow needles from hot water.

Anal. Calcd. for $C_5H_4N_2O_3S$: N, 16.28. Found: N, 16.28.

β-(2-Nitro-3-thenyl)-acrylic Acid (VIII) and Ethyl Ester (IX).—A mixture of 1.5 g. of 2-nitro-3-thenaldehyde (I), 2.0 g. of malonic acid and 5 ml. of dry pyridine containing two drops of piperidine was heated under reflux for 1 hour. The cooled, red mixture was diluted with two volumes of ice-water and acidified with hydrochloric acid. The dark solid was collected by filtration, washed with water, and dried in air to give 1.5 g. (79%), m.p. 217–219° dec. with rapid heating, of β-(2-nitro-3-thienyl)-acrylic acid (VIII). Recrystallization from hot water (charcoal) was accompanied by considerable loss but gave nearly colorless needles of the acid, m.p. 220–222° dec.

Anal. Calcd. for $C_7H_5NO_4S$: C, 42.21; H, 2.53; N, 7.03. Found: C, 42.21; H, 2.54; N, 6.92.

Decomposition of the β-(2-nitro-3-thienyl)-acrylic acid began as low as 175° as noted when the melting point was approached slowly. The evolution of carbon dioxide was shown by allowing the decomposition gas to bubble through a faintly pink, dilute phenolphthalein solution.

Ethyl β-(2-nitro-3-thienyl)-acrylate (IX) was prepared by treating the above acid VIII with absolute ethanol containing a trace of sulfuric acid. After recrystallization from ether–petroleum ether (b.p. 30–60°) and from ethanol–water, the ester IX melted at 73–74°.

Anal. Calcd. for $C_9H_9NO_4S$: C, 47.57; H, 3.99; N, 6.16. Found: C, 47.46; H, 3.93; N, 6.19.

Condensation of 2-Nitro-3-thenaldehyde (I) with Acetophenone.—Four ml. of a 1% solution of sodium hydroxide in 95% ethanol was added to a cold solution of 1.40 g. of 2-nitro-3-thenaldehyde (I) and 1.08 g. of acetophenone in 9 ml. of ether. The reaction mixture immediately darkened and became warm enough to boil away most of the ether. After 30 minutes the mixture was cooled, acidified with acetic acid and diluted with 20 ml. of water. Filtration gave 1.45 g. of brown solid, m.p. 116–130°. Extraction of this material with 50 ml. of boiling 95% ethanol left 0.85 g., (36%) m.p. 165–181°, which, after two recrystallizations from absolute ethanol, was obtained as long, light yellow needles, m.p. 181–182°, of 2-nitro-3-thenylideneacetophenone (X).

Anal. Calcd. for $C_{13}H_9NO_3S$: C, 60.22; H, 3.50; N, 5.40. Found: C, 60.24; H, 3.69; N, 5.47.

From the original filtrate and the ethanol extract of the reaction product, 0.54 g. of material melting below 130° was obtained by evaporation and dilution with water. Fractional crystallization of the material, from ethanol by the addition of water, gave material melting 131–134°. No further improvement of the melting point could be obtained. Concentrated hydrochloric acid–zinc chloride solution (Lucas reagent) converted the material to 2-nitro-3-thenylideneacetophenone (X). The material was presumed to be the aldol, 1-(2-nitro-3-thienyl)-3-phenylpropan-1-ol-3-one (XI).

6-Phenylthieno[2,3-b]pyridine (XII).—2-Nitro-3-thenylideneacetophenone (X) (0.26 g., 0.001 mole) was suspended in a solution of 1.80 g. (0.008 mole) of stannous chloride dihydrate in 5 ml. of concd. hydrochloric acid and 5 ml. of 95% ethanol. Cooling was applied as necessary to keep the reaction temperature at 40°. After no further evidence of reaction was noted, the resulting solution was allowed to stand at 35° for two hours. The entire reaction mixture was added dropwise with stirring to 25 ml. of aqueous 50% potassium hydroxide cooled below 10°. Evaporation of the ether extract of the alkaline mixture and crystallization of the residue from ethanol–water gave 0.14 g. (66%) of 6-phenylthieno[2,3-b]pyridine (XII) as orange platelets, m.p. 74–76°. Additional crystallizations from ethanol–water gave colorless material, m.p. 77–78° (c).

Anal. Calcd. for $C_{13}H_9NS$: C, 73.90; H, 4.29; N, 6.63. Found: C, 74.01; H, 4.34; N, 6.70.

Nearly identical yields of 6-phenylthieno[2,3-b]pyridine (XII) were obtained when the low melting by-product or the crude reaction product from the acetophenone condensation were reduced and cyclized under the above conditions.

Fusion of 6-phenylthieno[2,3-b]pyridine (XII) with an equal weight of picric acid gave the picrate, m.p. 149–150° after recrystallization from 95% ethanol.

Anal. Calcd. for $C_{13}H_9NS \cdot C_6H_3N_3O_7$: N, 12.72. Found: N, 12.78.

β-(3-Thienyl)-acrylic Acid (XIV) and Ethyl Ester (XV).—3-Thenaldehyde[16] (XIII) (11.2 g., 0.1 mole) was condensed with 20.4 g. (0.2 of mole) of malonic acid as described by King and Nord[17] for the preparation of β-(2-thienyl)-acrylic acid. The crude solid, wt. 16.0 g., m.p. 141–149°, was obtained pure in 78% yield after a single recrystallization from 30% ethanol, m.p. 153–153.5° (c). Recrystallization from petroleum solvent (b.p. 89–98°) for analysis gave β-(3-thienyl)-acrylic acid (XIV) with no change in m.p.

Anal. Calcd. for $C_7H_6O_2S$: C, 54.53; H, 3.93. Found: 54.53; H, 3.72.

By substituting ethyl hydrogen malonate for malonic acid in the above procedure and isolating the liquid ester by ether extraction, an 86% yield of ethyl β-(3-thienyl)-acrylate (XV) was obtained after distillation through a six-inch Vigreux column; b.p. 147–152° (14 mm.), $n^{20}D$ 1.5755. For analysis the ester was fractionated in a Podbielniak column,[21] b.p. 154–155° (17 mm.), $n^{20}D$ 1.5819, $n^{25}D$ 1.5796, d^{20}_4 1.163 (Schuetz and Houff[18] reported $n^{25}D$ 1.5562).

Anal. Calcd. for $C_9H_{10}O_2S$: C, 59.32; H, 5.53. Found: C, 59.33; H, 5.71.

Ethyl β-(3-thienyl)-acrylate (XV), b.p. 148° (14 mm.), $n^{25}D$ 1.5790, was obtained from the esterification of β-(3-thienyl)-acrylic acid (XIV) with absolute ethanol containing a trace of sulfuric acid.

Nitration of β-(3-Thienyl)-acrylic Acid (XIV).—Fuming nitric acid (2.1 ml., 0.05 mole, sp. gr. 1.51) was added slowly to a stirred mixture of 4.6 g. (0.03 mole) of β-(3-thienyl)-acrylic acid (XIV), 10 ml. of acetic acid and 15 ml. of acetic anhydride cooled below 5°. Stirring at 0° was continued for 1 hour after completion of the addition, then the temperature was allowed to rise slowly to 15°. The "mushy" yellow mixture was filtered, and the solid washed and dried; wt. 4.7 g., m.p. 187–197°. An additional 0.5 g., m.p. 177–195°, was obtained from the diluted filtrate. By repeated fractional crystallization from absolute ethanol in which the material was moderately soluble, 0.1 g. of β-(2-nitro-3-thienyl)-acrylic acid (VIII), m.p. 219–222° dec., was obtained. The mixed m.p. with a sample of the acid prepared from the condensation of 2-nitro-3-thenaldehyde (I) with malonic acid was not depressed. No other acid of constant melting point was obtained. The decomposition and dependence of the melting point on rate of heating added to the difficulty of separating any isomers present.

Bis-Ammonium Salts. Unsymmetric Derivatives of Substituted Pyridine Bases that Are Potent and Selective Hypotensive Agents[1]

BY ALLAN P. GRAY, WESLEY L. ARCHER, ERNEST E. SPINNER AND CHESTER J. CAVALLITO

RECEIVED FEBRUARY 4, 1957

In continuation of earlier work, a series of unsymmetric bis-quaternary salts has been prepared in which the large head is derived from a substituted pyridine (or piperidine) base. Variations in size and point of attachment of the substituent(s) have been introduced. Among the derivatives have been found compounds that are remarkably potent *and selective* hypotensive agents. Structure–activity relationships as well as certain implications of the biological findings are discussed.

Reports from these laboratories have described several series of unsymmetric bis-quaternary salts in which hypotensive and peripheral autonomic blocking activity could be independently varied.[2] A central component of action was implicated.[2,3] In our earlier reports, requirements for biological activity had been quite sharply delineated with respect to size of the small cationic head, distance between charged nitrogens, charge distribution and degree of ionization. Although the limitations as to size, shape and polarity of the large cationic head had been somewhat less clearly defined, it had been established that pyridine[2] and N-methylpiperidine[4] were too small to provide active derivatives.[5a,b]

In continuing these studies, many facets of the problem of structure–activity relationships have been explored. One approach to a more detailed examination of the structural limits imposed on the large head has been, logically enough, to determine the effects on pharmacological properties of attaching a variety of substituents at different points on a pyridine or piperidine nucleus. This has led not only to further clarification of the question but also to some remarkably potent and pharmacologically selective hypotensive agents. The present paper deals with a selected group of these unsymmetric bis-quaternary salts which are described in Tables I and II.

The route to most of the bis-ammonium salts—*i.e.*, quaternization of the appropriate pyridine (or piperidine) base with bromopropyltrimethylammonium bromide—has become more or less standard in these laboratories[2] and requires no further comment here. The preceding paper[6] describes the preparation of some indolyl- and indenyl-substituted pyridine bases, derivatives of which have been prominent in this study. IV, VII and XIII (Table I) were prepared by the base-catalyzed condensation[7] of benzaldehyde, 1-naphthaldehyde and 3-indolecarboxaldehyde (respectively) with trimethylene-1-(4-picolinium)-3-trimethylammonium dibromide (II).

4-Benzyl-1-methylpiperidine readily was obtained by the catalytic hydrogenation of 4-benzylpyridine methobromide. Hydrogenation of 4-benzylpyridine at room temperature over Adams catalyst proceeded slowly in aqueous acetic acid but provided 4-benzylpiperidine in good yield and without evidence of any concomitant saturation of the benzene ring.[8] XXIV (Table II) was prepared by alkylation of 4-benzylpiperidine with dimethylaminoethyl chloride followed by bis-quaternization of the product with methyl iodide.

Pharmacological Activity.—Of principal interest are the marked hypotensive activity of a number of these compounds and the lack of relationship between hypotensive and ganglionic blocking action. The present series confirms and extends more dramatically previously discussed hypotheses.[2] In order to facilitate comparisons, activities are expressed in potencies relative to unity for hexamethonium bromide.[9] The figures attempt to take into consideration the factors of dosage and intensity and duration of action. It is apparent that whereas ganglionic blocking action varies within a rather narrow range, there is a spread of two orders of magnitude in hypotensive activity.[10]

Inasmuch as the effects of variations in chain length and in the small head were established earlier, these factors are here kept essentially constant. In regard to the large head, the present report more clearly defines the requirement of a bulky, lipophilic, cationic moiety. This may be seen by comparing activities in the series of salts derived from: pyridine (I), N-methylpiperidine (XXIII) and picoline (II) (practically inert); 4-benzylpyridine (III) (comparable to hexamethonium); and 4-diphenylmethylpyridine (V) (more active). Although sufficient size is a minimal requirement for an effective large head, there are

[a] Most of the salts melt with decomposition. Melting points are corrected for stem exposure. [b] Either volumetric or gravimetric determination of ionic halogen. [c] Intravenously in anesthetized dogs; relative activities are primarily weighted on the basis of duration at about the same per cent. maximum fall. [d] Superior cervical ganglion in the cat; relative activities are primarily weighted on the basis of duration of about the same degree of block. [e] On this scale hexamethonium = 1. The slopes of the dose-response curves for these compounds vary; for purposes of approximation, however, the compounds are compared at doses equivalent (in potency) to 2 mg./kg. of hexamethonium bromide. [f] See Gray, *et al.*, ref. 2. [g] Monohydrate; Karl Fischer titration for water. [h] Sealed tube. [i] Dichloride salt. [j] See ref. 4.

[a] See footnotes, Table I.

quite evidently other factors (*e.g.*, shape or configuration and, possibly, flexibility) which determine the influence of this size on activity. Differences in activity between corresponding 2- and 4-substituted pyridine isomers are not consistent, and both types may be very active (X, XI, XIV, XV). However, very marked differences exist among a group of derivatives of approximately the same mass (V–IX). The greater potencies of VI, VIII and IX than of the less flexible and non-planar V should be principally related to the arrangement of bulk-contributing structures (*cf.* also XVIII and XIX). The lower activities of VII and IV, possessing planar heads with completely conjugated systems (compare VI and VII; *cf.* also the indole derivatives, XI and XIII), might be ascribable to more rapid biological destruction as well as to more diffuse distribution of the positive charge. A reasonably good example of the influence of polar structures is provided by a comparison of XI and XXI (although stability also may be a factor). These observations emphasize the difficulties in controlling individual variables in the course of structural modification (note that V and XIII can yield neutralized large heads by the loss of a proton).

That there is an upper limit on size of the large head is perhaps best demonstrated by comparison of XV[11] and XVI. Apparently XVI has a larger head than that which appears to be approximately optimum (as exemplified in XV and XII). It is of interest that the indole N-methylated derivatives XIV and XV show reduced ganglionic blocking action in comparison with X and XI, but this effect is unrelated to changes in hypotensive activity. This could be a result of elimination of the bonding capacity of the indole N–H as well as of a reduction in polarity.

Providing that the compounds have minimal

(11) This compound, bearing the laboratory designation IN 391, is the subject of extensive clinical investigations. Intravenously in the anesthetized dog, a dose of 0.025 mg./kg. lowers the blood pressure 50% for more than 1 hr.

structural features, the relative intensities of the measured responses will be influenced by the distribution of the compounds among responsive receptors and the many non-specific adsorption sites throughout the organism.[12] Several of the present compounds have been observed to be more active in barbiturate anesthetized than in unanesthetized dogs. Since these are relatively lipophilic substances, the potentiation by anesthetics could well be the result of competition at sites of loss.[13]

The broad class of short chain, unsymmetric diquaternary salts include compounds of much greater hypotensive activity than the early C_{5-6} symmetric bis-onium types. If we assume that the compounds of both groups act as specific acetylcholine antagonists, hypotheses of spatial relationships of receptor structures formulated on the basis of the earlier blocking agents will require reconsideration. The active C_{5-6} compounds can assume configurations in which the two onium groups are separated by distances equivalent to those in the C_{2-3} unsymmetric analogs. This would make possible bonding at two adjacent anionic sites or, quite possibly, ion pair formation of the bis-onium moiety with a single anionic function in the low dielectric region of the receptor surface.[14] The non-ionic portion of the diquaternary salt would influence the relative distribution of the compound among adsorption sites and also the stability of the cation–receptor complex.

Experimental[15]

Preparation of Intermediates.—Indolyl- and indenyl-substituted pyridine bases are described in an accompanying paper[6]; the method used for the preparation of 3-bromopropyltrimethylammonium bromide has appeared earlier.[16] 2-(1-Naphthylethyl)-pyridine, hydrochloride salt, m.p. 174.5–175.5°, was obtained by the alkylation of α-picoline with 1-chloromethylnaphthalene using sodamide in liquid ammonia.[17] 4-Diphenylmethylpyridine was supplied by the Reilly Tar and Chemical Corp.

4-Phthalimidoethylpyridine.—This compound was prepared in a manner similar to that described for the 2-isomer.[18] A mixture of 14.7 g. (0.1 mole) of phthalimide, 15.9 g. (0.15 mole) of freshly distilled 4-vinylpyridine and 1 ml. of piperidine was refluxed for 5 hr. at an oil-bath temperature of 190–200°. The cooled, solid reaction mixture was dissolved in 10% hydrochloric acid. The acid solution was filtered, made alkaline and the resultant tan precipitate recrystallized from aqueous isopropyl alcohol to yield 16.5 g. of light tan needles, m.p. 157–158°.[19]

Anal. Calcd. for $C_{15}H_{12}N_2O_2$: C, 71.41; H, 4.80; N (basic), 5.55. Found: C, 71.68; H, 4.79; N (basic), 5.71.

The hydrochloride melted at 220° dec. *Anal.* Calcd. for $C_{15}H_{13}ClN_2O_2$: C, 62.39; H, 4.54; Cl, 12.28. Found: C, 62.81; H, 4.70; Cl, 12.27.

The methobromide, prepared in ethanol and recrystallized from ethanol–ether, showed m.p. 204.5–205.5° dec. *Anal.* Calcd. for $C_{16}H_{15}BrN_2O_2$: C, 55.34; H, 4.35. Found: C, 55.38; H, 4.25.

4-Benzyl-1-methylpiperidine.—4-Benzylpyridine was converted to its methobromide salt, m.p. 84–87°. A solution of 15 g. of the recrystallized salt in 100 ml. of methanol was hydrogenated over 0.5 g. of Adams platinum oxide at 40 p.s.i. and room temperature. The reduction was complete in about 20 minutes. After removal of the solvent *in vacuo*, the residue was distilled to yield 7.2 g. (66%) of 4-benzyl-1-methylpiperidine, b.p. 100–103° (3.5 mm.), $n^{25}D$ 1.5189[20]; picrate, m.p. 185–186°, after recrystallization from ethanol.

Anal. Calcd. for $C_{13}H_{19}N$: N, 7.40. Found: N (basic), 7.34.

4-Benzylpiperidine.—A solution of 51.0 g. (0.3 mole) of 4-benzylpyridine in a mixture of 100 ml. of purified glacial acetic acid and 50 ml. of water was hydrogenated over 1.0 g. of Adams catalyst at room temperature and 50 p.s.i. Hydrogen absorption was complete in 72 hr. The filtered solution was concentrated *in vacuo*, the residue was treated with excess 20% sodium hydroxide and extracted with ether. After washing with water and drying, the organic layer was distilled to yield 44.5 g. (85%) of 4-benzylpiperidine, b.p. 90–92° (0.6 mm.), $n^{25}D$ 1.5357; picrate, m.p. 192–193° dec.[21]

Anal. Calcd. for $C_{12}H_{17}N$: N, 7.99. Found: N (basic), 7.96.

1-Dimethylaminoethyl-4-benzylpiperidine.—A stirred mixture of 28.0 g. (0.16 mole) of 4-benzylpiperidine, 34.6 g. (0.24 mole) of dimethylaminoethyl chloride hydrochloride and 50 g. of anhydrous, powdered sodium carbonate in 200 ml. of 1-butanol was refluxed (oil-bath) for 24 hr. The cooled, filtered solution was concentrated *in vacuo* and the residue was extracted with ether. Drying and removal of the ether and distillation of the residual oil afforded 12.3 g. (31% yield) of the product, b.p. 135–140° (0.5 mm.), $n^{24}D$ 1.5167.

Anal. Calcd. for $C_{16}H_{26}N_2$: N, 11.37. Found: N (basic), 11.22.

The dihydrochloride XXV, recrystallized from wet methanol, melted above 270°.

The dimethiodide XXIV, prepared in ethanol and recrystallized from methanol–ethyl acetate, showed m.p. 225–226° dec.

Preparation of Bis-salts by Quaternization with 3-Halopropyltrimethylammonium Halides. A. Trimethylene-1-(4-picolinium)-3-(trimethylammonium) Dibromide (II).—An ethanol solution of 9.3 g. (0.1 mole) of γ-picoline and 26.1 g. (0.1 mole) of 3-bromopropyltrimethylammonium bromide was refluxed on the steam-bath for 15 hr. The crystalline precipitate that formed upon refrigeration of the solution was recrystallized from ethanol to yield 21.8 g. (62%) of colorless crystals of II, m.p. 244–245° with gas evolution.

B. Trimethylene-1-[2-(3-indolylethyl)-pyridinium]-3-(trimethylammonium) Dibromide (X).—To 130.5 g. (0.5 mole) of 3-bromopropyltrimethylammonium bromide dissolved in 600 ml. of acetonitrile was added 111 g. (0.5 mole) of 2-(3-indolylethyl)-pyridine, and the solution was refluxed for 30 hr. The precipitate was recrystallized from ethanol to yield 120 g. (63%) of pale yellow crystals of X, m.p. 201–203°.

C. Trimethylene-1-[4-(1-methyl-3-indolylethyl)-pyridinium]-3-(trimethylammonium) Dibromide (XV).—A solution of 1420 g. (6 moles) of 4-(1-methyl-3-indolylethyl)-pyridine and 1570 g. (6 moles) of 3-bromopropyltrimethylammonium bromide in 4.5 liters of acetonitrile was refluxed, with stirring, for 18 hr. Recrystallization of the resultant precipitate from isopropyl alcohol afforded a yield of 2390

(12) In a recent review, Veldstra, *Pharmacol. Rev.*, **8**, 339 (1956), refers to these as "sites of loss."

(13) A similar relationship recently has been demonstrated with another type of acetylcholine blocking agent (C. J. Cavallito, J. G. Arrowood and T. B. O'Dell, *Anesthesiology*, **17**, 547 (1956)).

(14) See O. V. Brody and R. M. Fuoss, *J. Phys. Chem.*, **60**, 156 (1956), and earlier papers of Fuoss, *et al.*, for physical chemical evidence of this type of association; S. A. Rice, THIS JOURNAL, **78**, 5247 (1956); *cf.* F. Bergmann and R. Segal, *Biochem. J.*, **58**, 692 (1954).

g. (79%) of XV as hygroscopic, light tan crystals, m.p. 133° dec.

D. Dichloride Salt of XV (XVa).—A solution of 600 g. of XV in 12 liters of distilled water was passed through a column of Amberlite anion exchange resin, IRA 401 (regenerated with aqueous sodium chloride), and the column was washed with fresh water. The eluate was concentrated *in vacuo* and the residue was crystallized from ethanol–acetone to yield 425 g. (86%) of the dichloride salt, XVa, m.p. 195° dec.

Two alternative routes to XVa have been found quite satisfactory: 1. A solution of 4-(1-methyl-3-indolylethyl)-pyridine and 3-chloropropyltrimethylammonium bromide[22] in dimethylformamide was heated at 120–125° (oil-bath temperature) for 24 hr. and the crude mixed halide product passed through a column of Amberlite IRA 401. 2. A dimethylformamide solution of the pyridine base and 3-chloropropyltrimethylammonium chloride[23] was heated at 120° (oil-bath) for 24 hours, thus directly affording a 55% yield of XVa.

Condensation of II with Aldehydes. A. Benzaldehyde. The Preparation of IV.—To a solution of 6.3 g. (0.018 mole) of II and 3.8 g. (0.036 mole) of freshly distilled benzaldehyde in 50 ml. of methanol was added 1 ml. of piperidine. After 4 hr. reflux on the steam-bath, the deep purple solution was cooled, diluted with ether and the purple precipitate was recrystallized from ethanol to provide 4.3 g. (54% yield) of IV, melting with decomposition and gas evolution at 150°.

B. 1-Naphthaldehyde. The Preparation of VII.—Refluxing a solution of 4.4 g. (0.028 mole) of 1-naphthaldehyde and 10 g. (0.028 mole) of II in 50 ml. of ethanol containing 1 ml. of piperidine for 3 hr., diluting with ether and crystallizing the resultant purple, oily precipitate from ethanol–ether yielded 9.6 g. (69%) of VII, m.p. 178° dec.

C. 3-Indolecarboxaldehyde. The Preparation of XIII.—In similar fashion, 3-indolecarboxaldehyde[24] was condensed with II to yield, after recrystallization from methanol–ethyl acetate, 56% of bright orange crystals of XIII, melting with decomposition and gas evolution at 275°.

Acknowledgments.—The authors wish to thank Mrs. Dorothy Schlieper for assistance with some of the synthetic work and Mr. Dean F. Cortright for the ionic halogen and basic nitrogen determinations.

(22) This salt was prepared from trimethylene chlorobromide and trimethylamine, m.p. 204–206°.

(23) Prepared from 3-chloropropyltrimethylammonium bromide by passage over the anion exchange resin, m.p. 202° dec.

(24) Prepared as described by F. T. Tyson and J. T. Shaw, THIS JOURNAL, **74**, 2273 (1952), from indole and dimethylformamide with phosphorus oxychloride.

Quinone Imides. XLIV. The Orientation of Groups in Addition Reactions to Substituted p-Quinonedibenzimides

BY ROGER ADAMS AND HARRY J. NEUMILLER, JR.[1]

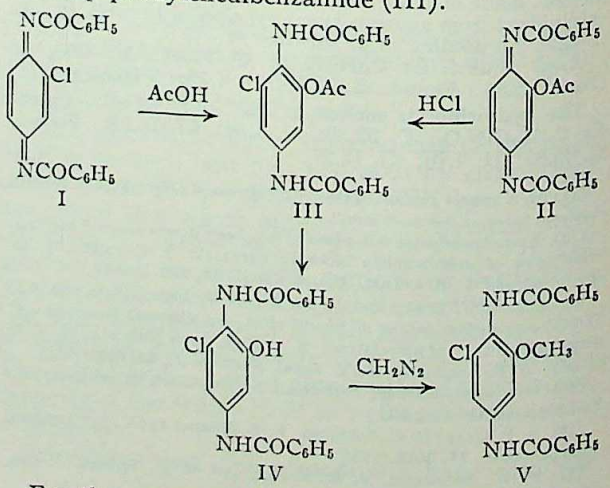
RECEIVED FEBRUARY 1, 1957

The acetoxychloro-*p*-phenylenedibenzamide isomer, which results both from the addition of acetic acid to 2-chloro-*p*-quinonedibenzimide and from the addition of hydrogen chloride to 2-acetoxy-*p*-quinonedibenzimide, has been identified as 2-acetoxy-6-chloro-*p*-phenylenedibenzamide. The oxidation of 2-methoxy-*p*-phenylenedibenzamide with lead tetraacetate affords 2-methoxy-*p*-quinonedibenzimide which adds hydrogen chloride to give a mixture of 2-chloro-5-methoxy- and 2-chloro-6-methoxy-*p*-phenylenedibenzamides, both identified by unequivocal syntheses.

In a recent paper[2] the orientation of groups in the adducts of 2-substituted *p*-quinonedibenzenesulfonimides and 2-substituted *p*-quinonedibenzimides was summarized. 2-Chloro-*p*-quinonedibenzenesulfonimide adds hydrogen chloride to afford a mixture of 2,3- and 2,5-dichloro-*p*-phenylenedibenzenesulfonamides. The addition of hydrogen chloride and a number of other reagents to 2-methoxy-*p*-quinonedibenzenesulfonimide results in substituted *p*-phenylenedibenzenesulfonamides having exclusively the 2,5-orientation.

In contrast to the foregoing, the addition of hydrogen chloride to 2-chloro-*p*-quinonedibenzimide (I) affords 2,6-dichloro-*p*-phenylenedibenzamide; the addition to 2-methyl-*p*-quinonedibenzimide yields exclusively 6-chloro-2-methyl-*p*-phenylenedibenzamide. The 2-phenylmercapto analog gives 3-chloro-2-phenylmercapto-*p*-phenylenedibenzamide and the 2-benzenesulfonyl derivative gives a mixture of 2-benzenesulfonyl-3-chloro- and 2-benzenesulfonyl-6-chloro-*p*-phenylenedibenzamides.

Previous investigators demonstrated that both the addition of acetic acid to 2-chloro-*p*-quinonedibenzimide (I) and the addition of hydrogen chloride to 2-acetoxy-*p*-quinonedibenzimide (II) yielded the same acetoxy-chloro-*p*-phenylenedibenzamide isomer as the sole product of each reaction.[3] The product has now been identified as 2-acetoxy-6-chloro-*p*-phenylenedibenzamide (III).



For the purpose of its identification, III was hydrolyzed with dilute aqueous sodium hydroxide to

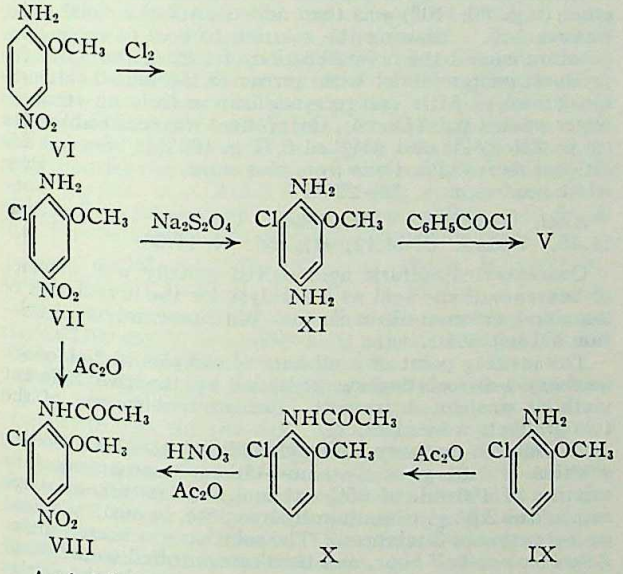
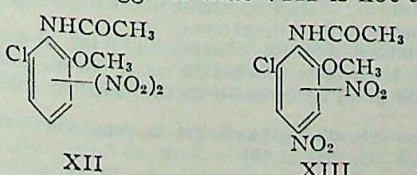
2-chloro-6-hydroxy-*p*-phenylenedibenzamide (IV), and this was methylated with diazomethane to give 2-chloro-6-methoxy-*p*-phenylenedibenzamide (V). The unequivocal synthesis of V was then accomplished through the following steps. 2-Amino-5-nitroanisole (VI) was chlorinated to 2-amino-3-chloro-5-nitroanisole (VII). The position of the chlorine atom in this compound was established by its acetylation to afford 2-chloro-6-methoxy-4-nitroacetanilide (VIII); the same compound resulted from a sequence involving acetylation of 2-amino-3-chloroanisole (IX) to 2-chloro-6-methoxyacetanilide (X) followed by nitration to VIII. Compound VIII is the only possible common product of these two reaction sequences. By reduction with sodium hydrosulfite, VII was converted to 2-chloro-6-methoxy-*p*-phenylenediamine (XI), which was then benzoylated to the desired 2-chloro-6-methoxy-*p*-phenylenedibenzamide (V). Through comparison of infrared spectra and melting points, the compound prepared in this manner was shown to be identical with the sample of V obtained from 2-chloro-*p*-quinonedibenzimide (I).

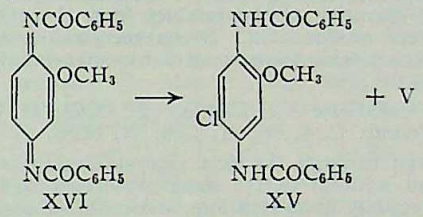


An initial attempt was made to prepare V through 2′-chloro-6′-methoxy-4′-nitrobenzanilide, the benzoyl derivative of VII. Benzoylation of VII was difficult and was achieved only by a long period of refluxing with benzoyl chloride in pyridine and subsequent separation of the benzoyl derivative from unreacted amine by chromatography.

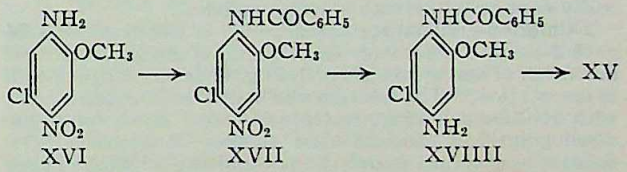
While studying the conditions under which X could best be mononitrated to VIII, it was found that 2-chloro-6-methoxyacetanilide (X) was dinitrated (XII) by means of a mixture of cold concentrated sulfuric and nitric acids. When 2-chloro-6-methoxy-4-nitroacetanilide (VIII), prepared from 2-amino-3-chloro-5-nitroanisole, was nitrated in a similar fashion a different dinitro compound XIII resulted. This suggests that VIII is not an intermediate in the formation of the dinitro derivative of X.



2-Methoxy-*p*-quinonedibenzimide (XIV) could not be isolated in a crystalline state, but treatment of the solution in which it was prepared with hydrogen chloride resulted in a mixture of chloromethoxy-*p*-phenylenedibenzamide isomers. The mixture was cleanly separated by chromatography on a column of aluminum oxide into 2-chloro-5-methoxy-*p*-phenylenedibenzamide (XV) and 2-chloro-6-methoxy-*p*-phenylenedibenzamide (V). The unequivocal synthesis of the latter of these two



isomers already has been described. The former was synthesized through the following sequence: 2-Amino-4-chloro-5-nitroanisole (XVI) was benzoylated to 5′-chloro-2′-methoxy-4′-nitrobenzanilide (XVII), reduced to 4′-amino-5′-chloro-2′-methoxybenzanilide (XVIII) and benzoylated to XV.



Acknowledgment.—The authors are indebted to Mr. Joseph Nemeth, Mrs. Lucy Chang, Mrs. Esther Fett and to Mr. R. Maria Benassi for the microanalyses, and to Mr. James Brader, Mrs. Louise Griffing and Miss Helen Miklas for the determination and interpretation of the infrared spectra.

Experimental

All melting points are corrected. The infrared spectra were run in Nujol mulls, using a Perkin–Elmer model 21 double beam spectrophotometer.

2-Acetoxy-6-chloro-*p*-phenylenedibenzamide.—A solution of 0.52 g. of 2-chloro-*p*-benzoquinonedibenzimide[4] in 10 ml. of glacial acetic acid was prepared by gentle warming. The red solution was allowed to stand at room temperature for 14 hours. The addition of 20 ml. of petroleum ether (b.p. 80–110°) did not cause the precipitation of the product, as previously reported,[3] and most of the petroleum ether was retained as an upper layer. As much as possible of the petroleum ether was therefore removed *in vacuo*, and 25 ml. of water was added, causing the precipitation of the very crude product. After one recrystallization from benzene (Darco) it weighed 0.24 g. (39%). Two more recrystallizations from benzene (Darco) afforded small white lustrous crystals, m.p. 179.5–181° dec. (lit.[3] m.p. 181–182°).

2-Chloro-6-hydroxy-*p*-phenylenedibenzamide.—A suspension of 0.08 g. of 2-acetoxy-6-chloro-*p*-phenylenedibenzamide in 25 ml. of 5% aqueous sodium hydroxide was allowed to stand at room temperature for 7.5 hours. The solid went slowly into solution during the course of this period. The mixture was filtered, and the filtrate was made acidic to congo red with concentrated hydrochloric acid, causing the precipitation of the very crude product. After one recrystallization from an ethyl acetate–petroleum ether (b.p. 80–110°) solvent pair, it weighed 0.03 g. (43%). Further recrystallization from the same solvent pair (Darco) gave white needles, m.p. 240–243° (lit.[3] m.p. 246–246.5°).

2-Amino-3-chloro-5-nitroanisole.—Into a stirred suspension of 8.40 g. of 2-amino-5-nitroanisole in 200 ml. of concentrated hydrochloric acid and 100 ml. of glacial acetic acid, maintained at a temperature of 5–15°, was passed a stream of chlorine gas (dried by passage through concentrated sulfuric acid) at a moderate rate until the increase in the weight of the mixture was 5.8 g. (45 minutes). The mixture was filtered through a sintered-glass funnel and the precipitate was stirred with 200 ml. of 10% aqueous sodium bisulfite for *ca.* 20 minutes. The product was then collected by suction filtration, washed with water, and recrystallized once from 95% ethanol, after which it weighed 3.76 g. Concentration of the ethanolic mother liquors afforded an additional 1.42 g. of the product, and thus the total crude yield was 5.18 g. (51%). Attempts to obtain an additional quantity of the product from the chlorination liquors were unsuccessful. Seven recrystallizations from carbon tetrachloride gave small flat orange-yellow prisms, m.p. 122–124°.

Anal. Calcd. for $C_7H_7ClN_2O_3$: C, 41.49; H, 3.48; N, 13.83. Found: C, 41.66; H, 3.28; N, 13.86.

The steps through the first recrystallization should be carried out without delay, since unrecrystallized product darkened rapidly upon standing, and could subsequently be purified only with great loss. In runs in which concentrated hydrochloric acid was used as the solvent for chlorination a very impure grade of product was obtained. The use of dimethylformamide resulted in the formation of an uncrystallizable tarry product. When glacial acetic acid, or a hydrochloric acid–glacial acetic mixture containing a relatively large proportion of the latter substance, was used as the solvent the chlorination was incomplete, and the product was badly contaminated with starting material.

2-Chloro-6-methoxyacetanilide.—To a solution of 1.58 g. of 2-amino-3-chloroanisole[5] in 10 ml. of glacial acetic acid and 3 ml. of water was added 1.23 g. of acetic anhydride all in one portion. The solution was boiled for 10 minutes and, with continued boiling, water was added slowly until the cloud point was attained after another 40 minutes. The solution was cooled under the tap and the oil which began to form was scratched with a glass rod to initiate crystallization. After the resulting mixture had cooled to room temperature, filtration gave 1.64 g. of crystalline product, m.p. 145–146.5° with sintering at 144°. By concentration of the filtrate and further addition of water an additional 0.06 g. of the product was obtained and thus the total yield was 1.70 g. (85%). Three recrystallizations from water followed by two recrystallizations from a benzene–petroleum ether solvent pair afforded small lustrous white prisms, m.p. 145.5–147°, with sintering at 144.5°.

Anal. Calcd. for $C_9H_{10}ClNO_2$: C, 54.15; H, 5.05; N, 7.02. Found: C, 54.19; H, 5.09; N, 6.70.

This compound was reported by Meldola and Eyre[6] as melting at 147–148°, with softening between 115 and 125°, and by Hodgson and Kershaw[5] as melting at 123°. Furthermore, the latter investigators reported that 2-chloro-N,N-diacetyl-6-methoxyaniline melted at 145.5°. The infrared spectrum of the compound prepared by the method described above showed N–H stretching absorption at 3195 cm.$^{-1}$, and a single amide C=O band at 1664 cm.$^{-1}$. These data, together with the composition of the compound, leave no doubt that it is the desired monoacetyl derivative of 2-chloro-6-methoxyaniline. In one attempt to monoacetylate 2-chloro-6-methoxyaniline, the amine was heated with acetic anhydride on the steam-bath for 1.5 hours, in accordance with the procedure described by Hodgson and Kershaw[5] for the preparation of the monoacetyl derivative. After the subsequent addition of water to decompose the acetic anhydride, the precipitate, m.p. *ca.* 100–123°, was repeatedly recrystallized from petroleum ether (b.p. 80–110°), water, and petroleum ether again, giving small white plates, m.p. 123–125°, in very low yield. This material was apparently the diacetyl derivative of the amine, since a mixture of it and the previously described monoacetyl derivative melted at 107–111°. Thus, the melting points as reported by Hodgson and Kershaw[5] for the monoacetyl derivative and the diacetyl derivative should be reversed. The compound reported by Meldola and Eyre[6] was undoubtedly the monoacetyl derivative.

(5) H. H. Hodgson and A. Kershaw, *J. Chem. Soc.*, 191 (1928).
(6) R. Meldola and J. V. Eyre, *ibid.*, **81**, 988 (1902).

2-Chloro-6-methoxy-4-nitroacetanilide. Method A.—A suspension of 0.33 g. of 2-chloro-6-methoxyacetanilide in 3.0 ml. of acetic anhydride was cooled to −10° by the direct addition of Dry Ice. While maintaining the temperature below 0°, a cooled solution of 0.12 g. of fuming nitric acid (sp. gr. 1.5) in 1.0 ml. of acetic anhydride was added, with constant agitation, over a period of 5 minutes. Agitation was continued for a period of 20 minutes during which the temperature was permitted to rise rapidly to 10° and was then held at 10–15°. All of the suspended solid went into solution during the period in which the temperature was rising. The solution was poured into 10 ml. of water and the resulting mixture was shaken until all of the acetic anhydride had decomposed. After allowing the mixture to stand overnight, 0.09 g. (22%) of the crystalline product was obtained by filtration. Dilution of the filtrate with water and subsequent concentration did not afford more product. The product was recrystallized three times from an ethanol–water solvent pair (Darco), giving white needles, m.p. 223.5–225°.

Anal. Calcd. for $C_9H_9ClN_2O_4$: C, 44.19; H, 3.71; N, 11.45. Found: C, 44.17; H, 3.45; N, 11.47.

Method B.—To a boiling solution of 1.01 g. of 2-amino-3-chloro-5-nitroanisole in 75 ml. of dry benzene was added a solution of 0.61 g. of acetic anhydride in 5 ml. of dry benzene, followed by several mg. of benzenesulfonic acid. The solution was allowed to continue to boil and evaporate until the volume had been reduced to *ca.* 20 ml. Petroleum ether (b.p. 80–110°) was then added until the cloud point was reached. Allowing the solution to cool to room temperature caused the crystallization of 1.02 g. (84%) of the product, contaminated with unreacted 2-amino-3-chloro-5-nitroanisole. After one recrystallization from an ethanol–water solvent pair (Darco), the product was reasonably pure (m.p. 221–224°) and weighed 0.77 g. (63%). Several additional recrystallizations from this same solvent pair gave white needles, m.p. 224–226°.

Anal. Calcd. for $C_9H_9ClN_2O_4$: C, 44.19; H, 3.71; N, 11.45. Found: C, 44.12; H, 3.54; N, 11.66.

Concentrated sulfuric acid served equally well in place of benzenesulfonic acid as a catalyst for the acetylation of 2-amino-3-chloro-5-nitroanisole. With no catalyst acetylation did not occur.

The melting point of a mixture of samples of 2-chloro-6-methoxy-4-nitroacetanilide prepared by the two different methods was not depressed. The infrared spectra of the two products were identical.

2-Chloro-6-methoxy-*p*-phenylenediamine.—To a boiling solution of 1.01 g. of 2-amino-3-chloro-5-nitroanisole in a mixture of 100 ml. of 95% ethanol and 100 ml. of water was added 2.65 g. of sodium hydrosulfite, in small portions over a period of 3 minutes. The solution was heated under reflux for one-half hour, and then concentrated to the cloud point on the hot-plate. Subsequent storage in the refrigerator at 0–5° for 3 hours caused the crystallization of 0.53 g. (62%) of the diamine. One recrystallization from a benzene–petroleum ether (b.p. 80–110°) solvent pair gave medium brown needles, m.p. 97–99.5° dec. The product deteriorated upon standing, and it was used in the following experiment without further characterization.

2-Chloro-6-methoxy-*p*-phenylenedibenzamide. Method A.—A solution of 0.28 g. of 2-chloro-6-methoxy-*p*-phenylenediamine and 0.56 g. of benzoyl chloride in 20 ml. of pyridine was heated under reflux for 2 hours. After cooling to room temperature it was poured into 200 ml. of 10% hydrochloric acid containing 75 g. of ice, causing the precipitation of 0.45 g. (74%) of light gray solid. Four recrystallizations from benzene (Darco) gave the pure compound; white needles, m.p. 224–225.5°.

Anal. Calcd. for $C_{21}H_{17}ClN_2O_3$: C, 66.23; H, 4.50; N, 7.36. Found: C, 66.15; H, 4.43; N, 7.36.

Method B.—The method used for the preparation of the ethereal solution of diazomethane in the following experiment was the one described in reference 7.

To a mixture of 30 ml. of ether and 9 ml. of 40% aqueous potassium hydroxide, cooled to *ca.* 5° in an ice-bath, was added 3.00 g. of α-nitroso-α-methylurea[8] in small portions

over a period of 3 minutes. The ether layer was decanted from the mixture and slowly added, with constant swirling, to a suspension of 0.15 g. of 2-chloro-6-hydroxy-*p*-phenylenedibenzamide in 15 ml. of methanol, cooled to *ca.* 5° in an ice-bath. Slight effervesence occurred, and the diamide went into solution. The solution was allowed to stand in the ice-bath for one-half hour, and 25 ml. of glacial acetic acid was then added to destroy excess diazomethane. The solvents were removed by means of a current of dry air, and the resulting residue was dissolved in 50 ml. of hot acetone. The hot solution was treated with Darco and filtered, and 0.07 g. (45%) of crystalline product was precipitated from the filtrate by the addition of water. Four recrystallizations from benzene gave white needles, m.p. 224–225.5°.

Anal. Calcd. for $C_{21}H_{17}ClN_2O_3$: C, 66.23; H, 4.50; N, 7.36. Found: C, 66.35; H, 4.78; N, 7.46.

The melting point of a mixture of samples of 2-chloro-6-methoxy-*p*-phenylenedibenzamide prepared by the two different methods was not depressed. The infrared spectra of the two products were identical.

2-Chloro-x,y-dinitro-6-methoxyacetanilide.—A solution of 0.28 g. of 2-chloro-6-methoxyacetanilide in 1.00 ml. of concentrated sulfuric acid was prepared by the slow addition of the solid to the acid. The solution was agitated and maintained at a temperature of 12–18°, and a solution of 0.18 g. of concentrated nitric acid (sp. gr. 1.42) in 0.25 ml. of concentrated sulfuric acid was added over a period of 5 minutes. The mixture was agitated at 12–15° for an additional 30 minutes, and was then allowed to stand at room temperature for 40 minutes. The mixture was poured onto 10 g. of ice, causing the precipitation of a yellow solid which was washed with water, 60 ml. of 5% aqueous sodium carbonate, and then with water again. It weighed 0.24 g. and melted at *ca.* 150–190° dec. Repeated fractional crystallization of this material from 95% ethanol gave 0.07 g. (24%, based on the amount of nitric acid employed) of white needles, m.p. 215.5–216.5° with simultaneous bubbling. For analysis, the compound was sublimed at 1.5–1.8 mm. pressure, which did not alter the melting point.

Anal. Calcd. for $C_9H_8ClN_3O_6$: C, 37.33; H, 2.78; N, 14.51. Found: C, 37.51; H, 3.07; N, 14.31.

The infrared spectrum showed N–H stretching absorption at 3190 cm.$^{-1}$, an amide C=O band at 1683 cm.$^{-1}$, and $-NO_2$ bands at 1537 cm.$^{-1}$ and 1350 cm.$^{-1}$.

2-Chloro-4,z-dinitro-6-methoxyacetanilide.—A solution of 0.49 g. of 2-chloro-6-methoxy-4-nitroacetanilide in 1.50 ml. of concentrated sulfuric acid was prepared by adding the solid to the acid over a period of 4 minutes. The solution was agitated and maintained at a temperature of 10–13°, and a solution of 0.23 g. of concentrated nitric acid (sp. gr. 1.42) in 0.30 ml. of concentrated sulfuric acid was added over a period of 4 minutes. The mixture was agitated at 10–16° for an additional 25 minutes, and was then allowed to stand at room temperature for 55 minutes. The mixture was poured onto 10 g. of ice, causing the precipitation of the product. Sufficient water was added to bring the volume to 25 ml., and the precipitate was collected by filtration and washed with water. After one recrystallization from an ethanol–water solvent pair it weighed 0.27 g. (47%). Five more recrystallizations from this same solvent pair (Darco) afforded white needles. The substance behaved in a peculiar fashion in the melting point determination: A sample inserted into the melting-point bath at room temperature melted at 221–223°, with slight decomposition, after previously softening at 213.5°, while a sample inserted at 217° immediately melted completely, with frothing and moderate decomposition. It is possible that the compound was contaminated to some extent with an isomer.

Anal. Calcd. for $C_9H_8ClN_3O_6$: C, 37.33; H, 2.78; N, 14.51. Found: C, 37.43; H, 2.83; N, 14.29.

The infrared spectrum had an amide C=O band at 1674 cm.$^{-1}$. The N–H stretching region contained two bands of only medium intensity, one at 3140 cm.$^{-1}$ and the other at 3060 cm.$^{-1}$.

A mixture of the 2-chloro-4,z-dinitro-6-methoxyacetanilide and the 2-chloro-x,y-dinitro-6-methoxyacetanilide described in the immediately preceding experiments melted at 180–195°.

2′-Chloro-6′-methoxy-4′-nitrobenzanilide.—A solution of 1.01 g. of 2-amino-3-chloro-5-nitroanisole and 0.84 g. of benzoyl chloride in 20 ml. of pyridine was heated under reflux for 21 hours. The bright red solution was allowed to cool to room temperature and then poured into 200 ml. of 10% hydrochloric acid containing 75 g. of ice, causing the precipitation of an orange-brown gum. After having been washed with water, the gum was dissolved in 150 ml. of carbon tetrachloride, and the solution was passed through a 1.7 × 32.8 cm. column of aluminum oxide (Merck, Reagent Grade). The column was eluted with *ca.* 275 ml. of chloroform. The eluate was collected in 25-ml. fractions, and each fraction was evaporated to dryness. Fractions 1–6 contained nothing, fraction 7 contained 0.05 g. of impure 2-amino-3-chloro-5-nitroanisole, fraction 8 contained 0.16 g. of the same substance, fairly pure, fraction 9 contained 0.07 g. of a mixture of 2-amino-3-chloro-5-nitroanisole and the product, and fractions 10–16 contained 0.68 g. of the product desired. Further elution afforded only colored amorphous material. The yield of the product, based on fractions 10–16, and corrected for reusable starting material recovered (fraction 8), was 53%. Several recrystallizations from carbon tetrachloride gave small white needles, m.p. 176.5–178°.

Anal. Calcd. for $C_{14}H_{11}ClN_2O_4$: C, 54.82; H, 3.62; N, 9.14. Found: C, 54.95; H, 3.47; N, 9.42.

A complete separation of the product from the unreacted starting material was obtained by using a mixture of equal parts by volume of carbon tetrachloride and chloroform as an initial elutant in the chromatogram. The process was considerably slower than the one described above, and the given procedure is more convenient from a preparative standpoint.

Reaction of 2-Methoxy-*p*-quinonedibenzimide with Hydrogen Chloride: 2-Chloro-5-methoxy-*p*-phenylenedibenzamide (Method A) and 2-Chloro-6-methoxy-*p*-phenylenedibenzamide (Method C).—A suspension of 0.87 g. of 2-methoxy-*p*-phenylenedibenzamide[9] and 1.14 g. of lead tetraacetate in 50 ml. of dry, thiophene-free benzene was stirred and heated under gentle reflux for 50 minutes. The mixture was allowed to cool to room temperature and filtered to remove the insoluble material, and 100 ml. of petroleum ether (b.p. 80–110°) was added to the orange-yellow filtrate.[10] Hydrogen chloride gas was passed into the solution at a moderate rate for 10 minutes, causing rapid bleaching of the color to light greenish-yellow and the concomitant formation of a precipitate. The solvents were removed *in vacuo* and the resulting residue was dissolved in a mixture of 300 ml. of carbon tetrachloride and 150 ml. of chloroform. This solution was passed through a 1.7 × 35.5 cm. column of aluminum oxide (Merck, Reagent Grade). The eluate was collected in 50-ml. fractions. The first 8.5 fractions resulted from the addition of the original solution; during the collection of the succeeding 16.5 fractions, 2:1 by volume carbon tetrachloride and chloroform was used as the elutant; and during the collection of the remaining fractions, chloroform was used as the elutant. The rate of elution ranged from 4.5 ml. per minute to 6.3 ml. per minute. The fractions were evaporated to dryness, and the following results were observed: Fractions 1–9 contained nothing, fractions 10–13 contained 2-chloro-5-methoxy-*p*-phenylenedibenzamide, fractions 14–19 contained unidentified traces of residues which melted over large ranges, fraction 20 contained nothing, fraction 21 contained a trace of residue which melted over a large range, fractions 22–27 contained 2-chloro-6-methoxy-*p*-phenylenedibenzamide, and fractions 28 and 29 contained only faint traces of residue.

The residues from fractions 10–13 were combined and recrystallized once from benzene (Darco), giving 0.22 g. (23%) of small lustrous white prisms, m.p. 225.5–226.5°. Two more recrystallizations from benzene did not alter the melting point.

Anal. Calcd. for $C_{21}H_{17}ClN_2O_3$: C, 66.23; H, 4.50; N, 7.36. Found: C, 66.46; H, 4.51; N, 7.11.

The melting point of a mixture of this product and the authentic 2-chloro-5-methoxy-*p*-phenylenedibenzamide, to be described, was not depressed. The infrared spectra of the two samples were identical.

(9) R. Adams and D. S. Acker, THIS JOURNAL, **74**, 5872 (1952).

(10) If the mixture was now cooled in a Dry Ice–methanol-bath, a yellow crystalline solid separated which became a brownish-orange viscous oil upon warming to room temperature after removing the solvent. The diimide turned darker on standing and was not obtained in a pure crystalline form.

Digitized by Arya Samaj Foundation Chennai and eGangotri

The residues from fractions 22–27 were combined and recrystallized once from benzene (Darco), affording 0.22 g. (23%) of crystalline product, m.p. 225–226°, with slight sintering at 223°. Two more recrystallizations from benzene gave white needles of 2-chloro-6-methoxy-*p*-phenylenedibenzamide, m.p. 225–226.5°.

Anal. Calcd. for $C_{21}H_{17}ClN_2O_3$: C, 66.23; H, 4.50; N, 7.36. Found: C, 66.24; H, 4.51; N, 7.23.

The melting point of a mixture of this product and the previously described authentic 2-chloro-6-methoxy-*p*-phenylenedibenzamide was not depressed. The infrared spectra of the two samples were identical.

The total yield of chloro-methoxy-*p*-phenylenedibenzamide isomers from the addition of hydrogen chloride to 2-methoxy-*p*-quinonedibenzimide was thus 0.44 g. (46%), based on the quantity of 2-methoxy-*p*-phenylenedibenzamide employed.

Although the two isomers melted at essentially the same point, the melting point of a mixture was depressed. The infrared spectra of the compound were different. The 2,5-isomer was more soluble in benzene than the 2,6-isomer.

5′-Chloro-2′-methoxy-4′-nitrobenzanilide.—To a solution of 0.72 g. of 2-amino-4-chloro-5-nitroanisole[11] in 10 ml. of pyridine was added 1.00 g. of benzoyl chloride. The reaction mixture was allowed to stand for 12 minutes and then boiled for 2 minutes, cooled to room temperature, and poured into 100 ml. of 10% hydrochloric acid containing 50 g. of ice. An oil precipitated which rapidly solidified. The solid was collected by filtration, washed with water, and recrystallized once from carbon tetrachloride, after which it weighed 0.79 g. (73%). A subsequent recrystallization from an acetic acid–water solvent pair (Darco) gave pinkish-yellow needles, m.p. 138–143° (lit.[12] m.p. 142°). Further recrystallization improved the melting point only very slowly.

4′-Amino-5′-chloro-2′-methoxybenzanilide.—To a boiling solution of 0.58 g. of 5′-chloro-2′-methoxy-4′-nitrobenzanilide in 35 ml. of ethanol, water was added until the cloud point was attained. To the still boiling solution was slowly added 1.01 g. of sodium hydrosulfite, followed by water until the cloud point was again attained. The solution was cooled, caused the crystallization of 0.28 g. of the product, m.p. 151.5–153°, which was collected by filtration. By dilution of the filtrate with water, followed by heating and recooling, an additional 0.02 g. of crystals was obtained, thus bringing the total yield to 0.30 g. (58%). The product was recrystallized once from an ethanol–water solvent pair, giving lustrous creamish needles, m.p. 152–154° (lit.[12] m.p. 152.5°).

2-Chloro-5-methoxy-*p*-phenylenedibenzamide. Method B.—To a solution of 0.11 g. of 4′-amino-5′-chloro-2′-methoxybenzanilide in 1.0 ml. of pyridine, cooled in an ice-bath, was added a solution of 0.07 g. of benzoyl chloride in 1.0 ml. of pyridine. The solution was allowed to stand at room temperature for 10 minutes, then boiled for 2 minutes, and finally cooled and allowed to stand at room temperature for another 5 minutes. The solution was poured into 20 ml. of 10% hydrochloric acid containing 5 g. of ice, causing the precipitation of 0.14 g. (93%) of the product, which was collected by filtration and washed with water. Two recrystallizations from benzene gave small lustrous white prisms, m.p. 225.5–226.5°.

Anal. Calcd. for $C_{21}H_{17}ClN_2O_3$: C, 66.23; H, 4.50; N, 7.36. Found: C, 66.24; H, 4.58; N, 7.31.

The Synthesis and Antibiotic Activity of Analogs of Citrinin and Dihydrocitrinin

BY HAROLD H. WARREN,[1] GREGG DOUGHERTY AND EVERETT S. WALLIS

RECEIVED FEBRUARY 22, 1957

A method has been developed for the preparation of 1-substituted dihydrocitrinin derivatives (II) by the cyclization of the carboxylic acid derivative of Compound A (III) with acetals, aldehydes and ketones, and the conversion of the dihydro derivatives to the corresponding 1-substituted citrinin derivatives (I) by oxidation. Assay of the antibiotic activity of the compounds prepared indicated that the 1-methyl-, 1-ethyl- and 1-phenylcitrinin derivatives possess considerably less activity than the parent compound. The 1-methyl-, 1-ethyl-, 1-phenyl- and 1,1-dimethyldihydrocitrinin derivatives are inactive as is dihydrocitrinin, while the 1-benzyl derivative shows moderate activity.

In a previous article[2] we reported a partial synthesis of citrinin[3] (I, R = H) involving the cyclization of the carboxylic acid derivative of Raistrick's Compound A[4] (III) with methylal to give dihydrocitrinin[5] (II, R = H; R′ = H) and the oxidation of the latter with bromine to citrinin. The purpose of the present work was to extend this synthesis to the preparation of dihydrocitrinin and citrinin derivatives bearing alkyl and aryl substituents at the 1-position and to determine the effect of such structural variation on their antibiotic activity.

It has been found that aldehydes, acetals and ketones will condense with the carboxylic acid derivative of Compound A in a fashion analogous to that of methylal. The reactants used and the products obtained are summarized in Table I.

The cyclization occurs readily at room temperature with zinc chloride or anhydrous hydrogen chloride as the catalyst. In the case of acetone and phenylacetaldehyde, both reagents are required to give a reasonably rapid reaction. Although the carboxylic acid derivative is only slightly soluble in benzene, the reaction occurs readily in that solvent, and its progress can be followed easily by observing the disappearance of the suspended material.

TABLE I

CONDENSATION PRODUCTS OF CARBONYL COMPOUNDS WITH THE CARBOXYLIC ACID DERIVATIVE OF COMPOUND A

Reactant	Product	Yield, %	M.p., °C.[a]
Acetal	1-Methyldihydrocitrinin (II, R = CH_3; R′ = H)	28	152.0–153.0
Propionaldehyde (or its acetal)	1-Ethyldihydrocitrinin (II, R = C_2H_5; R′ = H)	9	170.0–171.4
Acetone	1,1-Dimethyldihydrocitrinin (II, R = CH_3; R′ = CH_3)	31	166.5–167.5
Benzaldehyde	1-Phenyldihydrocitrinin (II, R = C_6H_5; R′ = H)	23	168.5–169.5
Phenylacetaldehyde	1-Benzyldihydrocitrinin (II, R = $CH_2C_6H_5$; R′ = H)	24	172.5–173.5

[a] Decomposition occurred at the melting point in all cases.

Purification of the products by recrystallization resulted in considerable loss and was complicated by the fact that, while the dihydrocitrinin derivatives crystallize most readily from halogenated hydrocarbon solvents or mixed solvents containing them, the products are contaminated by solvent of crystallization which cannot be removed completely by prolonged drying under vacuum at elevated temperature.

The smallness of the reported yields is due largely to the losses involved in the preparation of samples of analytical purity. Yields of crude material were ample (50–80%).

All of the dihydrocitrinin derivatives are readily soluble in dilute sodium bicarbonate and give the characteristic deep blue color with dilute alcoholic ferric chloride.

The oxidation with bromine in chloroform of the substituted dihydrocitrinins to the corresponding citrinin derivatives proved less satisfactory than in the case of dihydrocitrinin itself. Small but adequate yields of light lemon-yellow crystals of 1-methylcitrinin and orange crystals of 1-phenylcitrinin were obtained, but all attempts to oxidize 1-ethyldihydrocitrinin and 1-benzyldihydrocitrinin with this reagent produced brominated products, and in the case of the latter compound a small amount of a non-brominated lemon-yellow substance which did not possess the characteristic properties of citrinin derivatives.

1-Ethyldihydrocitrinin was oxidized successfully to 1-ethylcitrinin by means of red mercuric oxide in benzene, but this method failed when applied to the 1-benzyl derivative.

In an attempt to develop a more satisfactory method for carrying out the conversion, the catalytic dehydrogenation of dihydrocitrinin was investigated. It was found that a 50% yield of citrinin can be obtained by heating dihydrocitrinin with 30% palladium–charcoal in nitrobenzene through which oxygen is slowly passed. All attempts, however, to adapt this procedure to the dehydrogenation of 1-benzyldihydrocitrinin failed. The only product that could be isolated was a small amount of material which had all the properties of citrinin and which did not depress the melting point of an authentic sample of citrinin, indicating that under the conditions of the reaction the benzyl group is eliminated more readily than hydrogen.

All the citrinin derivatives prepared give the deep red color with dilute alcoholic ferric chloride characteristic of citrinin and are soluble in dilute sodium bicarbonate but with increasing difficulty as the size of the substituent group is increased.

The agar-streak technique of Waksman and Reilly[6] was chosen as a rapid and convenient method for comparing the antibiotic activity of the synthetic derivatives to that of citrinin and dihydrocitrinin.

At the highest concentration tested, 3000 dilution units (ml. of nutrient agar/g. of test compound), of all the synthetic derivatives only four compounds show any inhibition of growth of the test organisms used. The results are summarized in Table II. As expected, none of the compounds shows activity toward the gram-negative organisms, *E. coli*.

It is apparent that introduction of an alkyl or aryl group into citrinin greatly reduces the antibiotic activity of the compound compared to the parent compound. On the other hand, the potency of dihydrocitrinin, itself inactive at the highest concentration tested, is greatly enhanced by the presence of the benzyl group.

Work is under way to determine the effect of increasing the chain length of the alkyl substituent on the antibiotic activity of citrinin derivatives and to determine whether the effect of the benzyl group on the activity of dihydrocitrinin is due merely to its size or to a specific function of that group.

Acknowledgments.—The authors wish to express their appreciation to Merck and Co., Inc., Rahway, N. J., for providing many of the microanalyses; to Dr. John Wyllie of Queens University, Kingston, Ontario, who provided a culture of *A. candidus;* and to the E. I. du Pont de Nemours and Co., Wilmington, Del., for a grant-in-aid under which a portion of this work was carried out.

Experimental[7]

Starting Materials.—Citrinin was produced by the growing of *Aspergillus candidus* on a modified Czapek–Dox medium according to the method of Wyllie.[8] The hydrolysis of citrinin to Compound A and the preparation of the carboxylic acid derivative of compound A (III) by the carboxylation of Compound A have been described previously.[2] Ethyl acetate proved to be the most effective solvent for the purification of the carboxylic acid derivative. Dihydrocitrinin was prepared by the reduction of citrinin with Raney nickel according to the method of Schwenk, Schubert and Stahl.[9] The zinc chloride used was J. T. Baker, reagent grade.

1-Methyldihydrocitrinin (6,8-Dihydroxy-1,3,4,5-tetramethyl-7-isochromancarboxylic Acid).—To a suspension of 2.0 g. of the carboxylic acid derivative of Compound A (III) in 16 ml. of benzene was added 6.0 ml. of acetal and

[a] .... indicates no inhibition at highest concentration tested.

1.0 g. of zinc chloride. The mixture was allowed to stand at room temperature with frequent shaking for 15 minutes during which most of the suspended material dissolved. After standing for 2 hr. the clear orange solution was washed twice with dilute hydrochloric acid, once with water and dried over anhydrous sodium sulfate. Evaporation of the solvent yielded a red tar which was taken up in warm ethylene dibromide. Addition of petroleum ether and vigorous stirring initiated the formation of white crystals. After five recrystallizations from ethylene dibromide and petroleum ether followed by two from 1:10 toluene–ligroin, the product melted at 152.0–153.0° dec., yield 0.62 g. (28%).

Anal. Calcd. for $C_{14}H_{18}O_5$: C, 63.12; H, 6.81. Found: C, 63.32; H, 6.83.

1-Methylcitrinin (4,6-Dihydro-8-hydroxy-1,3,4,5-tetramethyl-6-oxo-3H-2-benzopyran-7-carboxylic Acid).—To a solution of 0.20 g. of 1-methyldihydrocitrinin in 10 ml. of chloroform was added 3.0 ml. of 0.5 *M* bromine in chloroform. The solution was allowed to stand at room temperature for 15 minutes and then was washed with 5% sodium bisulfite solution, with water, dried over anhydrous sodium sulfate and evaporated to a red tar which crystallized when stirred with a small amount of ether. The product was filtered and recrystallized twice from chloroform–petroleum ether and once from absolute ethanol. The yield of lemon-yellow crystals was 0.03 g. (15%) melting at 259.2–260.0° dec. A sample introduced into the melting point apparatus preheated to 170° melted immediately, resolidified and remelted at the higher temperature.

Anal. Calcd. for $C_{14}H_{16}O_5$: C, 63.60; H, 6.10. Found: C, 63.45; H, 6.30.

The product could be purified readily by recrystallization from absolute ethanol, but it underwent decomposition in aqueous ethanol or aqueous methanol, forming a deep green solution and a deposit of dark green tar. This was the only citrinin derivative to exhibit such behavior.

1-Ethyldihydrocitrinin (1-Ethyl-6,8-dihydroxy-3,4,5-trimethyl-7-isochromancarboxylic Acid).—Dry halogen chloride was passed for 30 seconds through a suspension of 1.0 g. of the carboxylic acid derivative of Compound A (III) in 10 ml. of benzene and 3.0 ml. of propionaldehyde. The mixture was allowed to stand at room temperature for 2 hr. during which time the suspended material rapidly dissolved followed by spontaneous crystallization of the product. The mixture was diluted with sufficient ether to dissolve the crystalline deposit and was extracted twice with 5% sodium bicarbonate. The aqueous extract was acidified with excess dilute hydrochloric acid, and the resulting insoluble oil was extracted with ether. After drying over sodium sulfate, the ethereal solution was evaporated to a yellow oil which crystallized when stirred with benzene and cooled thoroughly. Recrystallization of the product once from amyl acetate and once from acetone yielded 0.10 g. (9%) of white crystals melting at 170.6–171.4° dec.

Anal. Calcd. for $C_{15}H_{20}O_5$: C, 64.27; H, 7.19. Found: C, 63.97; H, 7.01.

The diethyl acetal of propionaldehyde was found to react in exactly the same fashion as the free aldehyde.

1-Ethylcitrinin (1-Ethyl-4,6-dihydro-8-hydroxy-3,4,5-trimethyl-6-oxo-3H-2-benzopyran-7-carboxylic Acid).—A mixture of 0.20 g. of 1-ethyldihydrocitrinin, 3.0 g. of red mercuric oxide, 1.0 g. of anhydrous magnesium sulfate in 10 ml. of benzene was refluxed for 45 minutes. After cooling, sufficient dilute hydrochloric acid was added to dissolve the sludge. The organic layer was separated, washed with dilute hydrochloric acid, once with water and then dried over sodium sulfate. Evaporation of the solvent yielded an orange oil which crystallized readily from dilute ethanol. Two recrystallizations of the product from the same solvent yielded 10 mg. (5%) of lemon-yellow crystals melting at 139.0–139.8°, resolidifying and remelting at 263.0–267.0° dec.

Anal. Calcd. for $C_{15}H_{18}O_5$: C, 64.73; H, 6.52. Found: C, 64.86; H, 6.57.

1,1-Dimethyldihydrocitrinin (6,8-Dihydroxy-1,1,3,4,5-pentamethyl-7-isochromancarboxylic Acid).—To a suspension of 0.5 g. of the carboxylic acid derivative of Compound A (III) in 6.0 ml. of benzene and 1.5 ml. of acetone was added 0.1 g. of zinc chloride, and dry hydrogen chloride was bubbled through for 10 seconds. Within 10 minutes the suspended material had dissolved. After standing at room temperature for 4 hr. the nearly colorless solution was washed once with dilute hydrochloric acid and twice with water, dried over sodium sulfate and evaporated to a colorless oil which crystallized spontaneously. The product was recrystallized once from *p*-cymene and once from cyclohexane–carbon tetrachloride, yielding 0.18 g. (31%) of white crystals melting at 166.5–167.5° dec.

Anal. Calcd. for $C_{15}H_{20}O_5$: C, 64.27; H, 7.19. Found: C, 64.26; H, 7.03.

1-Phenyldihydrocitrinin (6,8-Dihydroxy-3,4,5-trimethyl-1-phenyl-7-isochromancarboxylic Acid).—Four-tenths of a gram of zinc chloride was added to a suspension of 1.5 g. of the carboxylic acid derivative of Compound A (III) in a solution of 3.0 ml. of benzaldehyde and 15 ml. of benzene at room temperature. The suspended material completely dissolved within 30 minutes. After standing for 4 hr. the solution was washed with dilute hydrochloric acid and with water, dried over sodium sulfate and evaporated to a yellow oil which crystallized readily from carbon tetrachloride. The product was recrystallized once by dissolving it in 2 ml. of methanol, adding 15 ml. of hot carbon tetrachloride and cooling. A second recrystallization from 1:5 methyl ethyl ketone–ligroin yielded 0.57 g. (23%) of white crystals melting at 168.5–169.5° dec.

Anal. Calcd. for $C_{19}H_{20}O_5$: C, 69.49; H, 6.14. Found: C, 69.23; H, 6.30.

1-Phenylcitrinin (4,6-Dihydro-8-hydroxy-3,4,5-trimethyl-6-oxo-1-phenyl-3H-2-benzopyran-7-carboxylic Acid).—To a solution of 0.20 g. of 1-phenyldihydrocitrinin in 5.0 ml. of chloroform at room temperature was added slowly 0.7 ml. of 1.0 *M* bromine in chloroform. After standing for five minutes the orange solution was evaporated to an oil and then vacuum desiccated. The resulting glass crystallized when dissolved in hot ethanol to which water was cautiously added. Three recrystallizations of the product from dilute ethanol yielded 10 mg. (5%) of orange crystals melting at 249.5–251.5° dec. Though no shrinkage occurred at a lower temperature, a sample introduced into the apparatus preheated to 200° melted, resolidified and remelted at the higher temperature. The color of the pure product remained orange as compared to the lemon-yellow of most citrinin derivatives.

Anal. Calcd. for $C_{19}H_{18}O_5$: C, 69.94; H, 5.56. Found: C, 69.77; H, 5.43.

1-Benzyldihydrocitrinin (1-Benzyl-6,8-dihydroxy-3,4,5-trimethyl-7-isochromancarboxylic Acid).—Dry hydrogen chloride was bubbled for 15 seconds through a suspension of 1.0 g. of the carboxylic acid derivative of Compound A

(III) and 0.2 g. of zinc chloride in a solution of 13 ml. of benzene and 2.0 ml. of freshly distilled phenylacetaldehyde. After standing at room temperature for 4 hr. the resulting yellow solution was washed with three portions of water, dried over sodium sulfate and evaporated to an oil which crystallized when stirred with petroleum ether. The product was recrystallized once from ethylene bromide and petroleum ether, once from *p*-cymene and three times from xylene yielding 0.34 g. (24%) of white crystals melting at 172.5–173.5° dec.

Anal. Calcd. for $C_{20}H_{22}O_5$: C, 70.15; H, 6.48. Found: C, 70.28; H, 6.39.

Catalytic Dehydrogenation of Dihydrocitrinin.—Oxygen was bubbled slowly through a mixture of 0.10 g. of dihydrocitrinin and 0.05 g. of 30% palladium–charcoal in 1.0 ml. of nitrobenzene. After 23 minutes the solution gave a red color with ferric chloride indicating complete conversion of the dihydro compound. The solution was cooled, diluted to a convenient volume with ether, filtered to remove the catalyst and extracted with 5% sodium bicarbonate solution. Acidification of the aqueous extract with dilute sulfuric acid produced an orange-yellow crystalline precipitate. One recrystallization from hot ethanol yielded 0.05 g. (50%) of lemon-yellow crystals melting at 171.0–171.5° dec. No depression of the melting point was noted when this product was mixed with an authentic sample of citrinin.

The reaction proceeded in the absence of oxygen, but a longer reaction time was required, and the yield was considerably less.

Attempted Catalytic Dehydrogenation of 1-Benzyldihydrocitrinin.—The reaction was carried out using the same quantities and conditions given above for dihydrocitrinin. Heating was continued for 45 minutes before the blue ferric chloride test due to the dihydro compound became negative and a brown color was obtained. No appreciable product could be isolated by extraction of the reaction mixture.

The reaction was repeated using successively higher temperatures. At 150° a reaction time of nine minutes was required. Extraction of the solution yielded 0.02 g. of a yellow crystalline material which after one recrystallization from ethanol melted at 165.0–168.0° dec. A mixture of this product with citrinin melted at 166.0–169.0° dec.

Assay for Antibiotic Activity.—The comparison of the antibiotic activity of the synthetic derivatives to that of citrinin and dihydrocitrinin was made by the agar-streak method of Waksman and Reilly[6] using four organisms, *E. coli*, *S. aureus*, *B. mycoides* and *B. subtilis*. Stock solutions of the compounds to be tested were made up by dissolving the appropriate amount of substances (usually 5.0, 10.0 or 20.0 mg.) in three drops of acetone and three drops of 5% sodium bicarbonate and diluting to a volume of 10.0 ml. In no case did the latter reagents, at a concentration equal to the maximum present in the test cultures, inhibit the growth of control cultures. The stock solutions were used immediately after preparation to avoid decomposition of the sample in the slightly basic solution. A maximum concentration of test substance corresponding to 3,000 dilution units was used. The test cultures were examined after incubation for 20 hr. at 28°. The results for all compounds showing any inhibition of bacterial growth are summarized in Table II.

Ethylenimine Ketones. XII. Stereoisomerism of 1-Cyclohexyl-2-(*o*-nitrophenyl)-3-benzoylethylenimine. Quinoline Syntheses

BY NORMAN H. CROMWELL AND GERALD D. MERCER

RECEIVED FEBRUARY 9, 1957

A *trans* configuration has been assigned to the low melting form of 1-cyclohexyl-2-(*o*-nitrophenyl)-3-benzoylethylenimine which results from the reaction of 2-nitrochalcone with iodine and cyclohexylamine. Both the *cis* and *trans* forms are obtained in nearly equal amounts from 2,3-dibromo-3-(*o*-nitrophenyl)-propiophenone. The assignment of configuration is based upon the diagnostic phenylhydrazine reaction and absorption spectra studies. The catalytic hydrogenation of either the *cis*- or *trans*-ethylenimine ketone to 3-cyclohexylamino-2-phenylquinoline provides a new method of synthesis of such materials not readily available by conventional means. The course of this reaction is considered and the ultraviolet and infrared spectra of several 2-phenylquinolines are discussed.

Several pairs of *cis*- and *trans*-arylaroylethylenimines[1] and one pair of *cis*- and *trans*-alkylaroylethylenimines[2] have been prepared by the reaction of primary amines with α,β-dibromoketones. These isomeric pairs have been separated by fractional recrystallization or by chromatographic means and characterized by chemical and physical methods.

To study the sterical and electrical effects of the *o*-nitro group on the β-aryl ring of these ketones and to investigate certain synthetic possibilities, we have now prepared the *cis* and *trans* forms of 1-cyclohexyl-2-(*o*-nitrophenyl)-3-benzoylethylenimine. A comparable study in the epoxyketone series has been reported.[3]

The reaction of cyclohexylamine with 2,3-dibromo-3-(*o*-nitrophenyl)-propiophenone[4] in benzene solution gave an 89% yield of a nearly 50–50 mixture of the *cis* (Ia) and *trans* (Ib) forms of the ethylenimine ketone. These racemic geometrical isomers were separated by column chromatography.[2] The higher-melting *cis* isomer (Ia) in this series was the more strongly absorbed on the alumina. This appears to be a general property of the *cis* forms of the ethylenimine ketones.[2,5]

The low-melting *trans* form (Ib) also was prepared in 64% yield from 2-nitrochalcone,[4] cyclohexylamine and iodine in benzene solution, using a procedure similar to that outlined by Southwick and Christman[6] for a related reaction.

The configurations of Ia and Ib were assigned by methods which have been described previously for analogous compounds.[1–3] The high-melting ethylenimine ketone isomer (Ia) reacted with phenylhydrazine in the presence of acetic acid in an alcohol–chloroform mixture to produce an 85% yield of 1,3-diphenyl-5-(*o*-nitrophenyl)-pyrazole (II).[3] Under similar conditions the low-melting isomer (Ib) gave what appeared to be, from elemental analysis

and ultraviolet spectral studies,[1a] see Fig. 1, a mixture of the pyrazole II and 1,3-diphenyl-4-cyclohexylamino-5-(*o*-nitrophenyl)-pyrazoline (III). This mixed material gave a positive Knorr test[7] for pyrazolines.

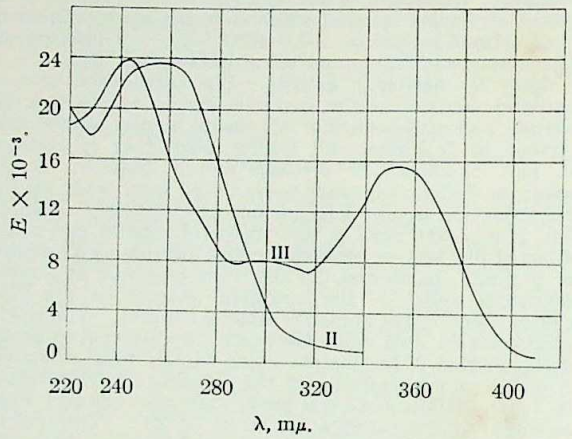

Fig. 1.—Ultraviolet absorption spectra in 95% ethanol of 1,3-diphenyl-5-(*o*-nitrophenyl)-pyrazole (II) and impure (contaminated with II) 1,3-diphenyl-4-cyclohexylamino-5-(*o*-nitrophenyl)-pyrazoline (III).

Attempts to separate the pyrazoline from the pyrazole by chromatographic adsorption on alumina led to conversion of all of the material to the pyrazole. The pyrazoline readily loses cyclohexylamine to produce the pyrazole, probably because the electron attraction of the *o*-nitro group on the phenyl ring at position-5 of the pyrazoline ring allows the proton to be lost readily from this carbon atom-5.

The aminopyrazolines with an unsubstituted phenyl group in position-5, which have been obtained from other *trans*-ethylenimine ketones,[1] are considerably more stable. The *trans*-arylaroyl ethylenimines are expected to produce aminopyrazolines while the *cis* isomers have been found to give only the pyrazoles.[1,2] The ultraviolet and infrared absorption spectra studies further confirmed the configurations assigned to Ia and Ib; see Absorption Spectra Discussion.

Hydrogenation of the isomeric ethylenimine ketones (Ia and Ib) using W-2 Raney nickel catalyst produced 3-cyclohexylamino-2-phenylquinoline (IV) isolated as its picrate. The isomeric 4-cyclohexylamino-2-phenylquinoline (IX) readily was prepared in good yield from 4-chloro-2-phenylquinoline by reaction with cyclohexylamine.

Colonna and Passerini[8] have prepared 3-arylamino-2-phenylquinolines by applying the Pfitzinger reaction[9] using isatin and ω-arylaminoacetophenones to obtain the 3-arylamino-2-phenyl-4-cinchonic acids, which were readily decarboxylated. Using ω-cyclohexylaminoacetophenone and isatin we obtained a good yield of 3-cyclohexylamino-2-phenyl-4-cinchonic acid (V). This acid was decarboxylated by heating alone to give 3-cyclohexylamino-2-phenylquinoline (IV), the picrate of which was identical with that obtained from the product of the catalytic hydrogenation of Ia and Ib.

When the cinchonic acid (V) was heated with 85% phosphoric acid or concd. sulfuric acid, dealkylation as well as decarboxylation occurred and the known 3-amino-2-phenylquinoline (VI) was produced.

3-Bromo-2-phenylquinoline (VIII) was obtained by a chemical reduction of α-bromo-2-nitrochalcone (VII) which was prepared by dehydrobromination of 2,3-dibromo-3-(*o*-nitrophenyl)-propiophenone. Attempts to replace the 3-bromo group in VIII with the cyclohexylamino group were unsuccessful.

The catalytic hydrogenation of 2-nitrochalcone produced 2-phenylquinoline in 82% yield while reduction with hydroiodic acid[10] gave the same compound in 31% yield.

3-(*o*-Nitrophenyl)-propiophenone (X) and 3-(*p*-nitrophenyl)-propiophenone (XI) were prepared by a Friedel–Crafts synthesis employing the acid chlorides of *o*-nitrohydrocinnamic acid and *p*-nitrohydrocinnamic acid. These acids were obtained in good yields from the nitration of hydrocinnamic acid using a procedure similar to that outlined by Buckles and Bellis[11] for the nitration of cinnamaldehyde.

Reduction of 3-(*o*-nitrophenyl)-propiophenone with hydroiodic acid produced a 30% yield of 2-phenylquinoline, but catalytic hydrogenation gave a 40% yield of 1,2,3,4-tetrahydro-2-phenylquinoline, isolated as its hydrochloride XIII.

The formation of the 3-cyclohexylamino-2-phenylquinoline from both the *cis*- and *trans*-ethylenimine ketones (Ia and Ib) undoubtedly involves the reduction of the nitro group to the amino group as the first step. The electron-releasing effect of the *o*-amino group would be expected to facilitate a cleavage of the β-carbon-to-nitrogen bond in the ethylenimine ring. This cleavage could lead to a rearrangement of both the *cis* and *trans* forms of the intermediate 1-cyclohexyl-2-(*o*-aminophenyl)-3-benzoylethylenimine (A) to α-cyclohexylamino-2-aminochalcone (B). This latter compound would be expected to undergo a facile ring closure to produce the quinoline IV. A similar mechanism has been suggested[3] to explain the formation of 3-hydroxy-2-phenylquinoline from the catalytic hydrogenation of both *cis*- and *trans*-2-nitrochalcone oxide.

An expanded study of these and related methods of synthesis for 3-amino-2-phenylquinolines will be described in a forthcoming paper.

Absorption Spectra Discussion.—The *cis*- and *trans*-ethylenimine ketones Ia and Ib show ultraviolet maxima midway between those of the parent saturated and unsaturated ketones, with the *trans* form exhibiting the stronger absorption. The *trans* form is expected to have a higher degree of three-ring carbonyl hyperconjugation.[1] The 2-nitrochalcone, which is probably the *trans* form, shows a maximum to be expected for the vinyl-benzoyl chromophore. The steric effect of the *o*-nitro group seems to inhibit conjugation sufficiently to exclude maxima to be associated with either the nitrostyryl or ni-

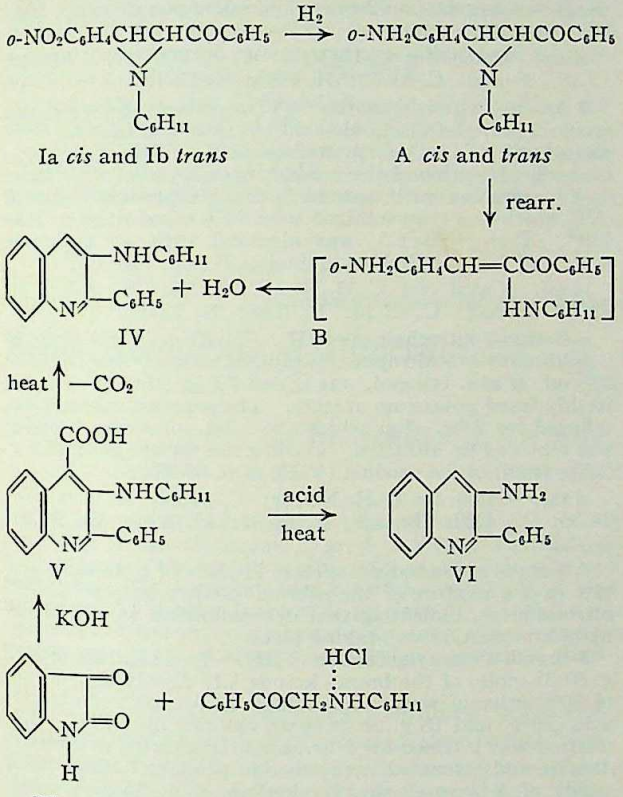
Digitized by Arya Samaj Foundation Chennai and eGangotri

trocinnamoyl grouping.[12] The ethylenimine ketone Ib showed a carbonyl stretching vibration infrared band at lower frequencies than did Ia, further confirming that the former is undoubtedly the *trans* form, with three-ring carbonyl hyperconjugation making a greater contribution to the ground state than is the case for the *cis* form Ia.



The α-bromo-2-nitrochalcone showed two ultraviolet maxima at 220 and 261 mμ, again indicating that the steric effect of the *o*-nitro group inhibits conjugation and excludes the maxima which might be associated with either the nitrostyryl or nitrocinnamoyl groupings.[12] The relatively high value of 1681 cm.$^{-1}$ for the carbonyl bond stretching frequency in the infrared for this compound VII as compared with the value 1671 cm.$^{-1}$ for 2-nitrochalcone indicates an increase in double bond character for the C=O group in the ground state. This shift may be associated with a decrease in conjugation between the benzoyl and bromovinyl group as well as with the inductive and coulombic field effects of the α-bromo group.[13]

The 2-phenylquinolines show strong ultraviolet absorption between 254 and 265 mμ. In general[14] the 3-amino-2-phenylquinolines absorb at shorter wave lengths and/or lower intensities than the 4-amino-2-phenylquinolines in this range of the spectrum, possibly because of steric crowding between the 2-phenyl group and the space-demanding N-substituted 3-amino groups. In general[14] N-substituted 3-amino-2-phenylquinolines absorb at higher wave lengths above 300 mμ but at lower intensities than the isomeric 4-amino derivatives. The 3-cyclohexylamino-2-phenylquinoline has a third high intensity band at 221 mμ.

All of the 2-phenylquinolines studied showed two moderately strong infrared bands between 1540 and 1620 cm.$^{-1}$. The assignment of bands in this range of the spectrum, where those to be associated with conjugated phenyl, phenyl, C=C, C=N and N—H (B) bending are expected, is difficult and often uncertain.

Summary of Absorption Spectra

Compound	No.	Ultraviolet max.[a] λ, mμ	ε × 10^{-3}	Infrared bands[b] Bond	Wave no.	Approx. % abs.

[a] The ultraviolet spectra were determined in the range of 220–450 mμ in 95% ethanol using 10^{-4} molar solutions with a Cary model 11 spectrophotometer. [b] The infrared spectra were determined over the range of 4000–600 cm.$^{-1}$ at 25° using 1.0-mm. matched NaCl cells with a Perkin–Elmer model 21 instrument; the solutions were 6 mg./ml. CCl_4 unless otherwise indicated. [c] Concn. was 12 mg./ml. CS_2. [d] See ref. 3. [e] Concn. was 12 mg./ml. CCl_4. [f] In 0.1-mm. cells. [g] Concn. was 21 mg./ml. CCl_4 in 0.1-mm. cells. [h] Concn. was 37 mg./ml. CCl_4 in 0.1-mm. cells. [i] Concn. was 30 mg./ml. CCl_4 in 0.1-mm. cells.

Acknowledgment.—This work was supported in part by a grant from the National Science Foundation, N.S.F. G-1091.

Experimental

***cis*- and *trans*-1-Cyclohexyl-2-(*o*-nitrophenyl)-3-benzoylethylenimines (Ia and Ib).**—To a well-stirred suspension of 50 g. (0.121 mole) of 2,3-dibromo-3-(*o*-nitrophenyl)-propiophenone[4] in 150 ml. of dry benzene, cooled to 5°, was added dropwise 36.2 g. (0.376 mole) of cyclohexylamine. The mixture was stirred for 3 hr. and then placed in the refrigerator for 16 hr. The solid cyclohexylamine hydrobromide was removed by filtration and the filtrate concentrated to a thick sirupy residue under vacuum. This residue was taken up in benzene and three successive crops of crystals removed by addition of petroleum ether (b.p. 30–60°); wt. 35.5 g. (89% yield), m.p. 98–120°. This mixed product was separated by column chromatography, using aluminum oxide, into nearly equal amounts of the *cis* isomer Ia, m.p. 130–131°, and the *trans* form Ib, m.p. 114–115°. The total recovery of material was 98% and the *trans* isomer was

the first to be eluted from the column by the benzene–alcohol mixture.

trans-1-Cyclohexyl-2-(*o*-nitrophenyl)-3-benzoylethylenimine (Ib).—A 11.4-g. (0.045 mole) sample of 2-nitrochalcone[4] and 17.9 g. (0.181 mole) of cyclohexylamine dissolved in 125 ml. of dry benzene was treated with a solution of 11.4 g. (0.045 mole) of iodine in 125 ml. of dry benzene with stirring and external cooling. The product, isolated as before, weighed 10.2 g. (64.6% yield), m.p. 114–115°, identical with Ib described above.

Anal. Calcd. for $C_{21}H_{22}N_2O_3$: C, 71.98; H, 6.33; N, 7.99. Found for Ia; C, 72.32; H, 6.56; N, 8.00. For Ib: C, 72.14; H, 6.28; N, 8.18.

Reaction of the Ethylenimine Ketones Ia and Ib with Phenylhydrazine.—The *cis isomer* Ia (2.1 g., 0.006 mole) was dissolved in 25 ml. of a 2:3 alcohol–chloroform mixture and to this solution was added 0.75 g. (0.006 mole) of phenylhydrazine and 0.75 g. (0.012 mole) of glacial acetic acid. The solution was warmed to about 40° for 30 minutes and then allowed to stand at room temperature for 45 hr. The product was isolated by cooling the reaction mixture and recrystallizing the crude product from methanol to yield 2.2 g. (85.7% yield) of 1,3-diphenyl-5-(*o*-nitrophenyl)-pyrazole (II), m.p. 178–179°, identical with the product previously prepared in this Laboratory.[3]

The *trans* isomer Ib (2.1 g., 0.006 mole) was treated in a similar manner, but without warming, and found to yield after 14 hr., 0.70 g. of 1,3-diphenyl-5-(*o*-nitrophenyl)-pyrazole.[3] Evaporation of the reaction filtrate produced an additional 1.01 g. of a solid material, m.p. 126–142°. Recrystallization of this product from alcohol gave material melting at 137–147°. Attempts at purification of this mixed product by chromatographic means gave only the pure pyrazole II. The 137–147° melting material gave a positive Knorr[7] pyrazoline test. This mixed product was undoubtedly a mixture of 1,3-diphenyl-4-cyclohexylamino-5-(*o*-nitrophenyl)-pyrazoline (III) and the pyrazole II.

Anal. Calcd. for $C_{27}H_{22}N_4O_2$: C, 73.61; H, 6.41; N, 12.72. Found: C, 73.29; H, 5.46; N, 12.33.

2-Phenyl-3-cyclohexylaminoquinoline (IV) from Ethylenimine Ketones Ia and Ib. (a) **From the *trans* isomer Ib.**—A 4.1-g. sample of Ib was dissolved in 20 ml. of ethyl acetate and shaken under 45 lb./in.^{2} of hydrogen in the presence of 0.50 g. of W-2 Raney nickel catalyst for 2 hr. Filtration and evaporation left an oil which could not be crystallized from ethanol. Treatment of the ethanol solution of the oil with picric acid produced 3.1 g. (50% yield) of the picrate of 2-phenyl-3-cyclohexylaminoquinoline, m.p. 203–205°, identical with the authentic compound described below.

b. **From the *cis* Isomer Ia.**—In a similar experiment, using 30 ml. of ethanol as solvent, after 3 hr. of hydrogenation 3.5 g. of Ia produced 2.69 g. (56% yield) of the picrate, m.p. 203–205°, identical with the one obtained in (a).

ω-Cyclohexylaminoacetophenone Hydrochloride.[15]—To 88.5 g. (0.894 mole) of cyclohexylamine in 200 ml. of ethyl ether and 132 ml. of dry benzene, held to 14°, slowly was added 88 g. (0.443 mole) of ω-bromoacetophenone dissolved in 160 ml. of ethyl ether and 55 ml. of dry benzene. The reaction mixture was stirred an additional hour. The by-product cyclohexylamine hydrobromide was removed and the product isolated as the hydrochloride by passing dry hydrogen chloride gas into the solution; wt. 60 g. (54% yield), m.p. 250–252° dec., recrystallized from abs. ethanol.

Anal. Calcd. for $C_{14}H_{20}NOCl$: Cl, 13.97. Found: Cl, 13.98.

3-Cyclohexylamino-2-phenyl-4-cinchonic Acid (V).—A solution of 25 g. (0.171 mole) of isatin in aqueous potassium hydroxide (400 g. in 500 ml. of water) was added to a hot solution of 43.5 g. (0.171 mole) of ω-cyclohexylaminoacetophenone hydrochloride in 800 ml. of 95% ethanol. The mixture was heated under reflux for 5 hr. and then 800 ml. of solvent removed by distillation. The residual solution was cooled to precipitate the potassium salt which was removed by filtration and converted to the yellow colored acid in hot water, acidified with glacial acetic acid. This product was recrystallized from 95% ethanol to give 38 g. (64% yield) of 3-cyclohexylamino-2-phenyl-4-cinchonic acid (V), m.p. 198–200° dec.

Anal. Calcd. for $C_{22}H_{22}N_2O_2$: C, 76.27; H, 6.40; N, 8.08. Found: C, 76.43; H, 6.53; N, 7.87.

3-Cyclohexylamino-2-phenylquinoline (IV).—A 6.92-g. sample of the cinchonic acid V was heated at its melting point (200°) for 30 minutes and then distilled under vacuum (pot temp. 240°, 300 μ pressure). A pale yellow oil (IV) was collected, 3.2 g. (51% yield). The spectra of this material was determined without further purification. A sample of this oil was treated with the picric acid to produce the 3-cyclohexylamino-2-phenylquinoline picrate, m.p. 204–205°, in a 95% yield.

Anal. Calcd. for $C_{27}H_{25}N_5O_7$: C, 61.01; H, 4.74; N, 13.18. Found: C, 61.36; H, 4.83; N, 13.47.

3-Amino-2-phenylquinoline (VI).—When 3-cyclohexylamino-2-phenyl-4-cinchonic acid (V) was heated with 85% phosphoric acid or concd. sulfuric acid at 200°, a gas was evolved. Isolation of the product upon dilution with water and basification with sodium hydroxide produced a solid (VI) which was recrystallized from 95% ethanol; m.p. 118–119°. This product V was identical with an authentic sample of 3-amino-2-phenylquinoline,[16] m.p. 118–119°.

Anal. Calcd. for $C_{15}H_{12}N_2$: C, 81.79; H, 5.49; N, 12.72. Found: C, 82.13; H, 5.68; N, 12.34.

α-Bromo-2-nitrochalcone (VII).—To 31 g. (0.075 mole) of 2,3-dibromo-3-(*o*-nitrophenyl)-propiophenone,[4] suspended in 300 ml. of abs. ethanol, was added 7.5 g. (0.0754 mole) of freshly fused potassium acetate. The reaction mixture was refluxed for 2 hr. after which the solid potassium bromide was removed by filtration. Cooling the filtrate gave 22.3 g. (93% yield) of the product (VII), m.p. 85–86°.

Anal. Calcd. for $C_{15}H_{10}NO_3Br$: C, 54.24; H, 3.03; Br, 24.06; N, 4.22. Found: C, 54.39; H, 3.15; Br, 23.81; N, 4.26.

Attempts to use sodium acetate in place of potassium acetate gave a mixture of the α-bromo-2-nitrochalcone and 2-nitrochalcone, indicating that debromination as well as dehydrobromination was taking place.

3-Bromo-2-phenylquinoline (VIII).—To a solution of 3.22 g. (0.01 mole) of the bromo ketone VII dissolved in 50 ml. of 50% ethanol–water, was added 50 ml. of hydrobromic acid (29%) and 18 g. of stannous chloride dihydrate. The mixture was warmed for 2 hr., made basic with sodium hydroxide and extracted with ether to produce 0.82 g. (30% yield) of 3-bromo-2-phenylquinoline, m.p. 85–86°, corresponding to that reported by John[17]; mixed m.p. with starting material, 60–65°.

Treatment of a sample of 3-bromo-2-phenylquinoline with cyclohexylamine in a sealed tube by the procedure used for the preparation of the 4-position isomer IX resulted in the recovery of the starting material.

4-Cyclohexylamino-2-phenylquinoline (IX).—A 1.2-g. sample of 4-chloro-2-phenylquinoline was heated in a sealed tube[17] at 200° for 10 hr. with 0.90 g. (an excess) of cyclohexylamine. The product was recrystallized from 95% ethanol; 1.35 g. (89% yield), m.p. 128–129°.

Anal. Calcd. for $C_{21}H_{22}N_2$: C, 83.40; H, 7.33; N, 9.27. Found: C, 83.26; H, 7.43; N, 9.12.

3-(*o*-Nitrophenyl)-propiophenone (X) and 2-(*p*-Nitrophenyl)-propiophenone (XI).—*o*-Nitro- and *p*-nitrohydrocinnamic acid were prepared by the nitration of hydrocinnamic acid using the procedure described by Buckles and Bellis[11] for cinnamaldehyde. The *o*- and *p*-isomers were obtained in an over-all yield of 69%; 64% of the product was the *o*-isomer. They were separated by fractional crystallization from hot water and alcohol; *o*-isomer, m.p. 111–112°[18]; *p*-isomer, m.p. 161–163°.[18]

o-Nitrohydrocinnamoyl chloride was prepared by treating 14.3 g. of the acid with thionyl chloride. A Friedel-Crafts reaction was carried out with the crude acid chloride and benzene, using aluminum chloride as the catalyst. Hydrolysis of the product complex gave 12.2 g. (66% yield) of 3-(*o*-nitrophenyl)-propiophenone; recrystallized from benzene and petroleum ether, m.p. 58–59°; Janeish[10] reported m.p. 68–69°.

Anal. Calcd. for $C_{15}H_{13}NO_3$: C, 70.58; H, 5.13. Found: C, 70.60; H, 5.12.

(15) This compound was first prepared in this Laboratory by E. A. Nielsen, M.S. thesis, 1950, Univ. of Nebraska.

(16) Prepared in this Laboratory by Dr. H. E. Baumgarten by the reduction of 3-nitro-2-phenylquinoline.

Using the above procedure, 35 g. of *p*-nitrohydrocinnamic acid produced 31.1 g. (69% yield) of 3-(*p*-nitrophenyl)-propiophenone, m.p. 94–96°.

Anal. Calcd. for $C_{15}H_{13}NO_3$: C, 70.58; H, 5.13. Found: C, 70.73; H, 5.24.

2-Bromo-3-(*p*-nitrophenyl)-propiophenone (XII).—A 25.5-g. sample of 3-(*p*-nitrophenyl)-propiophenone was dissolved in 100 ml. of glacial acid and warmed to 50°. To this solution was added 16 g. of bromine in 50 ml. of glacial acetic acid. The temperature of the reaction mixture was maintained at 50° for 1 hr., cooled and poured into 500 ml. of cold water. The oily solid residue was crystallized from ethanol; wt. 32.23 g. (96% yield), m.p. 100–101°.

Anal. Calcd. for $C_{15}H_{12}NO_3Br$: C, 53.91; H, 3.62; Br, 23.92. Found: C, 54.08; H, 3.62; Br, 24.32.

2-Phenyl-1,2,3,4-tetrahydroquinoline Hydrochloride (XIII).—A 3.0-g. sample of 3-(*o*-nitrophenyl)-propiophenone was dissolved in 50 ml. of ethyl acetate and shaken with 45 lb./in.^{2} of hydrogen in the presence of 0.5 g. of W-2 Raney nickel catalyst for 3 hr. at room temperature. The oily product isolated from the reaction mixture was converted to its hydrochloride salt upon passing dry hydrogen chloride gas into a dry ether solution of it; wt. 1.15 g. (40% yield), m.p. 220–225°, recrystallized from abs. ethanol.

Anal. Calcd. for $C_{15}H_{16}NCl$: Cl, 14.67. Found: Cl, 14.43.

2-Phenylquinoline.—A 2.0-g. sample of 2-nitrochalcone was dissolved in 60 ml. of ethyl acetate, and hydrogenated in the presence of W-2 Raney nickel as outlined above to produce 1.3 g. (82% yield) of 2-phenylquinoline, m.p. 81–82°. This product was identical with samples prepared by (a) refluxing *o*-nitrochalcone for 16 hr. with 48% hydroiodic acid (31% yield) or (b) by refluxing 3-(*o*-nitrophenyl)-propiophenone with the same reagent for 20 hr. (30% yield).[10]

Amino Derivatives of Nitrochalcones. I. Synthesis, Structure Studies and Absorption Spectra

BY NORMAN H. CROMWELL AND GERALD D. MERCER[1]

RECEIVED MARCH 16, 1957

2,3-Dibromo-3-(*o*-nitrophenyl)-propiophenone and the corresponding α-bromo-2-nitrochalcone react with morpholine, piperidine or dimethylamine to produce the expected 2,3-diamino-3-(*o*-nitrophenyl)-propiophenones, while secondary amines with greater steric requirements, such as diethylamine and N-methylcyclohexylamine, react to produce β-amino-2-nitrochalcones. The corresponding bromine derivatives of 3-nitro and 4-nitrochalcone react with both classes of secondary amines in the normal manner to produce 2,3-diamino-3-nitrophenylpropiophenones and/or α-aminonitrochalcones. The structures of the amino chalcones were established by acid hydrolysis studies. A discussion of the ultraviolet and infrared absorption spectra of these and related compounds is given.

The reactions of secondary amines with α,β-dibromoketones and α-bromo-α,β-unsaturated ketones have been the subject of numerous investigations reported from this Laboratory[2] and from others.[3]

The reaction of 2,3-dibromo-3-(*o*-nitrophenyl)-propiophenone[4] with morpholine, piperidine and dimethylamine produced the corresponding α,β-diamino ketones I, II and III. Only one of the two possible racemates was isolated in each case in at least 75% yield, and it was not possible to isolate either α-amino- or β-amino-α,β-unsaturated ketones from the highly colored reaction mixtures. These same products I, II and III also were obtained in slightly lower yields from α-bromo-2-nitrochalcone.[5]

When 2,3-dibromo-3-(*o*-nitrophenyl)-propiophenone was allowed to react with secondary amines having higher steric requirements, yellow colored products were produced which analysis, absorption spectra studies and acid hydrolysis showed were β-amino-*o*-nitrochalcones. Thus β-diethylamino- (IV) and β-(N-methylcyclohexylamino)-2-nitrochalcone (V) were produced in good yields using the corresponding amines. These same products were obtained in nearly the same yields from α-bromo-2-nitrochalcone.

The unsaturated amino ketones IV and V were difficult to hydrolyze, but long heating with dilute sulfuric acid produced the known *o*-nitrodibenzoylmethane which readily gave a copper chelate. This 1,3-diketone reacted with phenylhydrazine to give the known 1,3-diphenyl-5-(*o*-nitrophenyl)-pyrazole.[5,6]

In contrast with the *o*-nitro compound, both 2,3-dibromo-3-(*m*-nitrophenyl)-propiophenone and 2,3-dibromo-3-(*p*-nitrophenyl)-propiophenone reacted with diethylamine to produce the corresponding α-diethylamino-3-nitrochalcone (XI) and α-diethylamino-4-nitrochalcone (X), respectively. The structures of these products X and XI were established by analysis, absorption spectra studies and their acid hydrolysis to the corresponding 1,2-diketones. Compound X was hydrolyzed to *p*-nitrobenzylphenyl diketone (XII) which produced 2-(*p*-nitrobenzyl)-3-phenylquinoxaline (XIII) on heating with *o*-phenylenediamine. The α-amino-α,β-unsaturated ketone XI produced the corresponding 1,2-diketone which was converted to the known 2-(*m*-nitrobenzyl)-3-phenylquinoxaline on warming with *o*-phenylenediamine.

2,3-Dibromo-3-(*p*-nitrophenyl)-propiophenone reacted with morpholine to give a mixture of 2,3-di-(N-morpholino)-3-(*p*-nitrophenyl)-propiophenone (VI) and α-(N-morpholino)-4-nitrochalcone (VIII), which were separated readily by fractional recrystallization. Piperidine behaved in a similar

manner to produce the corresponding α,β-di-(N-piperidino) ketone VII and the α-(N-piperidino)-α,β-unsaturated ketone IX.

With anhydrous ammonia, 2,3-dibromo-3-(*p*-nitrophenyl)-propiophenone produced *trans*-2-(*p*-nitrophenyl)-3-benzoylethylenimine (XIV), previously prepared by Wieland[7] but assigned a piperizine structure without further investigation. A molecular weight determination and the measurement of absorption spectra (infrared and ultraviolet) clearly established the structure of this ethylenimine ketone.

Discussion of Reactions.—It has been shown[2] that α-bromochalcone or 2,3-dibromo-3-phenylpropiophenone reacts with secondary amines to produce either mixtures of α-amino-α,β-unsaturated ketones and α,β-diaminoketones (*i.e.*, morpholine and piperidine) or only the α-amino-α,β-unsaturated ketone (*i.e.*, diethylamine). An endocyclic α,β-unsaturated ketone, 8-bromoperinaphthenone-7, was found to react with secondary amines (*i.e.*, morpholine and piperidine) to produce either α-amino- or β-amino-α,β-unsaturated ketones, depending upon the conditions employed.[8] Recently it has been reported that 3-bromo-1,-1-dimethyl-2-keto-1,2-dihydronaphthalene reacts with morpholine to give a β-amino-α,β-unsaturated ketone.[9]

It seems probable that the first step in the reaction of amines with each of the 2,3-dibromo-3-arylpropiophenones (*o*-nitro, *m*-nitro and *p*-nitro) involves the loss of hydrogen bromide to produce the corresponding α-bromonitrochalcone (A). The second step in the presence of excess reagent is the addition of the amine to produce the reactive 2-bromo-3-amino-3-nitrophenylpropiophenones (B). With primary amines[5,10] or ammonia the last step in the sequence of reactions in all three series involves a ring closure to produce the ethylenimine ketone. Both the *m*-nitrophenyl and *p*-nitrophenyl series of bromo ketones react with diethylamine, morpholine and piperidine in the normal[2] manner to produce the expected results, *via* the intermediate quaternary ethylenimmonium ion, since α-amino-α,β-unsaturated ketones are included in the products.

The presence of an electron-attracting nitro group on the 3-aryl group in the 2,3-dibromo-3-(nitrophenyl)-propiophenones would be expected to activate the hydrogen atom in the 3-position and thus facilitate the loss of hydrogen bromide from the intermediate 2-bromo-3-amino-3-(nitrophenyl)-propiophenones (B) to produce β-aminonitrochalcones. However, since only the 2,3-dibromo-3-(*o*-nitrophenyl)-propiophenone behaved in this manner, it seems possible that a steric effect as well as the electrical effect of the *o*-nitro group is involved in determining the course of these reactions to produce the β-amino α,β-unsaturated ketones (IV) and (V). It is possible (but not certain) that the intermediate formation of the usual ethylenimmonium bromides[2] is not involved in the loss of hydrogen bromide from the intermediate 3-diethylamino- and 3-(N-methylcyclohexylamino)-2-bromo-3-(*o*-nitrophenyl)-propiophenones.

Steric controls[11] which are expected to operate in the formation of the 3-amino-2-bromo-3-arylpropiophenones suggest that the main products to be expected from the reactions involving ammonia are the *trans*-2-aryl-3-benzoylethylenimines (*i.e.*, XIV).

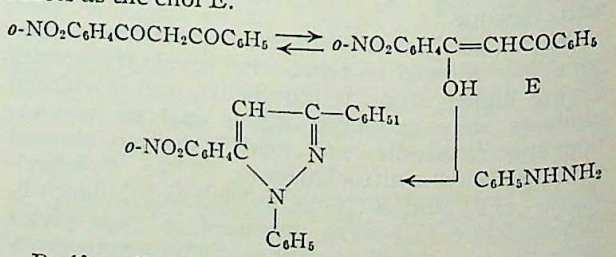
It was of interest to find that *o*-nitrodibenzoylmethane reacted with phenylhydrazine to produce the known 1,3-diphenyl-5-(*o*-nitrophenyl)-pyrazole. This result implies that *o*-nitrodibenzoylmethane reacts as the enol E.



Bodforss[12] came to a similar conclusion with regard to the reaction of *m*-nitrodibenzoylmethane and phenylhydrazine. Although the course of the reaction suggested by Bodforss has been disputed by Barnes and Dodson,[13] we are inclined to

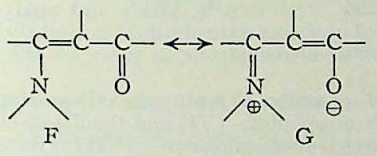
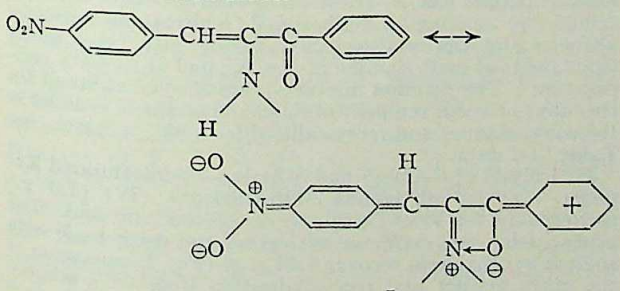
believe that Bodforss' description of these reactions is correct. The fact that 2,3-dibromo-3-phenyl-*m'*-nitropropiophenone reacts with a mixture of potassium hydroxide and phenylhydrazine to produce the same pyrazole[13] as does *m*-nitrodibenzoylmethane[12] cannot be taken as conclusive evidence for the structure of the pyrazole. The dibromide may have undergone an initial reaction with potassium hydroxide to produce *m*-nitrodibenzoylmethane. We believe that Bodforss' assignment of the 1,3-diphenyl-5-(*m*-nitrophenyl)-pyrazole structure to this derivative is correct.

Discussion of Absorption Spectra.—2-Nitrochalcone[5,6] has been shown to have only one maximum in the ultraviolet at 262 mμ, which is to be associated with the vinyl–benzoyl chromophore. The β-amino-2-nitrochalcones (IV) and (V) both showed benzoyl absorption in the range of 243–247 mμ and a new intense maximum at 340 mμ. Both of these β-amino-α,β-unsaturated ketones have carbonyl stretching frequencies near 1635 cm.$^{-1}$ in the infrared. As has been suggested previously,[14,15] such results indicate that the resonance implied by (F) ⟷ (G) makes an important contribution to both the ground and excited states of β-amino-α,β-unsaturated ketones.



F G

The α-amino-α,β-unsaturated ketones (VIII) and (IX) also showed vinyl–benzoyl absorption at 255 mμ and moderately strong bands near the visible-ultraviolet boundary of the spectrum, 390–425 mμ. These longer wave length bands may be ascribed[14] to chromophores involving the whole molecule, and resonance implied by H ⟷ J is suggested as making a considerable contribution to the excited state.



J

It is important to observe that the presence of the nitro group in the *p*-position, which would be expected to support a negative charge through interaction with the benzene ring, greatly enhances light absorption in this part of the spectrum. Although α-diethylamino-3-nitrochalcone (XI) also has an ultraviolet absorption band at 400 mμ, the intensity is much lower than for the α-amino-4-nitrochalcones. Resonance interaction of the *m*-nitro group with the benzene ring is, of course, not expected. Ketone XI also shows a moderately strong nitrocinnamoyl band at 313 mμ. The infrared carbonyl stretching frequencies of all of these α-aminochalcones were between 1677 and 1682 cm.$^{-1}$. This shift to higher frequencies with respect to the carbonyl values for nitrochalcones (1671 cm.$^{-1}$ or less)[5,6] indicates that the resonance H ⟷ J makes little or no contribution to the ground state and that instead the inductive and coulombic field effects[16] of the α-amino groups increase the double bond character of the carbonyl group in the α-aminochalcones.[15] This shift in carbonyl frequency also may be associated with a steric inhibition of conjugation between the benzoyl and vinyl groups caused by the presence of the α-amino group.[5]

3-(*p*-Nitrophenyl)-propiophenone shows benzoyl absorption in the ultraviolet at 246 mμ and a slightly less intense band at 274 mμ, possibly to be associated with the nitrophenyl grouping. The ethylenimine derivative XIV showed similar absorption characteristics with an increase in wave length and intensity for the benzoyl and nitrophenyl bands. The infrared carbonyl stretching frequency of the ethylenimine ketone XIV was found at 1680 cm.$^{-1}$ as compared with a value of 1686 cm.$^{-1}$ for 3-(*p*-nitrophenyl)-propiophenone. These ultraviolet and infrared studies imply that hyperconjugation of the three-ring with the carbonyl and *p*-nitrophenyl groups makes a small contribution to both the ground and excited states of XIV, and that it has a *trans* configuration.[5]

The infrared spectrum for the copper chelate XV of *o*-nitrodibenzoylmethane showed the characteristics to be expected of such materials.[17]

Acknowledgment.—This work was supported in part by a grant from the National Science Foundation, N.S.F. G-1091.

Experimental

2,3-Di-*sec*-amino-3-(*o*-nitrophenyl)-propiophenones.—The 2,3-di-N-morpholino- (I), the 2,3-di-N-piperidino- (II) and the 2,3-bis-dimethylamino-3-(*o*-nitrophenyl)-propiophenone (III) were prepared by stirring a suspension of 10 g. (0.0242 mole) of 2,3-dibromo-3-(*o*-nitrophenyl)-propiophenone[4] in 50 ml. of abs. ethanol with 0.097 mole of the corresponding amine for 15 minutes with ice-bath cooling. These reaction mixtures were allowed to stand in the refrigerator for 24 hr. The yellow-orange colored solids were removed by filtration and the filtrates concentrated to yield several more crops. These crude materials were combined in each run, washed with water and recrystallized from benzene–alcohol mixtures using charcoal to decolorize the solutions; see Table I for yields, anal. and m.p. Attempts to isolate α-amino or β-amino α,β-unsaturated ketones from these three reaction mixtures were unsuccessful. These products, I, II and III, also were obtained in slightly lower yields from α-bromo-2-nitrochalcone.[5]

Several attempts to prepare 2-bromo-3-morpholino-3-(*o*-nitrophenyl)-propiophenone by mixing α-bromo-2-nitrochalcone with one molar equiv. of morpholine in dry ether produced only small amounts of the diamino ketone I. Treatment of 2-nitrochalcone with N-bromomorpholine using Southwick's[18] procedure failed to give the α-halo-β-amino ketone in this case, and only small amounts of I could be isolated.

β-Diethylamino-(IV) and β-(N-Methylcyclohexylamino)-2-nitrochalcone (V).—The dibromoketone (0.05 mole) was

[a] The ultraviolet spectra were determined with a Cary model 11 spectrophotometer in the range of 220–450 mμ in 95% ethanol using 10^{-4} molar solutions. [b] The infrared spectra were determined over the range of 4000–600 cm.$^{-1}$ at 25° using 0.10-mm. matched cells with a Perkin–Elmer model 21 instrument and 12–20 mg./ml. CCl_4 solutions, unless otherwise indicated. [c] See W. Black and R. Lutz, THIS JOURNAL, 77, 5134 (1955). [d] Determined as a Nujol mull. [e] Determined with a satd. soln. in CCl_4.

suspended in 100-ml. amounts of abs. ethanol and treated with 0.21 mole of diethylamine and 0.15 mole of N-methylcyclohexylamine, respectively. These reaction mixtures were allowed to stand in the dark at room temperature for two days. The solvent was removed under reduced pressure and the oil–solid residues mixed with 400 ml. of ether. The ether solutions were filtered to remove the by-product amine hydrobromides, washed with water and dried over anhyd. magnesium sulfate. Concentration of these ether solutions by evaporation followed by the addition of petroleum ether, b.p. 30–60°, caused the crystallization of the crude products which were recrystallized from 95% ethanol; see Table I for m.p.'s, yields and analyses. These yellow colored products were obtained in slightly lower yields using α-bromo-2-nitrochalcone in place of the dibromoketone.

2,3-Di-*sec*-amino-3-(*p*-nitrophenyl)-propiophenones.—The 2,3-di-N-morpholino- (VI) and the 2,3-di-N-piperidino-3-(*p*-nitrophenyl)-propiophenone (VII) were prepared by stirring at room temperature for 3 hr., suspensions of 12.39 g. (0.030 mole) of 2,3-dibromo-3-(*p*-nitrophenyl)-propiophenone in 250 ml. of abs. ethanol with 0.120 mole of the corresponding amine. The working up of these reaction mixtures in the usual manner produced both the diamino ketones VI and VII and the corresponding α-amino-α,β-unsaturated ketones, **α-morpholino-*p*-nitrochalcone (VIII) and α-piperidino-*p*-nitrochalcone (IX)**; these products were recrystallized from 95% ethanol, see Table I for yields, m.p.'s and analytical data.

α-Diethylamino-4-nitrochalcone (X) and α-Diethylamino-3-nitrochalcone (XI).—These orange-red products were obtained by mixing 2,3-dibromo-3-(*p*-nitrophenyl)-propiophenone and the *m*-nitrophenyl analog with three molar equivalents of diethylamine in abs. ethanol at ice-bath temperature. The reaction mixtures were allowed to stand for two days at room temperature and the products isolated in the usual manner and recrystallized from 95% ethanol; see Table I for data.

Hydrolysis of β-Amino and α-Amino-α,β-unsaturated Ketones.—(a) **β-Diethylamino-2-nitrochalcone (IV)** (1.0 g.) was refluxed for 16 hr. in 20 ml. of 15% sulfuric acid. The acid solution was extracted with ether and made basic with sodium hydroxide to recover 0.49 g. of IV. Evaporation of the ether extract and recrystallization from 95% ethanol produced 0.090 g. (22% yield) of *o*-nitrodibenzoylmethane,[19] m.p. 115–116°. This product gave a deep-red color with alcoholic ferric chloride.

A 0.05-g. sample of *o*-nitrodibenzoylmethane was dissolved in 10 ml. of 50% acetone–water and treated with a saturated solution of cupric acetate in 50% acetone–water. **The bis-[1-(*o*-nitrophenyl)-3-phenyl-1,3-propanedione]-copper** was filtered from the solution and recrystallized from dioxane and benzene; m.p. 287–288°, wt. 0.045 g. (80% yield).

Anal. Calcd. for $C_{31}H_{21}N_2O_8Cu$: Cu, 10.58. Found: Cu, 10.69.

A 0.025-g. sample of *o*-nitrodibenzoylmethane was dissolved in 5 ml. of 1:1 alcohol–chloroform and one molar equivalent of phenylhydrazine and a drop of gl. acetic acid added. The mixture was warmed and allowed to stand at

room temperature for a day. The yellow crystalline product was recrystallized from 95% ethanol, 0.02 g. (63% yield), m.p. 178–180°. This product was identical with an authentic sample of 1,3-diphenyl-5-(*o*-nitrophenyl)-pyrazole.[6]

(b) β-(N-Methylcyclohexylamino)-2-nitrochalcone (V) was hydrolyzed in a similar manner, as in (a), to produce a 47% yield of *o*-nitrodibenzoylmethane. Almost half of the starting material was recovered after 12 hr. of reflux with 15% sulfuric acid.

(c) α-Diethylamino-4-nitrochalcone (X) (1.0 g.) was refluxed for 6 hr. with 20 ml. of 15% sulfuric acid and the reaction mixture cooled and extracted with ether. Evaporation of the ether extract produced an oily solid which was recrystallized from 95% ethanol after decolorizing with charcoal; m.p. 119–120°, wt. 0.70 g. (84.5% yield), *p-nitrobenzylphenyl diketone* (XII).

Anal. Calcd. for $C_{15}H_{11}NO_4$: C, 66.91; H, 4.12. Found: C, 67.09; H, 4.34.

A 0.027-g. (0.001 mole) sample of XII was heated for a few minutes with 0.108 g. (0.001 mole) of *o*-phenylendiamine in 5 ml. of abs. ethanol. Cooling the mixture produced 2-(*p*-nitrobenzyl)-3-phenylquinoxaline (XIII); recrystallized from 95% ethanol, m.p. 124–125°, wt. 0.292 g. (86% yield).

Anal. Calcd. for $C_{21}H_{15}N_3O_2$: C, 73.89; H, 4.43; N, 12.31. Found: C, 74.09; H, 4.29; N, 12.78.

(c) α-Diethylamino-3-nitrochalcone (XI) (1.0 g.) was refluxed with 20 ml. of 15% sulfuric acid for 3 hr., cooled and extracted with ether. Evaporation of the ether gave an oil which was dissolved in 5 ml. of abs. ethanol and warmed with 0.329 g. of *o*-phenylenediamine. Cooling produced 2-(*m*-nitrobenzyl)-3-phenylquinoxaline,[12] recrystallized from 95% ethanol, m.p. 120–121.5°, wt. 0.83 g. (78% yield).

2-(*p*-Nitrophenyl)-3-benzoylethylenimine (XIV).—A 4.13-g. (0.010 mole) sample of 2,3-dibromo-3-(*p*-nitrophenyl)-propiophenone was suspended in 50 ml. of abs. ethanol and the mixture saturated with anhydrous ammonia and allowed to stand in the dark at room temperature for one week. The dibromide dissolved in about three days. The solvent was removed under reduced pressure and the residue mixed with water and extracted with ether. Evaporation of the ether and recrystallization of the oily residue from 95% ethanol produced 2.23 g. (78% yield) of XIV, m.p. 142–143°. This product appears to be identical with that reported by Wieland[7] as either the ethylenimine ketone or a dimer having a piperazine structure, which he preferred. A mol. wt. determination by the cryoscopic method showed the structure of this product actually to be XIV.

No other identifiable products could be isolated from this reaction mixture.

meso-Dihydroguaiaretic Acid and its Derivatives[2]

BY ANTHONY W. SCHRECKER

RECEIVED FEBRUARY 28, 1957

The contaminant of crude guaiaretic acid (I, R = H) has been identified as *meso*-dihydroguaiaretic acid (II, R = H). II (R = Me) and its DL-isomer have been synthesized by a stereospecific method. The infrared spectra of diastereoisomers in this series are discussed.

Guaiaretic acid (I, R = H), a key compound in the elucidation of the absolute configuration of lignans,[3] occurs in *Guaiacum officinale* L.[4] together with a number of related compounds.[5] Its isolation has, however, been complicated by the presence of a contaminant, which lowers the optical rotation of the crude product and from which it is not readily separated. Schroeter, who was the first to obtain pure I (R = H) (m.p. 99–100.5°, $[\alpha]_D$ −94° in ethanol),[6] informed Haworth[7] that his crude material was contaminated with an optically active (IIIa, R = H) and an inactive dihydro derivative of I (R = H), both of which occurred naturally in Guaiac resin; however, he never published these findings. He had previously prepared the dimethyl ethers of these dihydro compounds by reduction of I (R = Me) and assigned the *meso* configuration (II, R = Me) to the inactive ether, m.p. 100–101°, because of its mode of formation and because its diamino derivative could not be resolved.[6] Haworth,[7] however, prepared the same compound, m.p. 101–102°, by reduction of synthetic (DL)-I (R = Me) and named it "*dl*-dihydroguaiaretic acid dimethyl ether." He and Cartwright[8] later isolated I (R = Ac) and one of its dihydro derivatives from Guaiac resin after acetylation, but reported no optical rotations.[9]

Although it is generally assumed[4] that Schroeter's inactive dimethyl ether does possess the *meso* rather than the DL-configuration, confirmatory proof was desired. This was accomplished by a stereospecific synthesis of both II and IIIb (R = Me). In addition, the contaminant that lowers the rotation of crude I (R = H) was identified as its

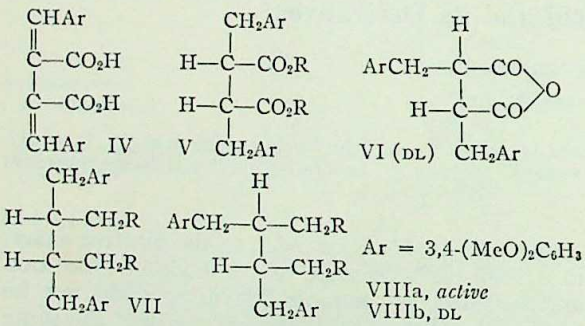
meso-dihydro derivative II (R = H), while none of the diastereoisomeric IIIa (R = H) could be detected. The present paper deals with these findings.

Haworth and Woodcock[10] have shown that reduction of diveratrylidenesuccinic acid (IV) afforded *meso*-diveratrylsuccinic acid (V, R = H), which was converted to DL-diveratrylsuccinic anhydride (VI) by heating with acetic anhydride. The configurational assignments are correct because careful saponification of VI yielded an acid which was different from V (R = H) and which could be resolved.[10] *meso*-2,3-Diveratryl-1,4-butanediol (VII, R = OH), previously obtained[11] by lithium aluminum hydride reduction of isomataireresinol dimethyl ether, has now been prepared from V (R = H or Me) by the same method. Following the procedure employed in the synthesis of IIIa (R = Me),[12] the ditosylate VII (R = OTs) was converted to II (R = Me), which melted at 101.5–102° and was identical with the known inactive dihydroguaiaretic acid dimethyl ether. Therefore, the latter is definitely *meso*. VI was converted similarly, *via* VIIIb (R = OH and OTs), to DL-dihydroguaiaretic acid dimethyl ether (IIIb, R = Me), m.p. 70.4–71.2°.



The preparation of guaiaretic acid from Guaiac resin *via* the sodium salt by Schroeter's procedure[6] led to a product, m.p. 83–86°, $[\alpha]_D$ −48 to −51° (ethanol), from which pure I (R = H), m.p. 100.8–101.3°, $[\alpha]_D$ −91°, was obtained in low yield by repeated recrystallizations from ethanol. Attempts to separate the mixture by chromatography on silica or alumina failed. *meso*-Dihydroguaiaretic acid (II, R = H), m.p. 87–88°, was isolated by recrystallizing the crude sodium salt repeatedly from dilute ethanol; its dimethyl ether, m.p. 101.9–102.2°, was identical with the product prepared from VII (R = OTs). The crude phenol yielded a mixed dimethyl ether, $[\alpha]_D$ −51 to −54°, which would indicate the presence of 54–57% of I (R = Me) if the sole contaminant was II (R = Me). Since the percentage of unsaturated material, determined by hydrogen uptake, was about the same, the presence of the levorotatory IIIa (R = Me)[6,12] in any appreciable amount was unlikely.

Different lots of commercial Guaiac resin varied considerably in quality[4a]; this made it difficult to obtain reproducible results. In subsequent experiments, therefore, *Guaiacum* heartwood was extracted by King and Wilson's[5] procedure. Pure I (R = H), identical in its properties with the compound isolated from the resin, was obtained by fractional recrystallization of the crude phenol. Pure II (R = Me or Ac, resp.), devoid of optical activity, was isolated by methylating or acetylating the material remaining in the mother liquors, then oxidizing the residual I. Saponification of II (R = Ac) afforded II (R = H), m.p. 87.8–88.6°. No trace of any derivative of IIIa could be detected.[13] This demonstrates the presence of II (R = H) in *Guaiacum officinale* L. and shows that it is the contaminant of crude guaiaretic acid.[14]

Infrared Spectra.—Solutions of diastereoisomers, as contrasted with those of enantiomers, generally do not possess identical infrared spectra.[17] The diastereoisomeric dihydrosmilagenin and dihydrosarsasapogenin, chloroform solutions of which exhibit essentially identical spectra,[18] are an exception to this rule. Similarly, the infrared spectra of II (R = Me), its dibromo and dinitro derivative,[19] and of the ditosylate VII (R = OTs) in chloroform solution differ from those of the corresponding diastereoisomers by only one or two minor bands (Fig. 1).[21] Interaction of the polar hydroxyl groups in the diols VII and VIII (R = OH) leads to somewhat larger differences. In all these compounds, free rotation between the asymmetric centers is possible. When free rotation is prevented by cyclization, the infrared spectra show pronounced differences in the 9–12.5 μ region, as in the case of the tetrahydrofurans VII and VIII (RR = O).

Experimental[22]

Veratrylidenesuccinic acid, prepared in 51–53% yield according to Horning and Walker,[23] melted at 172.5–173.5° dec. (lit. 169–171.5°,[23] 175°[24]). The dimethyl ester was obtained[25] by refluxing 30 g. of the acid with 450 ml. of

(12) A. W. Schrecker and J. L. Hartwell, THIS JOURNAL, **77**, 432 (1955).
(13) This negative evidence renders the presence of (−)-dihydroguaiaretic acid (IIIa, R = H) (*cf.* ref. 7) unlikely, but does not exclude it definitively.
(14) The "guaiaretic acid" isolated by Doebner[15] and Herzig[16] was probably impure II (R = H); this follows from their methods of isolation and from the melting points of the substance and its derivatives.

(19) The positions of the substituents in the dibromo and dinitro derivatives (Fig. 1) are postulated by analogy with the known bromination and nitration products of 3,4-dimethoxytoluene and 3,4-dimethoxypropylbenzene.[20]
(20) H. Thoms, *Ber.*, **36**, 854 (1903); T. G. H. Jones and R. Robinson, *J. Chem. Soc.*, **111**, 903 (1917).
(21) Only the 9–12.5 μ region is illustrated because the spectra of the *meso* compounds and the corresponding diastereoisomers were entirely identical in the 2–9 μ region. As expected,[17] the solution spectra of the optically active and DL-isomers were completely identical, while the Nujol mull spectra of the *meso* compounds were quite different from those of their diastereoisomers.
(22) Melting points were determined in Pyrex capillaries and are corrected. Infrared spectra were obtained with a Perkin–Elmer model 21 spectrometer; 0.1-mm. sodium chloride cells were used for chloroform solutions. Optical rotations were measured with 1.5% solutions in ethanol, unless specified otherwise.

methanol and 18 ml. of concd. sulfuric acid for 6 hr. and removing 360 ml. of the solvent by distillation. The chilled residue was treated with ether and ice-water, and the ether phase was washed with water and sodium carbonate solution, dried and evaporated. Distillation yielded 26.4 g. (80%) of pale yellow oil, b.p. 188–192° (0.5 mm.).

Anal. Calcd. for $C_{15}H_{18}O_6$: C, 61.21; H, 6.17; OCH_3, 42.18. Found: C, 61.39; H, 6.47; OCH_3, 42.22.

Diveratrylidenesuccinic Acid (IV).—The published procedure[24] resulted in a very low yield, while other attempts[10] to isolate the compound failed. The following method gave reproducible results. A suspension of 21.4 g. of 93.6% sodium methoxide in 100 ml. of dry ether was treated with stirring in an ice-bath with a mixture of 46.1 g. of veratraldehyde, 24.2 g. of ethyl succinate and 150 ml. of ether dropwise during 1 hr., stirred in the ice-bath for another hour and kept at room temperature overnight. Ether was then distilled off while 300 ml. of absolute ethanol was added gradually to maintain the volume of liquid. Distillation was continued, with removal of 400 ml. of solvent, while 150 ml. of water was added in portions. The solution was cooled, diluted with water to about 300 ml. and neutralized to *p*H 7 with hydrochloric acid. Dark impurities were extracted with chloroform, and the solution was made strongly acid. The yellow gum was extracted repeatedly with boiling water until it became crystalline, in order to remove monoveratrylidenesuccinic acid. Digesting the dried solid with 150 ml. of boiling ethyl acetate and cooling provided 15.2 g. (26%) of yellow solid, m.p. 213–215° dec. A similar run yielded 22% of material, m.p. 217–219° dec. (lit.[24] 220°).

IV also was obtained from 12.95 g. of veratraldehyde, 22.9 g. of dimethyl veratrylidenesuccinate and 4.77 g. of sodium in 110 ml. of ethanol by the general method of Horning and Walker.[23] The reaction mixture was neutralized with 26 ml. of 2 *N* hydrochloric acid, extracted with chloroform and made strongly acid. The yellow solid, digested with 150 ml. of boiling ethyl acetate, yielded 26.1 g. (81%) of IV, m.p. 217° dec. Refluxing the acid with acetyl chloride[24] gave **diveratrylidenesuccinic anhydride**, yield 92%, orange-red plates from benzene, m.p. 172–173° (lit.[24] 172–173°).

***meso*-Diveratrylsuccinic acid (V, R = H)**, previously obtained[10] by sodium-amalgam reduction of a reaction mixture containing IV, was prepared more conveniently by reducing 10.76 g. of IV in 320 ml. of 10% sodium hydroxide with 32 g. of Raney nickel–aluminum alloy at 90°.[26] The crude acid was redissolved in dilute sodium hydroxide and reprecipitated by stirring the solution into dilute hydrochloric acid; yield 10.78 g. (99%), m.p. 198–215°. Recrystallization from glacial acetic acid afforded 6.14 g. (57%) of colorless needles, m.p. 222–223° dec. (lit.[10] 223–224°).

V was also prepared by hydrogenating 15.1 g. of IV in 78 ml. of *N* sodium hydroxide with 3 g. of W-7 Raney nickel catalyst[27] at 80° and 1000 p.s.i. for 18 hr. The filtrate was acidified and the precipitate recrystallized from glacial acetic acid; yield 9.37 g. (62%), m.p. 221–222° dec.

Dimethyl *meso*-Diveratrylsuccinate (V, R = Me).—A suspension of 3.12 g. of V (R = H) in 30 ml. of acetone and 30 ml. of methanol was treated with ethereal diazomethane (distilled from 8.2 g. of nitrosomethylurea), kept for 24 hr., evaporated and the residue dissolved in chloroform. The solution was washed with aqueous sodium bicarbonate and sodium chloride, dried and concentrated with addition of ethanol to yield 3.06 g. (92%) of colorless needles, m.p. 142.2–143.5°. A sample, chromatographed on neutral alumina, eluted with chloroform and recrystallized from ethanol, melted at 143.2–143.7°.

Anal. Calcd. for $C_{24}H_{30}O_8$: C, 64.56; H, 6.77; OCH_3, 41.70. Found: C, 64.61; H, 6.85; OCH_3, 41.60.

DL-Diveratrylsuccinic anhydride (VI)[10] crystallized from benzene–hexane in rosettes of colorless prisms, m.p. 111–113° (lit.[10] 110–112°).

***meso*-2,3-Diveratryl-1,4-butanediol (VII, R = OH)** was prepared by the procedure employed for analogous diols,[12] except that the diacid (V, R = H) (2.0 g.) or the diester (V, R = Me) (2.8 g.) was added directly to an ice-cold suspension of lithium aluminum hydride (2.0 g.) in tetrahydrofuran, which was then stirred at room temperature for 3 hr., refluxed in the case of the acid for 0.5 hr. and decomposed as usual.[12] The residue obtained from the combined filtrate and ethanol extract was dissolved in ethyl acetate and the solution washed with water, dried, concentrated and diluted with hexane. Scratching caused slow separation of colorless rhombic plates; yields 62 and 75%, m.p.'s 90–92° and 91–93°, respectively, from V (R = H) and V (R = Me). Recrystallization from ethyl acetate–hexane afforded a product, m.p. 93.1–94.0°, unchanged after further recrystallization. Haworth and Wilson[11] report prisms, m.p. 94–95° for the same compound, prepared by reduction of isomatairesinol dimethyl ether.

Anal. Calcd. for $C_{22}H_{30}O_6$: C, 67.67; H, 7.74. Found: C, 67.68; H, 7.53.

Heating the diol with potassium hydrogen sulfate[11] gave ***meso*-3,4-diveratryltetrahydrofuran (VII, RR = O)**, which

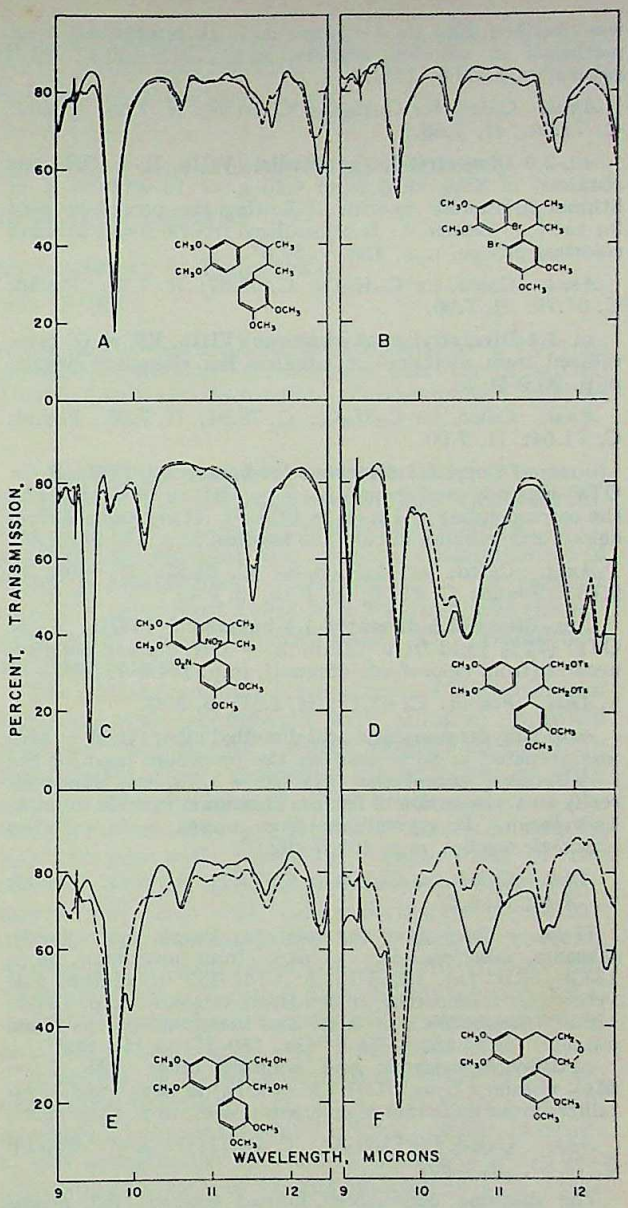

Fig. 1.—Infrared absorption spectra in chloroform of the optically active (————) and *meso* (— — —) isomers of: A, dihydroguaiaretic acid dimethyl ether; B, dibromo-A; C, dinitro-A; D, ditosyl-2,3-diveratryl-1,4-butanediol; E, 2,3-diveratryl-1,4-butanediol; F, 3,4-diveratryltetrahydrofuran.

was purified like its (−)-isomer.[12] It crystallized from methanol in colorless leaflets, m.p. 120.0–120.4° (lit.[11] prisms, m.p. 114–115°).

Anal. Calcd. for $C_{22}H_{28}O_5$: C, 70.94; H, 7.58. Found: C, 71.14; H, 7.68.

DL-2,3-Diveratryl-1,4-butanediol (VIIIb, R = OH) was obtained in 88% yield from 4.10 g. of VI and 3.1 g. of lithium aluminum hydride, following the procedure used for the (−)-isomer.[12] It crystallized from benzene in small colorless prisms, m.p. 128.7–129.6°.

Anal. Calcd. for $C_{22}H_{30}O_6$: C, 67.67; H, 7.74. Found: C, 67.79; H, 7.96.

DL-3,4-Diveratryltetrahydrofuran (VIIIb, RR = O) crystallized from methanol in colorless flat elongated prisms, m.p. 90.0–90.5°.

Anal. Calcd. for $C_{22}H_{28}O_5$: C, 70.94; H, 7.58. Found: C, 71.04; H, 7.90.

meso-Ditosyl-2,3-diveratryl-1,4-butanediol (VII, R = OTs) was prepared from VII (R = OH) in 96% yield like the corresponding VIIIa (R = OTs).[12] It crystallized from chloroform–ethanol in colorless needles, m.p. 140.5–141.0°.

Anal. Calcd. for $C_{36}H_{42}O_{11}S_2$: C, 61.87; H, 6.06; S, 9.18. Found: C, 61.76; H, 6.15; S, 9.46.

DL-Ditosyl-2,3-diveratryl-1,4-butanediol (VIIIb, R = OTs) (77% yield from VIIIb, R = OH) formed colorless needles (from chloroform–ethanol), m.p. 174.5–175.5°.

Anal. Found: C, 62.12; H, 6.17; S, 8.83.

meso-Dihydroguaiaretic acid dimethyl ether (II, R = Me) was prepared in 83% yield by the procedure used for the (−)-isomer,[12] except that VII (R = OTs) was added directly to a suspension of lithium aluminum hydride in tetrahydrofuran. It crystallized from methanol in colorless prismatic needles, m.p. 101.5–102.0°.

Anal. Calcd. for $C_{22}H_{30}O_4$: C, 73.71; H, 8.44. Found: C, 73.74; H, 8.62.

II (R = Me) gave the following known derivatives[19]: **dibromo**, colorless silky needles (from methanol), m.p. 133.3–133.9° (lit. 130.5–131.5°,[6] 131–132°[7]); **dinitro**, pale yellow flat transparent prisms (from ethanol), m.p. 138.2–138.9° (metastable), or cubic and hexagonal prisms (from ethanol), m.p. 152.9–153.6° (lit. 150–151°,[6] 151–152°[7]).

DL-Dihydroguaiaretic acid dimethyl ether (IIIb, R = Me), obtained from VIIIb (R = OTs) in 81% yield, crystallized from methanol in colorless prisms, m.p. 70.4–71.2°.

Anal. Calcd. for $C_{22}H_{30}O_4$: C, 73.71; H, 8.44. Found: C, 73.83; H, 8.30.

The dibromo derivative[19] formed colorless flat prisms (from methanol), m.p. 104.0–104.8°.

Anal. Calcd. for $C_{22}H_{28}Br_2O_4$: C, 51.18; H, 5.47; Br, 30.96. Found: C, 51.16; H, 5.35; Br, 30.91.

The dinitro derivative,[15] pale yellow flat prisms from chloroform–ethanol, melted at 181.1–181.9°.

Anal. Calcd. for $C_{22}H_{28}N_2O_8$: C, 58.92; H, 6.29; N, 6.25. Found: C, 58.75; H, 6.07; N, 6.05.

The following known derivatives were prepared from (−)-dihydroguaiaretic acid dimethyl ether[12] (IIIa, R = Me) and recrystallized from methanol: dibromo, colorless shiny flat prisms, m.p. 122.5–123.0° (lit.[6] 121–122°); dinitro, lemon-yellow flat prisms, m.p. 124.0–124.8° (lit.[6] 122–123°).

Guaiaretic Acid (I, R = H). (a) From Guaiac Resin.—The sodium salts (60–61 g.), obtained from 450 g. of resin[28] by Schroeter's procedure,[6] were suspended in 300 ml. of hot methanol and treated with 30 ml. of glacial acetic acid. The mixture was filtered (Celite) and the residue washed with 100 ml. of methanol. The filtrate and washings, diluted with 250 ml. of water, abandoned 34–35 g. of colorless flakes, m.p. 83–86°, $[\alpha]^{20}D$ −48 to −51°.[29] This crude phenol (11 g.), recrystallized thrice from ethanol, afforded 1.3 g. of I (R = H), m.p. 100.8–101.3° (lit. 100–101°,[5] 99–100.5°[6]), $[\alpha]^{20}D$ −91° (lit. −91°,[5] −94°[6]).

(b) From the Heartwood.[5]—The material soluble in both hot hexane and methanol (278 g.)[30] from 45.4 kg. of *Guaiacum officinale* L. wood chips was treated with 800 g. of 5% sodium hydroxide. The precipitate was collected after 64 hr. and additional sodium salt obtained by increasing the alkali concentration to 7%. The salts were washed with 7% sodium hydroxide and acetone, suspended in water and decomposed with carbon dioxide. The mixed phenols (120 g.) were recrystallized first from 3.5 l. of hexane (yield 87 g., $[\alpha]D$ −61°), then from 65% methanol (by vol.) (yield 75 g., $[\alpha]D$ −67°) and finally several times from 1.3 vol. of ethanol (thorough chilling, systematic recrystallization of second and third crops). The yield of pure I (R = H), m.p. 100.8–101.4°, $[\alpha]^{22}D$ −91°, was 29 g.

Methylation[6] of I (R = H), followed by chromatography on alumina, elution with chloroform and crystallization from ethanol, provided **guaiaretic acid dimethyl ether** (I, R = Me), colorless prismatic needles, m.p. 92.3–92.8° (lit.[6] 94–95°), $[\alpha]^{22}D$ −94° (*c* 1.00) (lit.[5,6] −92°).

Refluxing 1.0 g. of I (R = H) with 5 ml. of acetic anhydride and 1 g. of sodium acetate for 1 hr. and treating the mixture with water yielded 1.23 g. (98%) of **diacetylguaiaretic acid** (I, R = Ac), m.p. 83–85°, which after chromatography as above and recrystallization from aqueous methanol formed colorless prisms, m.p. 84.0–85.0° (lit.[8] 86–87°), $[\alpha]^{20}D$ −66°.

Anal. Calcd. for $C_{24}H_{28}O_6$: C, 69.88; H, 6.84. Found: C, 69.89; H, 7.04.

meso-Dihydroguaiaretic Acid (II, R = H). **(a) From the Resin.**—The mixed sodium salts[6] (24.6 g.) were recrystallized thrice from aqueous ethanol, decomposed with acetic acid in methanol, and the product (5.4 g.) was recrystallized from 60% methanol (by vol.) to yield 4.2 g. of colorless rectangular plates, m.p. 87–88°, $[\alpha]^{20}D$ −0.1 ± 0.1°.

Anal. Calcd. for $C_{20}H_{26}O_4$: C, 72.70; H, 7.93. Found: C, 72.44; H, 7.86.

Methylation[6] and chromatography afforded **II (R = Me)**, colorless prismatic needles (from methanol), m.p. 101.9–102.2°, no depression with a sample prepared from VII (R = OTs).

(b) From the Wood.—The hexane, aqueous methanol and ethanol mother liquors from the purification of I (R = H) were evaporated, and a portion of the residual mixed phenols was methylated. The mixed dimethyl ethers were treated with peracetic acid in acetic acid at room temperature to oxidize I (R = Me). The solution was diluted with water, extracted with benzene, and the extract was washed with alkali, dried and chromatographed on alumina. Elution with benzene and crystallization from aqueous methanol afforded II (R = Me), m.p. 101.4–102.1° (no depression with a sample prepared from VII, R = OTs), $[\alpha]^{22}D$ +0.1 ±0.1° (*c* 8.0, chloroform). No IIIa (R = Me) ($[\alpha]D$ −31° in chloroform[12]) could be detected.

Another portion of the residual phenols was acetylated and the product dissolved in benzene and treated with osmium tetroxide and pyridine.[3] The mixture was chromatographed on alumina, which retained preferentially the black osmate complex formed from I (R = Ac). Elution with benzene and crystallization from ethanol provided ***meso*-diacetyldihydroguaiaretic acid** (II, R = Ac), m.p. 115.2–116.0° (lit.[8] 112°), $[\alpha]^{19}D$ −0.04 ± 0.05° (*c* 4.0, chloroform). No other compound could be detected in the mother liquor.

Anal. Calcd. for $C_{24}H_{30}O_6$: C, 69.54; H, 7.30. Found: C, 69.46; H, 7.05.

Saponification of II (R = Ac) with potassium hydroxide in 50% ethanol afforded II (R = H) as small elongated plates (from 60% methanol), m.p. 87.8–88.6°.

Acknowledgments.—The author is greatly indebted to Dr. Frederick E. King of British Celanese Ltd., London, for a summary of his procedure[5] in advance of publication and other valuable suggestions, and to Dr. E. F. Woodward of S. B. Penick & Co., New York, for his collaboration in

(28) Glassy Select Guaiac Gum N.F., S. B. Penick & Co., New York, N. Y.

(29) Other lots gave much lower yields. Methylation[6] of the crude phenol provided a mixed dimethyl ether, m.p. 93.5–94.5°, $[\alpha]^{20}D$ −51 to −54° (*c* 1).

The Absolute Configuration of Lignans[2]

BY ANTHONY W. SCHRECKER AND JONATHAN L. HARTWELL

RECEIVED FEBRUARY 16, 1957

Guaiaretic acid dimethyl ether (I) has been correlated stereochemically with L-3,4-dihydroxyphenylalanine (VI) *via* (−)-4-(3,4-dimethoxyphenyl)-3-methyl-2-butanone (II), (−)-3,4-dimethoxy-α-methylhydrocinnamic acid (III, X = OH) and (−)-3,4-dimethoxy-α-methylphenethylamine (IV). I, II, III and IV belong to the D-series. This establishes the absolute configuration of a number of naturally-occurring lignans.

The stereochemical correlation of guaiaretic acid dimethyl ether[3] (I)[4] with (−)-3,4-dimethoxy-α-methylhydrocinnamic acid[7] (III, X = OH) has been reported in a preceding communication.[8] The enantiomer of III (X = OH) has the same sign and about the same magnitude of rotation as (+)-α-methylhydrocinnamic acid,[7,9] which by the Curtius degradation[7,10,11] yields the same (+)-α-methylphenethylamine that has been obtained[12,13] from D-phenylalanine. This led us to postulate that III, and hence I, possess the absolute D-configuration.[14]

A more rigorous demonstration than this proof by analogy has now been accomplished by correlating III with L-3,4-dihydroxyphenylalanine (VI), a natural amino acid, the absolute configuration of which is established.[17] The object of the present report is to present these new findings and the experimental details missing from our preliminary communication.

The osmate complex formed from I with osmium tetroxide was decomposed with alkaline mannitol solution,[18] a procedure which proved to be more satisfactory than reductive decomposition with alkaline formaldehyde.[19] The crude diol thus obtained, presumably a mixture of diastereoisomers, was cleaved with periodate. Separation of the oily (−)-4-(3,4-dimethoxyphenyl)-3-methyl-2-butanone (II), $[\alpha]_D$ −35° (chloroform), from veratraldehyde was accomplished with Girard reagent. A number of pilot experiments showed that this treatment did not cause any detectable racemization.[20] II was characterized by its semicarbazone, m.p. 159.5–160°, $[\alpha]_D$ −48° (chloroform).

Reaction of (−)-3,4-dimethoxy-α-methylhydrocinnamoyl chloride[7] (III, X = Cl) with a nearly equivalent amount of methylmagnesium bromide at low temperature afforded a mixture from which the semicarbazone of II was isolated in 17% yield. The product rotated −47.5° (chloroform) and proved to be identical with the semicarbazone obtained from I. The optical antipode of II, again isolated as the semicarbazone, $[\alpha]_D$ + 47°, was similarly derived from the enantiomer of III (X = Cl). Reaction of the acid chloride with dimethylcadmium,[21] while affording better yields (up to 46%), was always accompanied by partial racemization.

The Curtius degradation of III (X = Cl) to (−)-3,4-dimethoxy-α-methylphenethylamine[7] (IV) proves[11] that IV and III (and hence I and II) have identical configurations. IV and VI were corre-

(13) Retention of configuration in lithium aluminum hydride reductions has been demonstrated by D. S. Noyce and D. B. Denney, THIS JOURNAL, **72**, 5743 (1950).

(14) The assignment of the D-configuration to I, II, III, IV and V conforms to the convention proposed by Klyne and by McCasland,[15] according to which formulas are drawn so that the lower-numbered end of the chain[16] is at the top. The prefix "D" then refers to the fact that the reference group[15b] is to the right. VI, VII, VIII, IX and X are L in agreement with the nomenclature conventionally[5] used for amino acids and their derivatives. The shift from L to D in the conversion of X to V does not represent an actual change of configuration but is simply a matter of nomenclature. In X, the NHTs group is the reference group,[15b] while it becomes the chief function[16] and CH_3 becomes the reference group in V. Formula V (first series of formulas) is derived from V (second series) by a double interchange of substituents; therefore, both formulas represent an identical configuration.

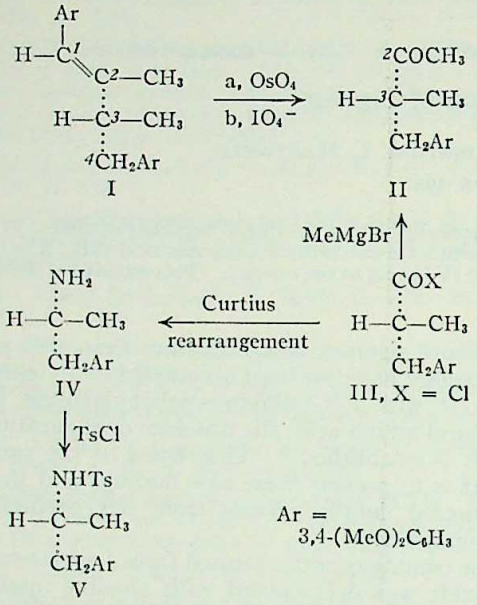
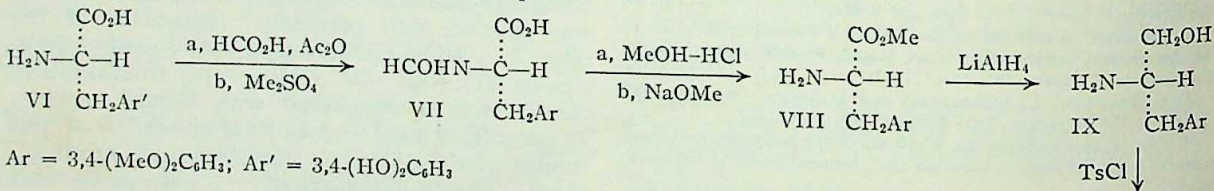
lated by a series of steps adapted from analogous reactions used in the phenylalanine and tyrosine series. Formylation[22] and methylation[23] of VI



provided *N*-formyl-L-3,4-dimethoxyphenylalanine (VII), m.p. 125–126°, $[\alpha]_D$ +72° (ethanol). Simultaneous[24] removal of the formyl group and



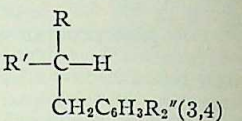
Ar = 3,4-$(MeO)_2C_6H_3$; Ar′ = 3,4-$(HO)_2C_6H_3$

esterification by means of methanolic hydrogen chloride yielded L-3,4-dimethoxyphenylalanine methyl ester (VIII) hydrochloride, m.p.158 –159° dec., $[\alpha]_D$ +7° (methanol). Reduction of VIII with lithium aluminum hydride[13,25] afforded L-3,4-dimethoxyphenylalaninol (IX), m.p. 79–80°, $[\alpha]_D$ −21.5° (ethanol), the *O,N*-ditosylate X, $[\alpha]_D$ −58° (ethanol), of which was further reduced[12] to *N*-tosyl-D-3,4-dimethoxy-α-methylphenethylamine[14] (V), m.p. 75.6–76.6°, $[\alpha]_D$ −29° (ethanol). Since IV yielded by direct tosylation the same levorotatory tosylate V, its absolute D-configuration,[14] and hence that of III, II and I is demonstrated unequivocally.

This result confirms the configurations previously[8] derived from rotational values. The assumption that introduction of phenolic ether groups into a benzene ring not directly attached to the asymmetric center would not greatly influence the sign and value of the optical rotation is in agreement with Tchúgaeff's rule.[26] Comparative rotational data on several phenyl and 3,4-dimethoxyphenyl derivatives, the configuration of which is pertinent to the present investigation, are shown in Table I.

TABLE I

SPECIFIC AND MOLECULAR ROTATIONS OF COMPOUNDS OF THE TYPE



R	R′	$[\alpha]_D$, degrees R″ = H	$[\alpha]_D$, degrees R″ = OMe	$[M]_D$, degrees R″ = H	$[M]_D$, degrees R″ = OMe	Solvent

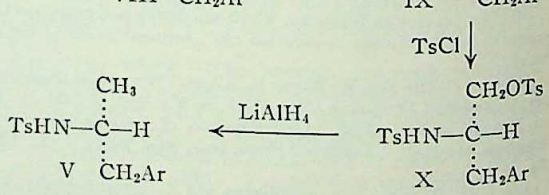
[a] Ref. 22. [b] Ref. 25. [c] Calculated from the reported rotation of the enantiomer. [d] Ref. 12. [e] W. Leithe, *Ber.*, **65**, 660 (1932). [f] Ref. 9b. [g] Ref. 7.

Discussion of the stereochemistry of I is not complete without mentioning the arrangement of the substituents about the ethylenic linkage. The *trans* configuration of sphingosine has been proved[27] by application of Bruni's rule.[28] By a similar reasoning it appears very likely that the hydrogen at C_1 and the methyl group at C_2 are *trans* in I. Indeed, *meso*-dihydroguaiaretic acid dimethyl ether[3] and I are isomorphous, as shown in Fig. 1, and hence the shape of their molecules should be very similar.



The relative configuration of a number of naturally-occurring lignans,[29] especially diarylbutanes (matairesinol, hinokinin, savinin) and 4-aryltetralins (conidendrin, podophyllotoxin, desoxypodophyllotoxin, α- and β-peltatin, galbulin), is now established; in addition it has been demonstrated that they possess the same configuration at C_3 as I.[30] The present findings, therefore, establish their absolute configuration.[31] The configuration

(31) The formulas previously published by us[30] to show the relative configurations of a number of lignans also happen to represent their absolute configurations. These formulas were drawn according to Linstead's "black dot" convention,[32] in which a black dot indicates that the hydrogen atom is above (or in front of) the molecule. In the Klyne and McCasland convention,[15] rings are drawn edgewise, so that the right side (numbered 1, 2, 3, 4) represents the front edge; the configuration at an asymmetric atom is then D, if the reference group[15b] is to the right. Thus a "black dot" indicates a D-configuration at the corresponding asymmetric center.[33]

Digitized by Arya Samaj Foundation Chennai and eGangotri

of tetrahydrofuran derivatives, such as lariciresinol and pinoresinol, is not yet known in all the details, but that at two of their asymmetric carbon atoms also has been correlated with I[30,34] and now can also be expressed in absolute terms. Thus the stereochemistry of another important class of natural products has largely been elucidated.

Experimental[36,37]

D-(−)-4-(3,4-Dimethoxyphenyl)-3-methyl-2-butanone (II). (a) From Guaiaretic Acid Dimethyl Ether[3] (I).—A solution of 2.80 g. of I, m.p. 92.3–92.8°, $[\alpha]^{22}D$ −94° (*c* 1.00, ethanol), in 75 ml. of dry ether and 1.4 ml. of dry pyridine[18] was kept with 2.08 g. of osmium tetroxide in 75 ml. of dry ether for 24 hr. at room temperature and the supernatant decanted from the black resin. Vacuum-evaporation provided a small amount of additional complex. The combined residues in 40 ml. of methylene chloride were shaken with 16 g. of mannitol and 5.33 g. of potassium hydroxide in 160 ml. of water for 1.5 hr., and the organic layer was washed with 0.5 *N* sulfuric acid, 0.5 *N* sodium hydroxide, then worked up.[37] The yellow gum, presumably a mixture of diastereoisomeric glycols, could not be crystallized. Its solution in 40 ml. of methanol was kept with 2.52 g. of sodium metaperiodate and 0.71 ml. of glacial acetic acid in 60 ml. of water at room temperature during 2 hr., diluted with more water and extracted with chloroform four times. The extracts were washed with aqueous sodium bicarbonate and evaporated.[37] The residual yellow oil (3.06 g.) was refluxed with 8.0 g. of Girard reagent P,[38] 8.0 ml. of glacial acetic acid and 106 ml. of methanol for 1 hr., the solution cooled, poured into an ice–water slurry (about 570 ml.) containing 6.66 g. of sodium carbonate and extracted twice with ether. The aqueous phase was then treated with 100 ml. of 8 *N* sulfuric acid, covered with 200 ml. of ether and kept with frequent shaking during 0.5 hr. It was then extracted twice with additional ether (150 + 100 ml.), and the extracts were washed with 0.5 *N* sulfuric acid and sodium bicarbonate.[37] The pale oil thus obtained (1.87 g., 107%) was further purified by repeating the treatment with Girard reagent P.[39] Distillation in a bulb tube assembly[40] provided 1.51 g. (86.5%) of colorless oil, b.p. 95° (air-bath temperature) (0.005 mm.), $n^{20}D$ 1.5252, $[\alpha]^{20}D$ −35.3° (*c* 4.30, chloroform).

Anal. Calcd. for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16. Found: C, 70.43, 70.10; H, 8.14, 8.10.

The semicarbazone was prepared by heating 1.0 g. of the ketone in 15 ml. of 30% methanol with 1 g. of semicarbazide hydrochloride and 1.5 g. of sodium acetate for a short time. Chilling yielded 1.19 g. (95%) of colorless solid, m.p. 158–159°, which after recrystallization from 30% methanol formed shiny scales, m.p. 159.5–160.0°, $[\alpha]^{20}D$ −48.0° (*c* 2.00, chloroform).

Anal. Calcd. for $C_{14}H_{21}N_3O_3$: C, 60.19; H, 7.58; N, 15.04. Found: C, 60.05; H, 7.57; N, 15.08.

II also was obtained in low yield by stirring 3.4 g. of I in 5 ml. of methylene chloride with 25 ml. of hydrogen peroxide–*t*-butyl alcohol reagent,[41] 20 mg. of vanadium pentoxide[42] and 5 g. of anhydrous sodium sulfate magnetically during 1 hr., keeping for 64 hr., and evaporating the filtrate *in vacuo*. Treatment with Girard reagent, then with semicarbazide provided 0.15 g. of impure semicarbazone, m.p. 155–156.5°, $[\alpha]^{20}D$ −45° (chloroform).

(b) From D-(−)-3,4-Dimethoxy-α-methylhydrocinnamic Acid[7] (III, X = OH).—The acid chloride (III, X = Cl), prepared by refluxing 1.95 g. of the acid with 2.25 ml. of oxalyl chloride for 1 hr., evaporating *in vacuo* and re-evaporating twice after addition of dry benzene, was dissolved in 14 ml. of dry ether. The solution was stirred magnetically with exclusion of moisture and treated dropwise at −74° during 10 minutes with 12.1 ml. of 0.7 *M* ethereal methylmagnesium bromide, stirred at −74° for another hour and allowed to come to −10° over a period of 45 minutes. It was then treated dropwise at −10° with water and 2 *N* sulfuric acid. The aqueous phase was extracted with additional ether, and the ether solutions were washed with 0.5 *N* sulfuric acid and bicarbonate, then worked up as usual.[37] The residual oil, treated with semicarbazide, provided 0.41 g. (17%) of the **semicarbazone**, which recrystallized thrice from 30% methanol melted at 159.3–160.0° (no depression with material prepared under (a)) and had $[\alpha]^{20}D$ −47.5° (*c* 1.99, chloroform).

A few other runs, carried out without any change in procedure, led to a considerably racemized product.

L-(+)-4-(3,4-Dimethoxyphenyl)-3-methyl-2-butanone semicarbazone, obtained in 17% yield from L-(+)-3,4-dimethoxy-α-methylhydrocinnamic acid,[7] had m.p. 156.5–157.5°, $[\alpha]^{21}D$ +47° (*c* 2.00, chloroform), and an infrared spectrum identical with that of the (−)-semicarbazone prepared above under (a). It was also prepared, although partially racemized, by treating the acid chloride with dimethylcadmium. In a representative run, 18.2 ml. of 0.65 *M* methylmagnesium bromide was stirred and refluxed with 1.19 g. of cadmium chloride (precipitated from its aqueous

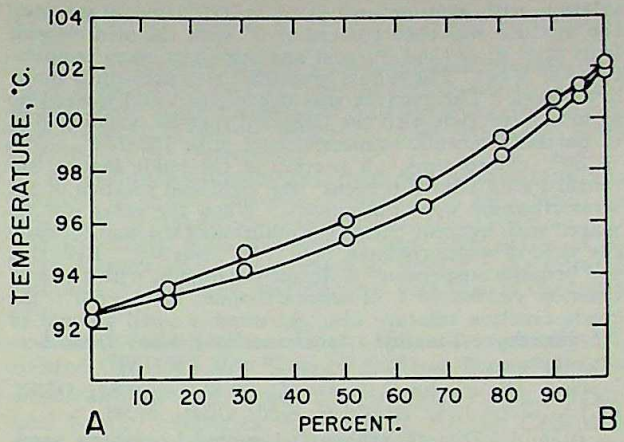

Fig. 1.—Initial and final melting temperatures of mixtures of: A, guaiaretic acid dimethyl ether (I), and B, *meso*-dihydroguaiaretic acid dimethyl ether (ref. 3), as determined by the method of H. Rheinboldt, *J. prakt. Chem.*, 111, 242 (1925).

(32) R. P. Linstead, W. E. Doering, S. B. Davis, P. Levine and R. R. Whetstone, THIS JOURNAL, **64**, 1985 (1942).

(33) While the "black dot" convention has primarily been employed for cyclic compounds, it was also used in our previous paper[30] to illustrate the configuration of open-chain lignans, in order to show their relation to the aryltetralin derivatives. Examination of a three-dimensional model demonstrates the equivalence of our previous formula XIII[30] and the present formula I. The aryltetralins were all numbered as 4-aryl derivatives so as to illustrate more clearly their relationship to guaiaretic acid. This numbering system is correct for derivatives of 4-aryl-2-naphthoic acid (*e.g.*, conidendrin), but it does not conform to standard nomenclature[16] for compounds like podophyllotoxin (our previous formula IV[30]), which are named more correctly as derivatives of 1-aryl-2-naphthoic acid. The configuration of podophyllotoxin, expressed previously[8] as 1D,2L,3D,4D[15a] (aryl at 4), then becomes 1L,2L,3D,4L or L(1,2,4)A[15b] (aryl at 1). This change is, of course, merely a matter of nomenclature and does not affect the true spatial relationships.

(34) The (−)-diol which was reduced to the (−)-dihydro derivative of I[30] could be obtained by hydrogenolysis[35] of lariciresinol and pinoresinol dimethyl ethers.

(35) R. D. Haworth and D. Woodcock, *J. Chem. Soc.*, 1054 (1939).

(36) Melting points are corrected and were determined in Pyrex capillaries with the Hershberg apparatus. Optical rotations were measured in 4-dm. tubes.

(37) Extracts were washed with dilute acid and base (if so specified), then with dilute sodium chloride solution, dried with sodium sulfate and evaporated *in vacuo* at room temperature, using a rotating evaporator (Rinco Instrument Co., Greenville, Ill.).

(38) Arapahoe Chemicals, Inc., Boulder, Colo.

(39) The ketone, after the first purification with Girard reagent, had $[\alpha]D$ −31° (chloroform) and still appeared to contain veratraldehyde, as indicated by the yield, the low rotation and by a low C analysis. In the second purification, 4.0 g. of Girard reagent was used, and the solution diluted with 285 ml. of water (sodium carbonate and extraction of non-ketonic materials omitted) and made 0.5 *N*, instead of *N*, with sulfuric acid.

Digitized by Arya Samaj Foundation Chennai and eGangotri

solution with acetone and dried at 110°) for 40 minutes; the mixture was then treated at 0° with the acid chloride from 2.03 g. of the (+)-acid and stirred at room temperature for 3 hr. The whole procedure was performed under dry argon. The mixture was decomposed and worked up as in the reaction with the Grignard reagent, yielding 46% of partially racemic semicarbazone, m.p. 155–156°, $[\alpha]^{21}D$ + 36° (chloroform). A portion of the crude ketone was purified with Girard reagent; the yield and rotation of the semicarbazone were unchanged. When the ether was replaced with benzene before the addition of the acid chloride, the yield of semicarbazone, $[\alpha]D$ +26°, was 8%. Refluxing the benzene suspension of dimethylcadmium with the acid chloride yielded 33% of semicarbazone, $[\alpha]D$ +5.5°; the crude reaction mixture also deposited a small amount of **5,6-dimethoxy-2-methyl-1-indanone** as needles from benzene–hexane, m.p. 132–133° (lit.[43] m.p. 129–130°).

Anal. Calcd. for $C_{12}H_{14}O_3$: C, 69.88; H, 6.84; OCH_3, 30.10. Found: C, 70.05; H, 6.66; OCH_3, 29.93.

DL-4-(3,4-Dimethoxyphenyl)-3-methyl-2-butanone semicarbazone, prepared by cocrystallizing the enantiomers from 30% methanol, formed small rectangular plates, m.p. 164.4–164.7°.

***N*-Formyl-L-3,4-dimethoxyphenylalanine (VII).**—A solution of 10.0 g. of L-3,4-dihydroxyphenylalanine (VI), $[\alpha]^{22}D$ −12.2° (*c* 1, *N* hydrochloric acid),[44] in 90 ml. of 90% formic acid was stirred and treated with 30 ml. of acetic anhydride (temperature rise to 63°), allowed to stand for 0.5 hr., evaporated *in vacuo* below 70° with magnetic stirring (Teflon-coated stirring bar) and re-evaporated several times after addition of water. The residual gummy *N*-formyldihydroxyphenylalanine, which could not be crystallized, was dissolved in about 15 ml. of water and treated, under argon and with magnetic stirring, with 15 ml. of 10 *N* sodium hydroxide, then with four 9.5-ml. portions of methyl sulfate at 20-minute intervals. The temperature was maintained at 35° and the *p*H kept at 7–8 by the dropwise addition of 29 ml. of 10 *N* sodium hydroxide. Finally, 0.5 hr. after all the methyl sulfate had been added, the solution was treated with another 2 ml. of 10 *N* sodium hydroxide, stirred for an additional 0.5 hr., chilled and acidified with 16 ml. of 8 *N* sulfuric acid. The mixture was extracted with ether continuously for 20 hr., and the partly gummy solid which separated from the extract was crystallized from ethyl acetate to give 7.69 g. of colorless solid, m.p. 123–126°. An additional 0.41 g., m.p. 124–126°, was isolated from the mother liquor, bringing the yield to 63%. A sample, recrystallized from ethyl acetate, formed colorless elongated prisms, m.p. 125–126°, $[\alpha]^{24}D$ +71.6° (*c* 2.00, ethanol).

***N*-Formyl-DL-3,4-dimethoxyphenylalanine**, prepared similarly from DL-3,4-dihydroxyphenylalanine in 77% yield, formed small colorless prisms, m.p. 134–135.5°.

Anal. Calcd. for $C_{12}H_{15}NO_5$: C, 56.91; H, 5.97; N, 5.53. Found: C, 56.99; H, 5.95; N, 5.52.

L-3,4-Dimethoxyphenylalanine Methyl Ester (VIII).—A solution of 8.06 g. of VII in 80 ml. of methanol was saturated with dry hydrogen chloride, refluxed for 1 hr. and evaporated *in vacuo*. The residual oil, digested with ether, gave a gum. Recrystallization from ethanol–ether (1:3) provided the **hydrochloride** as colorless needles, which were dried in a vacuum-desiccator over solid potassium hydroxide; yield 4.58 g., m.p. 151–155° dec. An additional 1.95 g., m.p. 142–152°, was isolated from the mother liquor, bringing the yield to 75%. A sample, recrystallized from ethanol–ether, had m.p. 158–159° dec. and $[\alpha]^{20}D$ +6.8° (*c* 2.00, methanol).

Anal. Calcd. for $C_{12}H_{18}ClNO_4$: Cl, 12.86. Found: Cl, 12.74.

The free base was obtained by treating a magnetically stirred solution of 2.17 g. of the hydrochloride in 10 ml. of methanol at −30° with 0.181 g. of sodium in 4.5 ml. of methanol, then with 10 ml. of ether. The mixture was stirred at −30° for 15 minutes, filtered and the filtrate evaporated *in vacuo;* the residue was dissolved in methylene chloride, the solution refiltered, re-evaporated and evaporated again after addition of dry benzene. The residue, dried in a high vacuum, formed a yellowish oil; yield 1.74 g. (92%).

DL-3,4-Dimethoxyphenylalanine Methyl Ester.—**The hydrochloride**, obtained in 76% yield, formed colorless needles, m.p. 185–186° dec.

Anal. Calcd. for $C_{12}H_{18}ClNO_4$: Cl, 12.86. Found: Cl, 12.86.

The free base was obtained in 85% yield with sodium methoxide as above but in 42% yield only by treating an aqueous solution of the hydrochloride with potassium carbonate and extracting with ether.

L-Phenylalanine methyl ester hydrochloride, prepared analogously from L-phenylalanine[45] *via* the *N*-formyl derivative,[22] crystallized from methanol–ether in colorless needles, m.p. 159–160° dec., $[\alpha]^{20}D$ +17.2° (*c* 2.00, methanol), $[\alpha]^{20}D$ −4.5° (*c* 4.00, water).[46]

Anal. Calcd. for $C_{10}H_{14}ClNO_2$: Cl, 16.44. Found: Cl, 16.19.

L-3,4-Dimethoxyphenylalaninol (IX).—A magnetically stirred suspension of 0.828 g. of lithium aluminum hydride in 22 ml. of dry ether was treated during 15 minutes with 1.74 g. of VIII in 23 ml. of ether, refluxed for 1.5 hr., cooled in ice, treated dropwise with 6.1 ml. of ethanol in 12 ml. of ether, then with 4.7 ml. of saturated sodium chloride solution and filtered through Celite. The residue was extracted with about 80 ml. of hot ethanol, and the combined filtrate and extract were evaporated *in vacuo*. The residue was dissolved in benzene, filtered from inorganic salts and re-evaporated to yield 1.47 g. of dark yellow oil, which was dissolved in hot ethanol and treated with 0.438 g. of oxalic acid dihydrate in a little water. **The neutral oxalate**, yield 1.32 g. (69.5%), was recrystallized from water–ethanol; colorless scales, m.p. 210–211.5° dec., $[\alpha]^{20}D$ −16.8° (*c* 3.96, water).

Anal. Calcd. for $2C_{11}H_{17}NO_3 \cdot C_2H_2O_4 \cdot 0.5H_2O$: C, 55.27; H, 7.15; N, 5.37; H_2O, 1.73. Found: C, 55.25; H, 6.93; N, 5.35; wt. loss at 139°, 1.59.

The oxalate (1.12 g.) was treated with 10 *N* sodium hydroxide, the mixture extracted with benzene continuously for 19 hr. and the extract evaporated *in vacuo* to yield 0.90 g. (99%) of the **free base** as a colorless oil, which crystallized on standing, m.p. 78–79°. Recrystallization from methylene chloride–pentane afforded long needles, m.p. 79–80°, $[\alpha]^{20}D$ −21.5° (*c* 7.99, ethanol).

Anal. Calcd. for $C_{11}H_{17}NO_3$: C, 62.54; H, 8.11; N, 6.63. Found: C, 62.80; H, 8.39; N, 6.54.

DL-3,4-Dimethoxyphenylalaninol.—**The neutral oxalate** formed colorless micro-crystals, m.p. 228–229° dec.

Anal. Calcd. for $2C_{11}H_{17}NO_3 \cdot C_2H_2O_4$: C, 56.24; H, 7.88; N, 5.47. Found: C, 56.19; H, 7.03; N, 5.70.

The free base, recovered from the oxalate, melted at 63–64.5° and was not recrystallized. It was very soluble in water.

Anal. Calcd. for $C_{11}H_{17}NO_3$: C, 62.54; H, 8.11; N, 6.63. Found: C, 62.69; H, 8.30; N, 6.03.

***O,N*-Ditosyl-L-3,4-dimethoxyphenylalaninol (X).**—A solution of 0.70 g. of IX and 2.1 g. of tosyl chloride in 5.7 ml. of dry pyridine was prepared at 0°, kept at room temperature for 24 hr., treated with ice and water, kept 15 minutes and extracted with chloroform. The extract was washed with 21 ml. of 4 *N* hydrochloric acid and with sodium bicarbonate solution, then worked up.[37] The residual yellow gum, which could not be crystallized, was dried at 80° (0.05 mm.), yield 1.65 g. (96%), $[\alpha]^{24}D$ −58° (*c* 1.99, ethanol).

Anal. Calcd. for $C_{25}H_{29}NO_7S_2$: C, 57.78; H, 5.63; S, 12.34. Found: C, 58.29; H, 5.79; S, 11.14.

***O,N*-Ditosyl-DL-3,4-dimethoxyphenylalaninol.**—The washed and dried chloroform extract was diluted with four volumes of hexane to yield 71% of pale yellow crystals, m.p. 133–135°. Recrystallization from chloroform–pentane provided small colorless prisms, m.p. 135.5–136.0°.

Anal. Calcd. for $C_{25}H_{29}NO_7S_2$: C, 57.78; H, 5.63; S, 12.34. Found: C, 57.72; H, 5.41; S, 12.15.

N-Tosyl-D-3,4-dimethoxy-α-methylphenethylamine[14] (V). (a) From X.—The gummy ditosylate (1.64 g.) in 58 ml. of dry purified[30] tetrahydrofuran was added dropwise during 15 minutes with magnetic stirring to a suspension of 0.82 g. of lithium aluminum hydride in 33 ml. of tetrahydrofuran. The mixture was stirred at room temperature for 0.5 hr., refluxed for 3 hr., chilled, treated with water and 4 *N* hydrochloric acid and extracted with chloroform. The extract was washed with sodium chloride and potassium carbonate solutions, dried with potassium carbonate, concentrated, chromatographed on neutral alumina and the product eluted with chloroform. Evaporation and crystallization from ether–pentane yielded 0.93 g. (84%) of colorless elongated prisms arranged in rosettes, m.p. 74.5–76.0°. Recrystallization from ether–pentane provided material, m.p. 75.6–76.6°, $[\alpha]^{20}D$ −29.3° (*c* 2.00, ethanol), $[\alpha]^{20}D$ −10.0° (*c* 2.00, chloroform).

(b) From D-(−)-3,4-Dimethoxy-α-methylphenethylamine[7] (IV).—A solution of 1.00 g. of IV and 3 g. of tosyl chloride in 15 ml. of dry pyridine was kept at room temperature for 1 hr. and poured into a slurry of ice, water and 20 ml. of concd. hydrochloric acid. The oil, which crystallized on standing in the refrigerator, was washed with water, then chromatographed and recrystallized as above; yield 1.20 g. (67%), m.p. 75.6–76.6° (no depression with a sample prepared under (a)), $[\alpha]^{20}D$ −28.9° (*c* 2.26, ethanol), $[\alpha]^{21}D$ −9.8° (*c* 2.00, chloroform). Samples prepared under (a) and (b) had identical infrared spectra.

Anal. Calcd. for $C_{18}H_{23}NO_4S$: C, 61.87; H, 6.63; N, 4.01; S, 9.18. Found: C, 61.86; H, 6.42; N, 4.12; S, 8.96.

N-Tosyl-L-3,4-dimethoxy-α-methylphenethylamine, prepared from L-(+)-3,4-dimethoxy-α-methylphenethylamine[7] in 59% yield, formed rosettes of colorless elongated prisms, m.p. 76.2–77.2°, $[\alpha]^{20}D$ +29.4° (*c* 2.00, ethanol), $[\alpha]^{20}D$ +10.6° (*c* 2.01, chloroform).

N-Tosyl-DL-3,4-dimethoxy-α-methylphenethylamine was obtained by mixing the enantiomers or (in 68% yield) by reduction of ditosyl-DL-3,4-dimethoxyphenylalaninol. It was crystallized with difficulty by slow evaporation of its ether solution at 3° and melted at 63–67°. Its infrared spectrum in chloroform was identical with that of the D-isomer.

Acknowledgments.—The authors are greatly indebted to Dr. W. Klyne of the Postgraduate Medical School of London for very valuable advice and to Dr. Frederick E. King of British Celanese Ltd., London, for suggesting an improved method for the isolation of guaiaretic acid. Miss Mary M. Trail carried out a large portion of the experimental procedures, including determination of the melting point diagram and of the optical rotations. Microanalyses were performed by Dr. W. C. Alford and his staff.

Reaction of Steroids with Diazomethane[1]

BY ALEXANDER L. NUSSBAUM AND FLORENCE EMILIE CARLON

RECEIVED FEBRUARY 18, 1957

The action of diazomethane in ether–methanol upon certain steroids has been investigated. This reagent not only saponifies acetate groups at C-21 but also causes homologation of the side chain. Evidence is presented that the new compounds are homologous 20,22-epoxides. A model compound possessing this structure was prepared and correlated with a known compound.

The recent report on the use of diazomethane as a catalyst in transesterification[2] led us to investigate that method in the hydrolysis of the 21-acetates of a number of physiologically active steroids, since the usual methods of saponification cause concomitant side reactions.[3]

When 17α,21-dihydroxy-Δ[1,4]-pregnadiene-3,11,-20-trione 21-acetate[4] (Ia) was exposed to the action of an excess of diazomethane in ether–methanol solution, the ester group was lost, but the resulting product was not identical with the predicted hydrolysate Ib. Although its melting point was similar to that of 17α,21-dihydroxy-Δ[1,4]-pregnadiene-3,11,20-trione[4] (Ib) and no depression of this melting point was observed upon admixture with the new material, the two compounds were definitely not identical, as shown by their infrared spectra, optical rotations and migration rates in paper chromatography. The same material could also be obtained directly from non-acetylated 17α,21-dihydroxy-Δ[1,4]-pregnadiene-3,11,20-trione (Ib). Elemental analysis indicated that the new substance was a homolog of its alcohol precursor. It could be monoacetylated and resaponified.

The new material possessed a high intensity maximum at 239 mμ in the ultraviolet. This could arise from either the original dienone or a newly formed enone chromophore. However, survival of the dienone system was indicated by the characteristic absorption doublet in the infrared at 6.16 and 6.22 μ[4] and by polarographic data.[5] Failure of diazomethane to attack the ring system was not entirely unexpected, since the work of Wettstein[6] and that of Djerassi and Scholz[7] has shown that the double bond of a steroidal Δ[4]-3-ketone is resistant to that reagent.[8]

(1) Part of the results reported in this paper were published in a communication to the editor of *Chemistry & Industry*, 1313 (1956); other parts were presented before the Miami Meeting of the American Chemical Society, April 7–12, 1957.

(8) Addition of diazomethane to α,β-unsaturated ketones was first described by E. Azzarello, *Gazz. chim. ital.*, II, **36**, 50 (1906). The validity of the statement[7] that the addition of diazomethane to steroidal α,β-unsaturated ketosteroids is characteristic of the Δ[16]-20-one-moiety has received further support from the failure of 3,17-diketo-Δ[1]-androstene to add diazomethane: Carl Djerassi and Alexander L. Nussbaum, unpublished experiment performed at Wayne University.

Oxidative degradation of the new substance with chromic acid[9] gave 3,11,17-triketo-$\Delta^{1,4}$-androstadiene(III).[10] It could be concluded, therefore, that the methylene group had entered into the side chain. This was supported by the observation that the original dihydroxyacetone grouping had not survived the reaction. The new substance failed to give a purple color with 2,3,5-triphenyltetrazolium chloride,[11] and the carbonyl band in the infrared spectrum of the starting material attributable to the interaction of the C_{21}-acetate with the C_{20}-ketone at 5.80 μ gave way to a simple acetate band at 5.74 μ[12] in the acetate of the new substance. The C_{20}-carbonyl seemed to be involved in the new transformation. In order to facilitate interpretation of the infrared spectrum, the reaction was carried out on prednisolone where there was no ketone function at C-11 which would complicate absorption in the carbonyl region. When 11β,17α,21-trihydroxy-$\Delta^{1,4}$-pregnadiene-3,20-dione 21-acetate (Ic) was exposed to the action of diazomethane in ether–methanol, there was again obtained a new homolog, which did not exhibit any infrared absorption typical of saturated ketones. Furthermore, sodium bismuthate[13] treatment of the new compounds failed to cleave the side chain, indicating the absence of a dihydroxyacetone group.

All these facts were in agreement with the view that a methylene group had added to the side chain carbonyl with the formation of an epoxide, a reaction often observed in diazomethane chemistry.[14] Thus, the reaction products of Ia (or b) and Ic were formulated as IIa and IIc, respectively. This formulation was supported by the fact that the free alcohols of these reaction products (see following) showed a new band in the infrared near 8.05 μ which can be attributed to the epoxide grouping.[15]

Their migration rates in a paper chromatographic system[16] were slightly greater than those of the parent substances, indicating a slight decrease in polarity expected from the proposed transformation. An analogous reaction has been observed by Prins and Reichstein[17] who obtained a 20,21-epoxide from the reaction of 17α-formyltestosterone.

An investigation of the scope of this reaction showed that, under the conditions used, only those steroids possessing the complete dihydroxyacetone side chain undergo the transformation described to any appreciable extent. In addition to Ia (or b) and Ic, the following compounds were submitted to the reaction: cortisone acetate (Id), Δ^6-cortisone (Ie)[18] and Compound S (If). The corresponding bisnorcholane-epoxides are formulated in Chart I. Desoxycorticosterone (IV), lacking a hydroxyl group at C-17, failed to react as smoothly as the preceding steroids of the cortisone type: only small amounts of the homolog V could be isolated after careful chromatography.

Also submitted to the reaction were 17-hydroxyprogesterone, 21-hydroxypregnenolone and allopregnanolone acetate. None of these compounds underwent the reaction here discussed; in each case starting material was recovered in high yield. A slight degree of acetate hydrolysis was observed in the case of allopregnanolone acetate (4%).

The new substances show uniform negative molecular rotation differences (see Table I). Their physical (especially spectral) properties are in agreement with the arguments here outlined.

TABLE I

MOLECULAR ROTATION DIFFERENCES

Starting material (1)	M_D of (1) (2)	M_D of product (alcohol) (3)	ΔM_D (3) − (2) (4)
Prednisone acetate (Ia)	617	402	−215
Prednisolone acetate (Ic)	364	82	−282
Cortisone acetate (Id)	754	519	−235
Δ^6-Cortisone (Ie)	932	723	−209
Compound S (If)	423	195	−228
Desoxycorticosterone acetate (IV)	589	328	−261
3β,17α,21-Trihydroxy-Δ^5-pregnen-20-one 3,21-diacetate	−106	−213	−107

In order to confirm the course of the proposed reaction, it was carried out on 3β,17α,21-trihydroxy-Δ^5-pregnen-20-one 3,21-diacetate (VIa)[19] (Chart II). The expected 3β,17α,21-trihydroxy-Δ^4-bisnorcholene-20 ξ,22-epoxide 3-acetate (VIIa) was obtained. Reduction of the diacetate VIIb with lithium aluminum hydride gave a mixture of tetrols (VIIIa), from which, upon acetylation, a homogeneous 3,21-diacetate (VIIIb) could be isolated in moderate yield. The same mixture of tetrols had been prepared previously[19] by a Grignard reaction on VIa, and upon repetition of this work, followed by acetylation, we were able to isolate the same diacetate (VIIIb) as had been obtained from the model compound. While this method of synthesis does not give any knowledge concerning the stereochemistry at C-20, it does establish the structure of the carbon skeleton.

Preliminary biological studies indicate compounds IIa, IIc and IId to be essentially devoid of eosinopenic, anti-inflammatory and glycogen-depositing activity. The homolog of desoxycorticosterone (V) appeared to have lost all of its sodium-retaining characteristics. We are indebted to Drs. S. Tolksdorf and P. Perlman of our laboratories for these data.

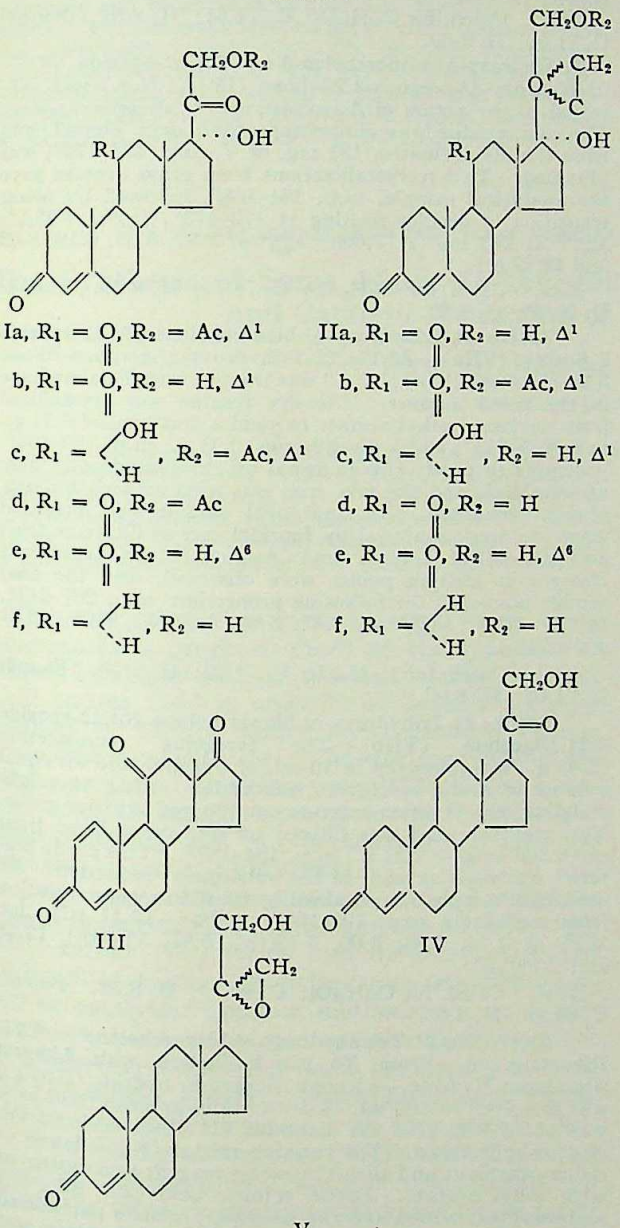
CHART I



Experimental[20]

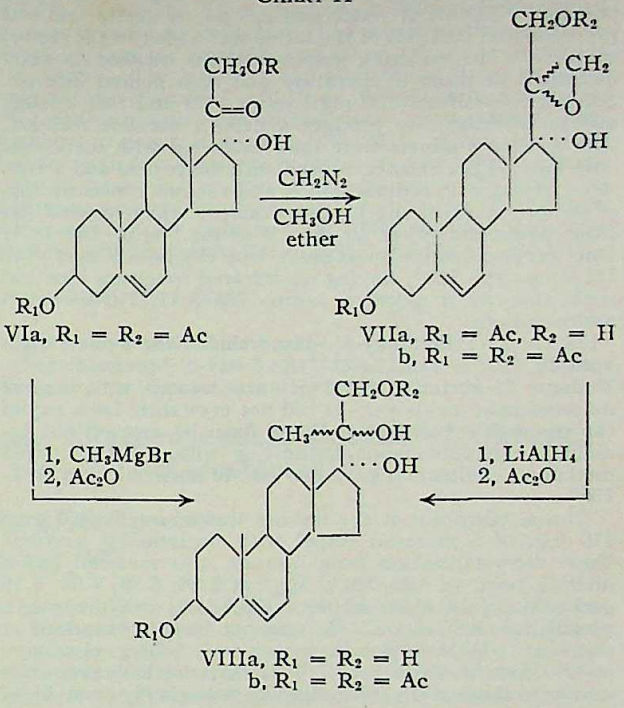
17α,21-Dihydroxy-Δ1,4-bisnorcholadiene-3,11-dione-20ξ,22-epoxide (IIa).—The following procedure is typical of all subsequent preparations of the homologs: 17α,21-Dihydroxy-Δ1,4-pregnadiene-3,20-dione 21-acetate (Ia) (600 mg.) was dissolved in 20 ml. of methanol, and into this solution was filtered another solution of *ca.* 1.2 g. of diazomethane in 60 ml. of ether,[21] and the mixture was allowed to stand for a period of five days at room temperature.[22]

(20) All melting points were taken on a Kofler block. Rotations were carried out in a 1-dm. tube at a concentration of *ca.* 1% in dioxane, unless otherwise specified. Analyses and spectral data were obtained by the Microanalytical and Physical Chemistry Departments of these laboratories.

(21) *Cf.* Th. J. de Boer *et al.*, *Org. Syntheses*, **34**, 2496 (1954).

(22) A subsequent study by paper chromatographic methods showed an optimum reaction time of 50 hr.

CHART II



The small amount of "polymethylene" which had appeared was then filtered off, the solution was concentrated to dryness under vacuum, and the crystalline residue was dissolved in methanol, treated with charcoal and recrystallized from the same solvent. A first crop of 420 mg., m.p. 226–231°, was obtained. Fourfold recrystallization from methanol gave the analytical sample, m.p. 239–241°, $[\alpha]^{25}D$ +108.2°, λ_{max}^{MeOH} at 239 mμ (ε 15,600); λ_{max}^{Nujol} at 3.03, 5.85, 5.99, 6.16, 6.22 and 8.03 μ.

Anal. Calcd. for $C_{22}H_{28}O_5$: C, 70.94; H, 7.58. Found: C, 70.90; H, 7.79.

17α,21-Dihydroxy-Δ1,4-bisnorcholadiene-3,11-dione-20ξ,22-epoxide 21-Acetate (IIb).—A sample of relatively crude free alcohol IIa (200 mg.) was dissolved in 1 ml. of pyridine, 1 ml. of acetic anhydride was added and the resulting solution allowed to stand overnight. It was then poured into ice, filtered and air-dried to give 185 mg. of a product melting 195–198°. Recrystallization from methylene chloride–ether gave 145 mg., m.p. 210–212°. A further wasteful recrystallization from acetone gave the analytical sample, m.p. 213–215°, $[\alpha]^{25}D$ +113.2; λ_{max}^{Nujol} at 2.97 5.74(sh), 5.85, 6.03, 6.16, 6.23 and 8.12 μ.

Anal. Calcd. for $C_{24}H_{30}O_6$: C, 69.52; H, 7.30. Found: C, 69.50; H, 7.00.

Saponification[23] of IIb.—The foregoing acetate (60 mg.) was suspended in 3 ml. of methanol and placed in an atmosphere of nitrogen. To this solution 0.2 ml. of a stock solution of 0.67 g. of sodium methylate in 15 ml. of methanol was added and the reaction was allowed to proceed at room temperature for 18 minutes. All of the material was observed to dissolve after 5 minutes, but some solid reappeared after 10 minutes. Aqueous methanol (0.06 ml. of a solution containing 3 ml. of methanol and 0.2 ml. of water) was then added and the reaction time extended another 6 minutes. Finally, 2 ml. of ice-water was added, and the mixture was concentrated under vacuum at 35°. A few pieces of ice were added, and the resulting suspension filtered with suction. The solid was washed well with water and air-dried to give 49.5 mg., m.p. 220–235°. One recrystallization from methanol gave paper chromatographically pure free alcohol IIa, m.p. 235–239°, identified by its infrared spectrum.

3,11,17-Triketo-Δ1,4-androstadiene (III).—17α,21-Dihydroxy - Δ1,4 - bisnorcholadiene - 3,11 - dione - 20ξ,22-epoxide (117.5 mg.) was dissolved in 6.6 ml. of glacial acetic acid previously distilled over chromium trioxide.

An oxidizing solution consisting of 300 mg. of chromium trioxide, 0.36 ml. of water and 3.6 ml. of acetic acid was prepared and 0.91 ml. of the latter was added to the steroid solution. The resulting suspension was allowed to react overnight at room temperature and then poured into ice. Sodium thiosulfate (100 mg.) was added and then enough sodium hydroxide to produce a definite alkaline reaction. The neutral products were then extracted with methylene chloride and the extract washed with dilute acid and water. After drying over sodium sulfate and vacuum concentrating, a yellow oil (51.6 mg.) was obtained, which crystallized from petroleum ether to give 26.5 mg., m.p. 158–187°. One recrystallization from methylene chloride–hexane gave III, m.p. 187–193°, having an infrared spectrum identical with that of a genuine sample of 3,11,17-triketo-$\Delta^{1,4}$-androstadiene.

11β,17α,21-Trihydroxy-$\Delta^{1,4}$-bisnorcholadiene-3-one-20ξ,22-epoxide (IIc).—11β,17α-21-Trihydroxy-$\Delta^{1,4}$-pregnadiene-3,-20-dione 21-acetate (Ic) (3 g.) was treated with 6 g. of diazomethane as above. It did not crystallize from any of the common solvents but did so from its own oil and remained crystalline upon trituration with a little ice-cold methanol. Filtration gave 880 mg. of material, m.p. 135–150°.

Chromatography of the mother liquors on Florisil gave 110 mg. of a material eluted with benzene–5% acetone. Upon recrystallization from acetone, this material had a melting point of 192–220°; λ_{max}^{Nujol} at 2.86, 5.86, 6.04, 6.19 and 6.24 μ (not identical with 11β,17α,21-trihydroxy-$\Delta^{1,4}$-pregnadiene-3,20-dione). It was not further examined at this time. With 30% acetone-benzene, 1.62 g. of a more polar eluate was obtained. This material had properties similar to those of the substance which originally crystallized from the crude reaction mixture. Like the latter, it was impossible to recrystallize from the common solvents, but eventually it was found to form a crystalline solvate with methylene chloride. One recrystallization from methanol–methylene chloride gave 960 mg., transition point with partial melting 135–150°, definite m.p. 213–222°. Two more recrystallizations from the same solvent gave the analytical sample, transition range 136–152°, definite m.p. 215–219°; λ_{max}^{MeOH} at 244 mμ (ϵ 15,000), $[\alpha]^{25}D$ +17.3°; λ_{max}^{Nujol} at 2.98, 6.04, 6.21, 6.26 and 8.05 μ.

Anal. Calcd. for $C_{22}H_{30}O_5 \cdot CH_2Cl_2$: C, 60.13; H, 7.02. Found: C, 60.25; H, 7.33.

An acetate was prepared in the usual manner and was found to have the following properties: m.p. 240–243°, λ_{max}^{MeOH} at 243 mμ (ϵ 15,000); λ_{max}^{Nujol} at 2.85(sh), 2.94, 5.74, 6.03 and 6.19 μ.

Anal. Calcd. for $C_{24}H_{32}O_6$: C, 69.21; H, 7.74. Found: C, 69.55; H, 7.98.

17α,21-Dihydroxy-Δ^4-bisnorcholene-3,11-dione-20ξ,22-epoxide (IId).—17α,21-Dihydroxy-Δ^4-pregnene-3,11,20-trione 21-acetate (Id) (1.5 g.) was treated with 3 g. of diazomethane as described. Chromatography on Florisil gave 510 mg. of product, m.p. 210–232°. Several recrystallizations from methanol failed to improve the sharpness of the melting point, and eventually the following properties were measured from a sample that had been recrystallized four times: m.p. 225–245°,[24] $[\alpha]^{25}D$ +138.1°, λ_{max}^{MeOH} at 238 (ϵ 15,400); λ_{max}^{Nujol} at 2.92, 5.89, 6.12 and 8.05 μ.

Anal. Calcd. for $C_{22}H_{30}O_5$: C, 70.56; H, 8.08. Found: C, 70.54; H, 8.08.

17α,21-Dihydroxy-$\Delta^{4,6}$-bisnorcholadiene-3,11-dione-20ξ,22-epoxide (IIe).—17α,21-Dihydroxy-$\Delta^{4,6}$-pregnadiene-3,11,-20-trione 21-acetate (Ie) (1 g.) was treated with the usual excess of diazomethane in the manner described. Crystallization from methanol gave 354 mg. of a product with m.p. 230–270°. Two recrystallizations from methanol gave the analytical sample, transition range 220–230°, m.p. 280–286, $[\alpha]^{25}D$ +194.2°, λ_{max}^{MeOH} at 280.5 (ϵ 24,700); λ_{max}^{Nujol} at 2.98, 5.84, 6.10, 6.19, 6.31 and 8.14 μ.

Anal. Calcd. for $C_{22}H_{28}O_5$: C, 70.94; H, 7.58. Found: C, 70.87; H, 7.33.

17α,21-Dihydroxy-Δ^4-bisnorcholen-3-one-20ξ,22-epoxide (IIf).—17α,21-Dihydroxy-Δ^4-pregnene-3,20-dione (If) (1.5 g.) was converted as usual. Crystallization from methanol gave 830 mg., m.p. 223–236°. Two recrystallizations from methanol gave the analytical sample, (vacuum capillary) m.p. 245–246°, $[\alpha]^{25}D$ +54.0°, λ_{max}^{MeOH} at 242 mμ (ϵ 16,800); λ_{max}^{Nujol} at 2.97, 5.99, 6.21(w) and 8.05 μ.

Anal. Calcd. for $C_{22}H_{32}O_4$: C, 73.30; H, 8.95. Found: C, 73.16; H, 8.95.

Preparation of an acetate in the usual manner gave a product with m.p. 217–220°, $[\alpha]^{25}D$ +78.5°, λ_{max}^{MeOH} at 242 (ϵ 15,800); $\lambda_{max}^{CHBr_3}$ at 5.74, 6.01, 6.19 and 8.13 μ.

Anal. Calcd. for $C_{24}H_{34}O_5$: C, 71.61; H, 8.51. Found: C, 71.60; H, 8.69.

21-Hydroxy-Δ^4-bisnorcholen-3-one-20ξ,22-epoxide (V).—21-Hydroxy-Δ^4-pregnen-3,20-dione (IV) (1.5 g.) was subjected to the action of diazomethane, as described above. The oily residue was chromatographed over Florisil, and from the ether eluates, 181 mg. of V, m.p. 166–172°, was obtained. Two recrystallizations from ethyl acetate gave the analytical sample, m.p. 164–168°, followed by phase transition to needles melting at 172–173°, $[\alpha]^{25}D$ +95.1°, λ_{max}^{MeOH} at 242 mμ (ϵ 17,000); λ_{max}^{Nujol} at 2.97, 6.09, 6.19, 8.02 and 12.22 μ.

Anal. Calcd. for $C_{22}H_{32}O_3$: C, 76.70; H, 9.36. Found: C, 76.96; H, 9.26.

3β,17α,21-Trihydroxy-Δ^5-bisnorcholene-20ξ,22-epoxide 3-Acetate (VIIa).—3β,17α,21-Trihydroxy-Δ^5-pregnen-20-one 3,21-diacetate (VIa) (7.5 g.) was treated with diazomethane in the usual manner. The dry residue was crystallized from methanol–ethyl acetate to yield a first crop of 3.51 g., m.p. 205–211°, and a second crop, 0.51 g., m.p. 180–195°. Attempts to purify this material by chromatography were unsuccessful, and the first crop was used as such for subsequent reactions. An analytical sample was prepared from the crude material by fourfold recrystallization from acetone, ethyl acetate and methanol. No significant changes in melting points were observed, and the final sample possessed the following properties: m.p. 207–213°, $[\alpha]^{25}D$ −52.9°; $\lambda_{max}^{CHBr_3}$ at 2.87, 5.81, 6.03(sh), 8.02, 12.31 and 12.48 μ.

Anal. Calcd. for $C_{24}H_{36}O_4$: C, 71.25; H, 8.97. Found: C, 71.09; H, 8.92.

3β,17α,21-Trihydroxy-Δ^5-bisnorcholene-20ξ,22-epoxide 3,21-Diacetate (VIIb).—The foregoing monoacetate (2.43 g.) was dissolved in 10 ml. of pyridine and an equal volume of acetic anhydride was added. After overnight standing, the reaction mixture was poured into ice-water. The resulting solid was filtered off and crystallized from methanol to give 2.21 g., m.p. 164–182°. This crude material was used as such in the subsequent reduction. An analytical sample was obtained by fourfold recrystallization from methanol: m.p. 190–196°, $[\alpha]^{24}D$ −13.1° ($CHCl_3$); $\lambda_{max}^{CHBr_3}$ at 2.76, 2.86, 3.00, 5.73(sh), 5.81, 5.94(sh), 12.28 and 12.50 μ.

Anal. Calcd. for $C_{26}H_{36}O_6$: C, 69.93; H, 8.58. Found: C, 69.88; H, 8.45.

3β,17α,20ξ,21-Tetrahydroxy-Δ^5-bisnorcholene 3,21-Diacetate. A. From Xb *via* Reduction with Lithium Aluminum Hydride.—Lithium aluminum hydride (2.00 g.) was dissolved in 100 ml. of dry tetrahydrofuran, and to it was added 2.03 g. of the diacetate VII dissolved in 75 ml. of tetrahydrofuran. The reaction mixture was allowed to reflux overnight and then the excess reagent was destroyed with ethyl acetate. Dilute sulfuric acid (200 ml., 5% aqueous) was added and the reaction products partitioned between water and ethyl acetate. The organic phase was washed with sodium bicarbonate and water and eventually dried and concentrated. Crystallization of the residue from ethyl acetate gave 500 mg. of a product, m.p. 185–215°, which did not show absorption in the carbonyl region of the infrared spectrum. The material was dissolved in 5 ml. of pyridine, and an equal volume of acetic anhydride was added. The solution was allowed to stand overnight and was then poured into ice-water. The resulting crude (m.p. 145–170°) was crystallized from ethyl acetate to give 267 mg. of VIIIb, m.p. 217–230°. After three recrystallizations from methanol, there remained 127.2 mg. of an analytical sample, m.p. 228–235°, $[\alpha]^{24}D$ −70.1°; λ_{max}^{Nujol} at 2.84, 5.76, 5.82, 5.98(sh) and 8.02 μ.

Anal. Calcd. for $C_{26}H_{40}O_6$: C, 69.61; H, 8.99. Found: C, 69.57; H, 8.85.

B. **From VIa *via* Grignard Reaction.**—Methylmagnesium bromide was prepared in the usual manner by allowing 15 ml. of methyl bromide to react with 5.7 g. of magnesium

(24) A capillary melting point, however, was 217–223°, as previously reported.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

turnings in 350 ml. of anhydrous ether. A solution of 5 g. of 3β,17α,21-trihydroxy-Δ⁶-pregnen-20-one 3,21-diacetate (VIa) was then added dropwise and the resulting reaction mixture was allowed to reflux overnight. The suspension was cooled, and 500 ml. of 5% sulfuric acid was added. After 2 hr. of agitation, the two phases were separated, and the aqueous layer was extracted with ethyl acetate. The combined organic fractions were washed with sodium bicarbonate and water to neutrality and dried over sodium sulfate. Vacuum concentration gave a crude product which was acetylated immediately. (In another experiment, methylation of 2.18 g. of VIa gave a crude which was crystallized from ethyl acetate to give 790 mg. with m.p. 214–248°. This material, in spite of the great discrepancy of the melting point, possessed an infrared spectrum very like that of the lithium aluminum hydride reduction product of VIIa. However, like the latter, it could not be purified by conventional techniques.) The entire residue was dissolved in 50 ml. of pyridine, and 50 ml. of acetic anhydride was added. The solution was allowed to stand at room temperature overnight and then poured into ice-water. The resulting solid was filtered and recrystallized from methanol to give 1.12 g., m.p. 185–202°. Three recrystallizations from ethyl acetate followed by two from methanol gave an analytical sample, 250 mg., m.p. 225–232°, no depression upon admixture of the diacetate from the lithium aluminum hydride reduction of VIIa, infrared spectrum identical with that of the latter, $[\alpha]^{25}_{D}$ −64.9°.

The Synthesis of Some 14-Iso-11-ketosteroids. Stereochemical Course of Chemical and Catalytic Reduction of a 14β-Δ⁸-11-Ketosteroid[1,2]

BY CARL DJERASSI AND G. H. THOMAS[3]

RECEIVED JANUARY 17, 1957

The lithium–ammonia reduction product of Δ⁸-22a,25a,5α,14β-spirosten-3β-ol-11-one (IVa) was shown to be 22a,25a,5α,-14β-spirostan-3β-ol-11-one (VIa) by converting the latter to the known 14β,17α-allopregnan-3β-ol-20-one acetate (XIb). With a reference compound (VI) of known stereochemistry now being available, application of conformational analysis leads to the assignment of the 8α,9α-orientation (V) to the *catalytic hydrogenation* product of IV. The elucidation of the stereochemistry of the *chemical reduction* product (VI) has a bearing on the evaluation of conformational factors involved in the metal–ammonia reduction of unsaturated ketones.

Recently, there has been undertaken in these laboratories a program aimed at the synthesis of steroid hormones with an abnormal configuration at C-8[4] and/or C-14 in order to evaluate the consequences of such a minor stereochemical change upon biological activity. The starting material for all the projected syntheses was Δ⁸-22a,25a,5α-spirosten-3β-ol-11-one (I)[5] since it is readily available[6] from diosgenin and can be transformed into the various C-8 and C-14 isomers.

Treatment of the unsaturated ketone I with base effects isomerization at C-14[6] and the resulting 14β-Δ⁸-11-ketone (IV) yields two different saturated 14-iso(β)-11-ketones depending upon whether chemical or catalytic reduction methods are employed. It already has been pointed out[6] that in the absence of a reference compound (as is the case with II in the 14α-series), a stereochemical assignment in the 14β-series is difficult since of the four possible isomers (V–VIII), all but one (VIII) can exist in an all-chair conformation.[7] Since precise information about the stereochemistry of these reduction products was necessary in order that the subsequent transformation to steroid hormone isomers be of stereochemical value, correlation of one of the reduction products of IV with a steroid of known configuration was attempted. The results of this work and its bearing upon certain aspects of carbanion reduction processes[8] form the subject of this paper.

The lithium–ammonia reduction product of Δ⁸-22a,25a,5α,14β-spirosten-3β-ol-11-one (IVa), now shown to be 22a,25a,5α,14β-spirostan-3β-ol-11-one (VIa), was transformed by a modified Wolff–Kishner reduction[9] and subsequent acetylation to 22a,-25a,5α,14β-spirostan-3β-ol acetate (IXb).[10] Con-

(10) The argument might be raised that even though the saturated 11-ketone was found to be stable to base, it could still have been represented by the 8β,9β-11-ketone VII and that IX (8β,9α) is produced in the Wolff–Kishner reduction by a "kinetic inversion" *via* the 8β,9α-ketone VI similar to the observed (ref. 5) reduction of the alkali-stable 14-iso(β)-digitogenone to gitogenin (14α). Such a kinetic inversion would require a considerable difference in the reactivity of the carbonyl groups in VI and VII which cannot be determined experimentally since only one isomer is known. However, two arguments can be offered against such an assumption: (a) the good yield in the Wolff–Kishner reduction (VI → IX) in contrast to the poor one observed in the digitogenin series (ref. 5); (b) conformational analysis which would suggest that VI should be more stable than VII in spite of the fact that both can exist in all-chair conformations. Not only is the 9–11 bond axial in VII, but there exists also a 1,3-diaxial interaction between the 7–8 and 13–17 bonds which is not found in VI. In any event, none of the other stereochemical assignments made in this paper are affected by this question since the 8β-orientation has been proved rigorously by conversion to XI.

It should be noted that in the 14α-series the 8β,9β-isomer can be isomerized with base to the natural 8β,9α-derivative (P. Bladon, H. B. Henbest, E. R. H. Jones, B. J. Lovell, G. W. Wood, J. Elks, R. M. Evans, E. E. Hathway, J. F. Oughton and G. H. Thomas, *J. Chem. Soc.*, 2921 (1953)), but on the other hand the conformational difference between the two isomers is a much more striking one (see Table I in ref. 6 and A. Crawshaw, H. B. Henbest, E. R. H. Jones and A. A. Woolland, *ibid.*, 3420 (1955)) as compared to the 14β-series.

a, R = H; b, R = CH_3CO; c, R = CH_3CH_2CO.

ventional side chain degradation yielded Δ^{16}-14β-allopregnen-3β-ol-20-one acetate (Xb), and catalytic hydrogenation led in good yield to 14β,17α-allopregnan-3β-ol-20-one acetate (XIb), which had been obtained[11] previously by catalytic hydrogenation of $\Delta^{14,16}$-allopregnadien-3β-ol-20-one acetate.[12]

The above correlation with a 14β-steroid (XI) of

(11) P. A. Plattner, L. Ruzicka, H. Heusser and E. Angliker, *Helv. Chim. Acta*, **30**, 385 (1947); P. A. Plattner, H. Heusser and A. Segre, *ibid.*, **31**, 249 (1948).

(12) While C-8 and possibly even C-9 could have been involved (*via* the enol) in the preparation and reduction of the $\Delta^{14,16}$-dien-20-one, this has been excluded by a correlation with a 14β-androstane derivative where participation of C-8 and C-9 need not be considered (A. F. St. André, H. B. MacPhillamy, J. A. Nelson, A. C. Shabica and O. Wintersteiner, THIS JOURNAL, **74**, 5506 (1952)).

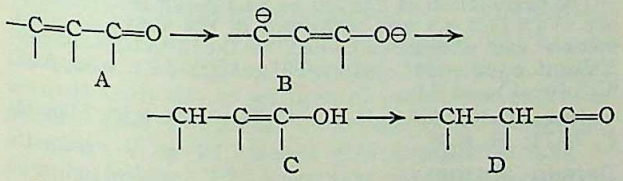
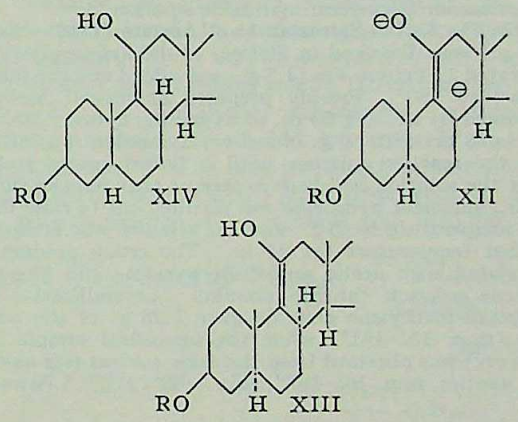
known configuration at C-8 and C-9 establishes[10] the stereochemistry of the *chemical reduction product* (VI) of the 14β-Δ^8-11-ketone IV and thus offers an important reference compound. The plausible criterion[8,13] that chemical reduction of an α,β-unsaturated ketone (under equilibration conditions) gives the thermodynamically more stable product could, *a priori*, not have been applied easily to the present case (IV) since the energy differences are probably small. While VIII is surely the least favored (ring B present as boat),[7] analysis by Johnson's method[14] —determination of number of equatorial and axial bonds by which the central ring is joined to its two neighbors—shows only a difference of one axial bond in favor of the all-chair 8β,9α-isomer VI over the all-chair 8α,9α-isomer V.[15]

The present chemical proof that the lithium–ammonia reduction product is represented by the 8β,9α-11-ketone VI offers also a means of establishing the stereochemistry of the *catalytic hydrogenation* product of the 14β-Δ^8-11-ketone IV. Since the hydrogenation product was stable to heating with alkali,[6] the 8β,9β-isomer VII is excluded since it would have led to the chemical reduction product VI, which was also unaffected by base. This leaves only 22a,25a,5α,8α,14β-spirostan-3β-ol-11-one (Va) as the appropriate structure for the hydrogenation product since it (all-chair conformation) would not be expected to be isomerized to the *trans*-isomer VIII (requiring ring B as a boat).[7]

It has been suggested[8] that reduction of α,β-unsaturated ketones A by metals in liquid ammonia proceeds *via* the dianion B which is protonated to the enol C and then furnishes the saturated ketone D. This implies that the controlling factor for the eventual stereochemistry of the saturated ketone D is the protonation step of the β-carbon atom, since the more stable orientation at the enolizable α-position (*cf.* C) will be governed by it.[16]



The above course of the reaction (A → D) is in accordance with all the reductions reported so far[8,13] for unsaturated alicyclic ketones and in each instance protonation of the β-position resulted in a *trans* or *anti* relationship with respect to hydrogen or methyl at the γ-carbon atom. The presently investigated reduction of the 14β-Δ^8-11-ketone IV demonstrates clearly that this need not be the case. Rather than indicating that protonation at the β-carbon atom does not occur first, the *syn* configuration for the present case provides good support for the conclusion that metal–ammonia reduction will give the more stable stereoisomer insofar as the β-position is concerned.[16,17] Conformational analysis suggests that the same factor[15] favoring the ketone VI (8β,9α) over V (8α,9α) also applies to the enols XIV (8β) and XIII (8α) and that consequently the *syn*-stereochemistry (XIV) is produced.



With the stereochemistry of the 11-oxygenated sapogenins (V and VI) established, these compounds can now serve as standard starting materials for the synthesis of 11-oxygenated steroids with abnormal configuration. Side chain degradation of V and VI led respectively to Δ^{16}-8α-14β-allopregnene-11,20-dione-3β-ol acetate (XVb) and Δ^{16}-14β-allopregnene-11,20-dione-3β-ol acetate (XVIb), which could represent key intermediates for the synthesis of 14-iso and 8-iso-14-iso 11-oxygenated cortical hormones. In the case of Δ^{16}-14β-allopregnene-11,20-dione-3β-ol acetate (XVI) it was also attempted to synthesize the corresponding 17-ketone XVIIb by Beckmann rearrangement of its oxime,[18] and while it was possible to isolate the desired substance, the yield was sufficiently poor to discourage further transformations.[19]

Experimental[20]

Δ^8-22a,25a,5α,14β-Spirosten-3β-ol-11-one Acetate (IVb). —Since only the propionate IVc had been described earlier,[6] a sample of the alcohol IVa[6] was acetylated with acetic anhydride–pyridine overnight and recrystallized from ether–hexane, m.p. 188–190°, $[\alpha]_D$ +86°; $\lambda_{max}^{CHCl_3}$ 5.76, 5.98, 6.18 (weak) and 8.0 μ.

Anal. Calcd. for $C_{29}H_{42}O_5$: C, 74.01; H, 9.00. Found: C, 74.33; H, 9.29.

(13) Leading references are given by H. Heusser, M. Roth, O. Rohr and R. Anliker, *Helv. Chim. Acta*, **38**, 1178 (1955).

(14) W. S. Johnson, *Experientia*, **7**, 315 (1951); THIS JOURNAL, **75**, 1498 (1953).

(15) The important factor to be considered is the nature of the non-bonded interaction produced by the additional axial linkage. In point of fact, this is rather serious in the 8α,9α-11-ketone V since ring C is now present in a different chair conformation (not possible in the 14α-series because of the *trans* C/D ring juncture) with an equatorial C-13 angular methyl group, whereby there is produced a 1,3-diaxial interaction between the C-10 angular methyl group and the 8–14 bond. No such interaction is present in the 8β,9α-isomer.

(16) Provided the reaction mixture is worked up under equilibration conditions. H. E. Zimmerman (THIS JOURNAL, **78**, 1168 (1956)) and A. J. Birch, H. Smith and R. E. Thornton (*J. Chem. Soc.*, 1339 (1957)) have called attention to the fact that under non-equilibrium conditions the unstable isomer (at the α-position) may be formed.

(17) An exception to this statement has been presented recently in the decahydrochrysene series in the reduction of a styrene double bond by W. S. Johnson, J. Ackerman, J. F. Eastham and H. A. De Walt (THIS JOURNAL, **78**, 6302 (1956)). However, a complicating factor was the presence of a hydroxyl group at the ring juncture which may have directed attack to the opposite side of the molecule because of electrostatic repulsion.

22a,25a,5α,14β-Spirostan-3β-ol-11-one (VIa).—The earlier reported reduction[6] (of the propionate IVc) was carried out in slightly modified form (with the acetate IVb) on a larger scale. A solution of 6.0 g. of the above acetate IVb in 50 cc. of dry ether was added with stirring at −40° to a solution of 400 mg. of lithium in 500 cc. of liquid ammonia. After stirring for 4 min., the excess metal was decomposed by the addition of ammonium chloride, the ammonia was allowed to evaporate and the residue was treated with 5% methanolic potassium hydroxide for 1 hr. with occasional warming. Isolation with ether yielded 5.2 g. of solid (m.p. 216–220°) which was chromatographed on 200 g. of alumina. Elution with benzene–ether and recrystallization from ether–hexane furnished 3.01 g. of the saturated ketone VIa[6] as needles, m.p. 236–239°. The substance was recovered unchanged after being heated under reflux for 20 hr. with 5% ethanolic potassium hydroxide solution.

22a,25a,5α,14β-Spirostan-3β-ol Acetate (IXb).—Sodium (2.0 g.) was dissolved in 200 cc. of diethylene glycol, the saturated 11-ketone VIa (1.5 g.) was added and the solution heated to 180°. Freshly prepared anhydrous hydrazine (obtained by heating 50 cc. of hydrazine hydrate under reflux for 3 hr. with 50 g. of sodium hydroxide) was distilled into the reaction mixture until it boiled gently at 180°. After the solution had been heated at that temperature for 18 hr., sufficient hydrazine was distilled out to raise the reflux temperature to 210°, and the mixture was maintained at that temperature for 24 hr. The crude product was acetylated with acetic anhydride–pyridine and filtered in benzene solution through alumina. Crystallization from methanol–methylene chloride gave 1.25 g. of the acetate IXb (m.p. 155–161°) while the analytical sample (85% recovery) was obtained from the same solvent pair as colorless needles, m.p. 165–167°, $[\alpha]_D$ −38°, $\lambda_{max}^{CHCl_3}$ 5.79 and 8.0 μ.

Anal. Calcd. for $C_{29}H_{46}O_4$: C, 75.94; H, 10.11. Found: C, 76.11; H, 10.05.

Δ16-14β-Allopregnen-3β-ol-20-one Acetate (Xb).—The above sapogenin IXb (1.5 g.) was heated in 10 cc. of acetic anhydride in a sealed tube for 9 hr. at 195°. The cooled reaction mixture was poured onto ice and the product was isolated with ether. Chromium trioxide (0.9 g.) in 10 cc. of 90% acetic acid was added dropwise to a solution of the furosten in 35 cc. of 80% acetic acid and 24 cc. of ethylene dichloride, the solution then being stirred for 2 hr. at room temperature. Extraction with ether yielded a gum which was adsorbed on 60 g. of basic alumina in benzene solution. After standing for 1 hr., the product was eluted with benzene and 1:1 benzene–ether and recrystallized from methanol; yield 0.33 g., m.p. 167–170°. Further recrystallization from methanol gave the analytical sample with the following constants: m.p. 170–172°, $[\alpha]_D$ +74°; λ_{max}^{EtOH} 242 mμ, log ε 3.95; $\lambda_{max}^{CHCl_3}$ 5.79, 5.99, 6.21 (weak) and 8.0 μ.

Anal. Calcd. for $C_{23}H_{34}O_3$: C, 77.05; H, 9.56. Found: C, 77.16; H, 9.71.

14β,17α-Allopregnan-3β-ol-20-one Acetate (XIb).—The Δ16-20-ketone Xb (250 mg.) in 50 cc. of ethyl acetate was shaken with 10% palladized charcoal (70 mg.) in an atmosphere of hydrogen for 1 hr. The uptake of hydrogen was rapid and the crude reduction product showed no significant ultraviolet absorption at 242 mμ. Crystallization from aqueous methanol yielded the saturated ketone (XIb) as laths (185 mg.), m.p. 109–110°, $[\alpha]_D$ +7°; $\lambda_{max}^{CHCl_3}$ 5.79, 5.85 and 8.0 μ. Identity with authentic specimens,[11,12] kindly provided by Dr. H. Heusser (E. T. H., Zurich) and Dr. H. B. MacPhillamy (Ciba Pharmaceutical Products, Summit, N. J.), was established by mixture melting point determination and by infrared comparison.

Anal. Calcd. for $C_{23}H_{36}O_3$: C, 76.62; H, 10.07. Found: C, 76.71; H, 10.10.

Δ16-14β-Allopregnene-11,20-dione-3β-ol Acetate (XVIb).—The side chain degradation of 1.3 g. of 22a,25a,5α,14β-spirostan-3β-ol-11-one (VIa) was carried out exactly as described above for the 11-desoxo compound and yielded 470 mg. of crude, crystalline ketone (λ_{max}^{EtOH} 235 mμ, log ε 3.89). Recrystallization from aqueous acetone furnished 390 mg. of the analytical sample as needles, m.p. 182–184°, $[\alpha]_D$ +34°; λ_{max}^{EtOH} 235 mμ,[21] log ε 3.90; $\lambda_{max}^{CHCl_3}$ 5.80, 5.84, 5.98, 6.15 (weak) and 8.0 μ.

Anal. Calcd. for $C_{23}H_{32}O_4$: C, 74.16; H, 8.66. Found: C, 74.57; H, 9.03.

14β-Androstane-11,17-dione-3β-ol Acetate (XVIIb).—The Δ16-11,20-diketone XVIb (390 mg.) in ethanol (2 cc.) and pyridine (0.5 cc.) was heated under reflux with 170 mg. of hydroxylamine hydrochloride for 30 min. No solid separated on leaving the solution at 20° for 18 hr. Accordingly, the oxime was precipitated with water, collected and dried *in vacuo* over phosphorus pentoxide.

The crude oxime was dissolved in 2 cc. of pyridine, cooled to 0° and a solution of *p*-acetamidobenzenesulfonyl chloride (0.5 g.) in 2 cc. of pyridine was added. The solution was kept at 20° for 2 hr. during which time a considerable amount of discoloration occurred. On addition of water a black gum separated which could not be induced to solidify. Sulfuric acid (5.5 cc. of 10%) was added and the reaction mixture was heated on the steam-bath for 2 hr. The residual solid was collected and extracted several times with benzene. Evaporation of the combined extracts afforded 90 mg. of a gummy solid which was crystallized from methanol to give 40 mg. of the 11,17-diketone XVIIb as needles, m.p. 248–253°. The analytical specimen was sublimed at 160° and 0.005 mm. and exhibited m.p. 251–255°; $\lambda_{max}^{CHCl_3}$ 5.75, 5.79–5.84 (broad) and 8.0 μ.

Anal. Calcd. for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73. Found: C, 73.02; H, 8.94.

It should be noted that no difficulty was encountered in duplicating the recorded yield[17] in a model experiment with Δ5,16-pregnadien-3β-ol-20-one acetate.

Δ16-8α,14β-Allopregnene-11,20-dione-3β-ol Acetate (XVb).—The degradation of 22a,25a,5α,8α,14β-spirostan-3β-ol-11-one (Va)[6] (1.2 g.) was performed in the above described manner and afforded 200 mg. of the Δ16-11,20-diketone XVb, m.p. 131–132°, $[\alpha]_D$ +99°; $\lambda_{max}^{CHCl_3}$ 5.81, 5.85, 5.98, 6.13 (weak) and 8.0 μ.

Anal. Calcd. for $C_{23}H_{32}O_4$: C, 74.16; H, 8.66. Found: C, 73.74; H, 8.58.

DETROIT, MICHIGAN

(21) A similar bathochromic shift due to the 11-ketone has been observed in the 14α-series (E. M. Chamberlin, W. V. Ruyle, A. E. Erickson, J. M. Chemerda, L. M. Aliminosa, R. L. Erickson, G. E. Sita and M. Tishler, THIS JOURNAL, **73**, 2396 (1951); C. Djerassi, E. Batres, J. Romo and G. Rosenkranz, *ibid.*, **74**, 3634 (1952)).

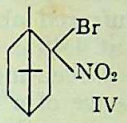
Structure of the Anhydrobromonitrocamphanes

BY EUGENE E. VAN TAMELEN AND JOSEPH E. BRENNER[1]

RECEIVED JANUARY 30, 1957

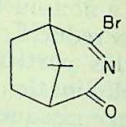
Structures I and II are proposed for anhydrobromonitrocamphane-I and -II, first prepared in 1899 by acid treatment of 2-bromo-2-nitrocamphane.[2]

During the course of his investigations dealing with the preparation and properties of (−)-2-bromo-2-nitrocamphane (IV), Forster[2] subjected

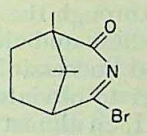


IV

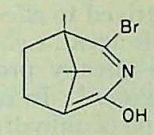
the substance to the action of concentrated sulfuric acid at 0° and found that there was formed, in addition to some 2-bromo-*p*-cymene, a crystalline *monodehydration product* (I). The same author noted further that hot, aqueous mineral acid induced the transformation of this anhydride into a well-defined *isomer* (II).[2] A similar pair of products was secured from 2-chloro-2-nitrocamphane,[3] although 2-nitro- and 3-bromo-2-nitrocamphane were indifferent to the acid reagent.[4] Following additional study,[4] Forster in 1901 suggested for I (referred to herein as "anhydrobromonitrocamphane-I") an *N-acyliminobromide structure* (V or VI), which Ginnings and Noyes[5] later adopted in



V



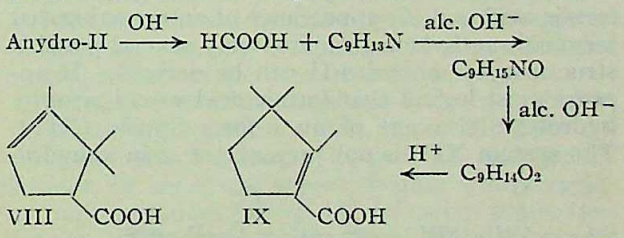
VI



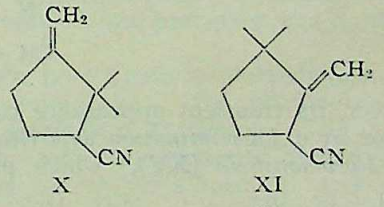
VII

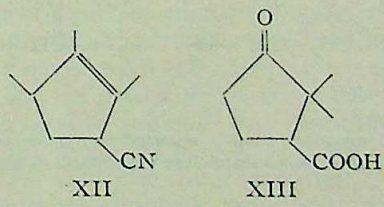
their *enol formulation* (VII) for the isomer II ("anhydrobromonitrocamphane-II"). For several, readily apparent, reasons the proposal VII can be dismissed. Moreover, Forster's structure hardly accords with the experimental facts; for example, mineral acid treatment of a compound possessing structure V or VI should give camphoric acid or camphorimide. The ineptness of the bromonitrocamphane structure for accommodating a dehydration reaction,[4] we, as did Forster, found arresting; consequently we took up the matter, which seemingly had lain unattended since 1922.[5]

Since there has been recorded more chemical information about anhydro-II, this isomer appeared better suited for initial study. Forster reported that, in addition to hot hydrochloric acid, various mild bases such as hydroxylamine, phenylhydrazine and alcoholic ammonia served to convert anhydro-I to -II,[4] and we have observed that the change can be brought about by heat alone. It is recorded that anhydro-II melts at 240° and is optically inactive. The substance was negative in the Liebermann nitroso reaction and was stable to bromine, permanganate and zinc dust and acetic acid. A benzoyl derivative resulted from treatment with benzoyl chloride. But by far the most provocative and valuable of Forster's observations is the change engendered by refluxing dilute aqueous alkali: *anhydro-II, as well as anhydro-I, was cleaved to formic acid and a liquid nitrile possessing the formula* $C_9H_{13}N$.[2] The latter substance, on hydrolysis with alcoholic alkali, led successively to the amide and acid.[6] The end product, isomeric with α-campholytic acid (VIII) and isolauronolic acid (IX), was transformed by mineral acid into the lat-



ter of these two previously known substances. Of the structures for the C_9-nitrile which can accommodate these results (*e.g.*, X-XII), 2,2-dimethyl-3-





methylenecyclopentanecarbonitrile (X) has been established as correct, in that ozonization led to formaldehyde and the known 2,2-dimethyl-3-ketocyclopentanecarboxylic acid (XIII).[7,8] The

(8) Before obtaining the new C_9-acid corresponding to the C_9-nitrile, Forster erroneously believed[2] that he had in hand the previously unknown nitrile (and amide) of α-campholytic acid (VIII). Later G. Blanc (*Bull. soc. chim.*, **23**, 695 (1900)) reported that sodium and alcohol reduction of Forster's nitrile afforded α-aminocampholene, identical with the product of hypohalite degradation of α-campholenamide, which at that time Blanc believed to possess structure i. The α-campholenamide structure was soon revised to ii, however; and Forster, on the basis of Blanc's experimental finding, therefore assigned[6] structure iii to his nitrile ("infracampholenonitrile"). Forster was then compelled to "revise" the structure for campholytic acid which is now known to be correct, and he regarded it as best represented by iv. With the structures of all these substances now estab-

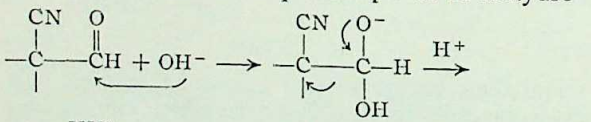
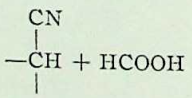
structure assignment was in agreement with the ultraviolet spectrum, showing no selective absorption, and the infrared spectrum, which revealed the nitrile function (4.48 μ) and the terminal methylene grouping (6.08 and 11.27 μ).

The nature of the reactive centers in anhydrobromonitrocamphane-II was clarified by means of its infrared spectrum: well-defined peaks at 2.80 and 4.48 μ definitely indicated the presence of hydroxyl and nitrile functions. Furthermore, the anhydro compound was virtually transparent in the ultraviolet, and infrared bands indicative of a terminal methylene grouping were absent; thus it appeared that this molecule was saturated. Forster's conversion of anhydro-II to a benzoyl derivative (absorption at 4.48 and 5.82 μ) also points to a hydroxyl substituent, and this conclusion has been supported further by the preparation of a methanesulfonate.

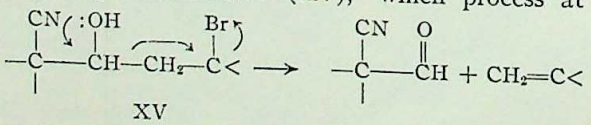
By incorporating the above information into a mechanistic scheme which satisfactorily accounts for (1) the conversion by base to the C_9-nitrile and formic acid and (2) appearance of an unconjugated terminal methylene grouping, only several possible structures for anhydro-II can be derived. It appears most logical that formic acid would arise by hydrolytic cleavage of an α-formylnitrile (XIV). The system XIV is not present *per se* in anhydro-



XIV

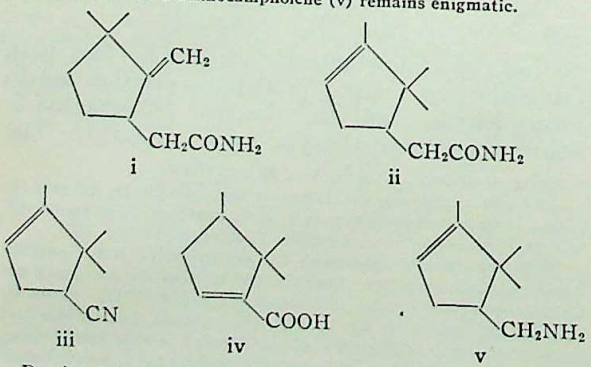


II; however, its transient appearance can be accounted for by *a 1,4-elimination with cleavage of a β-hydroxy-δ-bromonitrile* (XV),[9] which process at



XV

lished beyond question, Blanc's reported conversion of "infracampholenonitrile" to α-aminocampholene (v) remains enigmatic.



i ii iii iv v

Despite the conflicting and insufficient evidence, structure X has been assumed to represent Foster's nitrile (Beilstein's "Handbuch der Organischen Chemie," Vol. IX, Julius Springer, Berlin, 1926, p. 61; E. Josephy and F. Radt, Elsevier's "Encyclopedia of Organic Chemistry," *Ser. III*, Vol. 12A, Elsevier Publishing Co., Inc., New York, N. Y., 1948, p. 600).

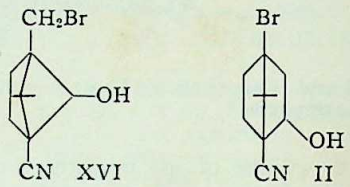
the same time generates the required olefinic linkage. Application to the case under consideration leads to the formulations XVI and II for anhydro-II. Now, chromic acid oxidation afforded a crys-



XVI II

talline ketone, m.p. 237°, which regenerated anhydro-II in high yield on reduction with sodium borohydride. The infrared absorption of the ketone featured bands at 4.48 μ—indicating that the nitrile portion had not been modified—and at 5.71 μ, revealing the presence of a cyclopentanone system, a result at variance with that anticipated for structure XVI. Apart from this, the indifference of anhydro-II toward hot silver nitrate is difficult to accommodate on the basis of XVI; II, however, bears a bridgehead halogen, well-recognized for its inertness under SN1 conditions.[10]

Although II (2-hydroxy-4-bromoapocamphane-1-carbonitrile) remains as the solely acceptable structure for anhydro-II, independent confirmation of the proposal was sought. The carbon–oxygen system of camphor is, of course, present, and it seemed that conversion to some appropriate member of that family would serve admirably as a structural proof. In that regard we faced hydrogenolytic removal of the bridgehead halogen, which we contrived to effect through the use of a non-nucleophilic agent, *e.g.*, sodium and alcohol, a reducing device already proved successful for this particular purpose.[11] In order to obviate the elimination reaction of anhydro-II, an almost certain consequence of employing the basic reducing agent, the hydroxyl group was protected by conversion to the tetrahydropyranyl ether (XVII).[12] Hydrogenolysis and

(10) In a related, but less likely, process, a β-cyano-δ-bromo alcohol eliminates, accompanied by bond migration from the alcoholic carbon

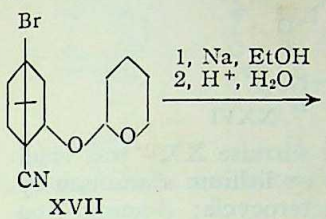
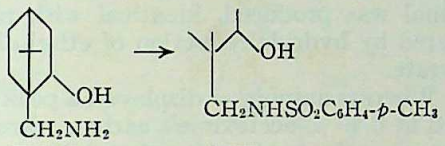
reduction of the nitrile to a primary amino group were effected simultaneously; and the intermediate ether was hydrolyzed without isolation to the free aminoalcohol XVIII, which in turn was converted

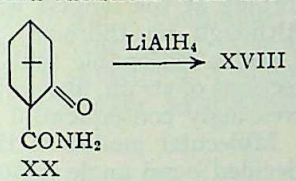


XVII



XVIII XIX

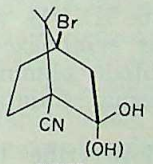
directly to the crystalline *p*-toluenesulfonamide XIX, m.p. 165–166°. This same sulfonamide was found to be derivable from the well-known ketopinic acid.[13] Preparation of ketopinamide (XX) was followed by lithium aluminum hydride reduction; the *p*-toluenesulfonamide of the resulting aminoalcohol was found identical with the corresponding



XX

derivative secured from anhydro-II. The sulfonamide was characterized by chromic acid oxidation to a crystalline ketone, which displayed carbonyl absorption in the infrared at 5.8 μ.

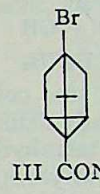
The stereoelectronic demands of the elimination reaction leading to the C_9-nitrile are satisfied by the proposed structure—halogen as well as carbons 2, 3 and 4 describe a plane, as illustrated in XXI.



XXI

Although the carbon–oxygen bond cannot lie in this plane, its geomtery is probably not critical for the elimination[14]; conversely, no conclusion regarding the configuration of the hydroxyl can be drawn from the elimination result.

During the period when we were gathering evidence bearing on the structure of anhydrobromonitrocamphane-I (*vide infra*), its reconstitution from anhydro-II was attempted. Concentrated sulfuric acid, acting for three days at room temperature on the stabler anhydride, did indeed bring about a change, although examination of the product showed it to be a *new isomer* (m.p. 201–202°), which was designated as *anhydrobromonitrocamphane-III*. Simple diagnostic tests revealed the substance to be neutral, and stable to bromine, chromium trioxide or permanganate in the Baeyer test; and infrared spectral analysis led to the conclusion that a primary amide (6.08 and 6.41 μ) grouping was present. Confirmation of this structural feature was found by conversion with nitrous acid to a carboxylic acid which, as its methyl ester, was reduced by lithium aluminum hydride to an alcohol, characterized as a 3,5-dinitrobenzoate. The chemistry described is well accommodated by the structure III for anhydro-III, which arises by



III

controlled nitrile hydrolysis accompanied by 2,6-dehydration with formation of a cyclopropane ring.[15] The formulation III (4-bromotricyclenamide) is strengthened by the persistence throughout the series of a strong band at *ca.* 10 μ, attributable to the presence of the three-membered ring.

Anhydrobromonitrocamphane-I is a colorless substance which does not melt, but at 210–220° decomposes and rearranges in part to anhydro-II. Forster, in his initial report dealing with this dehydration product,[2] listed the following properties: negative Liebermann nitroso test; stability to cold concentrated nitric acid, hot concentrated sulfuric acid, boiling pyridine and bromine in chloroform; oxidation by permanganate in dilute sulfuric acid. Like anhydro-II, the precursor was optically inactive.

Our own investigations started, again, with a spectral examination: the ultraviolet spectrum showed a single band at 225 mμ (ϵ 2300); in the infrared there was no evidence of hydroxyl or nitrile absorption but rather a medium peak at 6.40 μ, suggestive of a carbon–nitrogen double bond.

Since anhydro-I is transformed readily to -II (or products derived from -II[4]), acquisition of chemical evidence for the structure of the former under as mild conditions as possible was desirable. Reduction seemed most promising, and we accordingly studied the catalytic hydrogenation, as well as lithium aluminum hydride reduction, of the parent anhydride. The hydride reaction, carried out under normal conditions, provided a mixture of products, from which were separated two crystalline materials. One of these, isolated in about 20% yield, was indicated by analysis to be a dihydroanhydro-I, which was not investigated further. The second product, a base formed in 60% yield, was readily recognized as a tetrahydroanhydro-I and was characterized by conversion to N-toluenesulfonyl and N-benzoyl derivatives. The catalytic reduction of anhydro-I in ethanol–sulfuric acid proceeded to give a tetrahydro product, isolated as the sulfate salt, which was converted directly to an N-benzoyl derivative identical with that secured from the hydride reduction. This amine appeared to be a *bona fide* reduction product of anhydro-I, in that

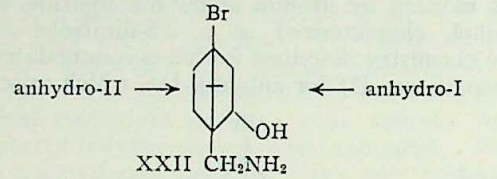
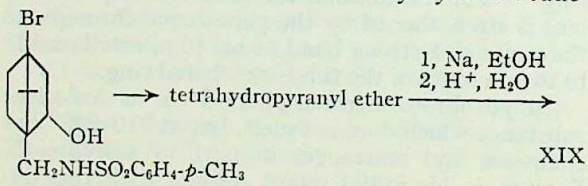
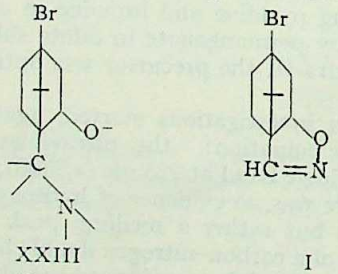
the latter remained unaltered when subjected, in the absence of hydrogen, to the catalytic hydrogenation conditions used. Structure assignment to the tetrahydro compound was made possible by the finding that *this same base resulted from lithium aluminum hydride or catalytic reduction of anhydro-II*—only the aminoalcohol formulation XXII is reasonable. This assignment was confirmed by relating the amine to one of already demonstrated structure. The sulfonamide of the tetrahydro compound, after conversion to the tetrahydropyranyl ether, was reductively debrominated by sodium and alcohol; mild acid hydrolysis then yielded the sulfonamide XIX of the same amine secured by hydride reduction of ketopinamide. These findings led to the important conclusion that *anhydro-I and -II possess the same carbon–oxygen–nitrogen skeleton* (*XXIII*).

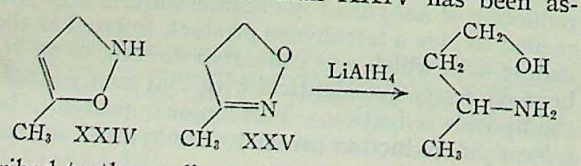




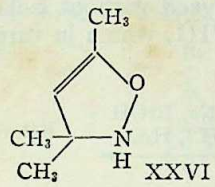


Moreover, the molecular formula requirement, taken together with the absence of –NH, –OH and –CN stretching absorption in the infrared region, invalidate all sterically possible structures for anhydrobromonitrocamphane-I but one: *the isoxazoline* (I).

In order to consolidate the evidence bearing on this proposal, we set about to gather, from model compounds, information which would impart significance to the spectral properties of anhydro-I. Unfortunately, there appeared to be no information available on the spectral behavior of oxime-O-ethers, and the literature seemed wanting in examples of purely aliphatic Δ^2-isoxazolines to which structures had not been assigned arbitrarily or on the basis of meager evidence. For example, the structure XXV rather than XXIV has been ascribed to the cyclic product obtained by the interaction of hydroxylamine with 2-methyl-*p*-chlorostyryl



ketone[16]; contrarily, elsewhere the inorganic reagent is claimed[17] to convert mesityl oxide to the Δ^4-isoxazoline XXVI. The surmise XXV was vindicated in this Laboratory by lithium aluminum hydride reduction of the heterocycle; 3-amino-1-butanol was produced, identical with material prepared by hydride reduction of ethyl *dl*-β-aminobutyrate.



Whereas anhydro-I displayed a peak in the infrared at 6.40 μ, acetoxime's carbon–nitrogen stretching was reflected by a band at 6.01 μ and that of 3-methyl-Δ^2-isoxazoline (XXV), at 6.17 μ. In the ultraviolet region, acetoxime-O-acetic acid[18] absorbed in the shorter wave length region without indication of a peak; the isoxazoline, however, possesses a band at 212 mμ (ϵ 2830). Thus the models and anhydro-I constitute, in both the infrared and ultraviolet regions, a short graded series with the terpenoid absorbing at the longest wave length in each case. Although no thorough analysis was carried out, it seems reasonable that the observed values are reflections of strain, absent in the acyclic cases, but increasingly consequential in the cycles XXV and I. Molecular models of the last structure showed decided bond angle distortion, apparently relieved by electronic displacement and thus accounting for the lower energy requirements for absorption in the ultraviolet. At the same time, the infrared values cited parallel those recorded for cycloalkenes and cyclic imines of medium ring size.[19]

Justification of structure I, insofar as rational conversion to anhydro-II is concerned, offers no great problem. The acid-catalyzed process may be represented by scheme XXVII, whereas the change initiated by base is symbolized by the process XXVIII.[20] Undoubtedly elimination is facilitated by release of the internal strain afflicting the starting isomer.

Inspection of models verifies that an isoxazoline I utilizing an *endo* bond for attachment of oxygen is almost impossibly strained. Accordingly the stereochemistry of anhydro-I can be depicted by

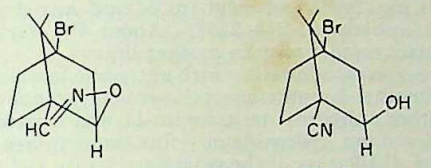
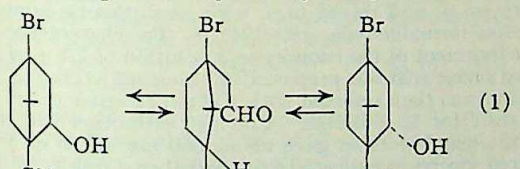
XXVII XXVIII

formula XXIX, *i.e.*, involving fusion of the hetero-



XXIX XXX

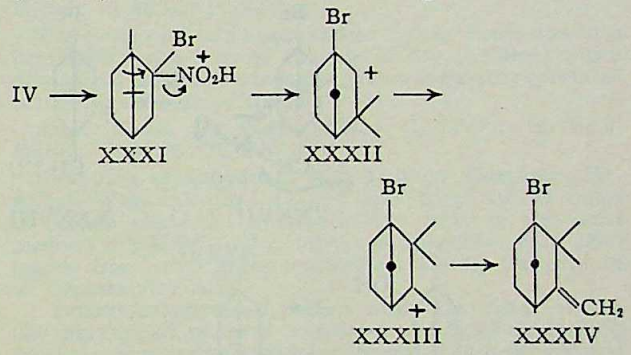
cyclic ring to the camphane system through an *exo* bond, an arrangement still implying definite distortion. The stereochemistry of anhydro-II cannot be disposed of so easily. If, in proceeding from I to II, we assume that no change other than that described by the mechanism considered above (XXVII or XXVIII) occurs, the stereochemical integrity of the hydroxyl group will be maintained, and the configurational assignment XXX is automatic. On the other hand, a subsequent equilibrium system (1) involving the bicyclic hydroxynitrile and the



XXX (1)

monocyclic aldehydronitrile is conceivable and would provide for conversion of the *exo* (less stable[21]) configuration of XXX to the *endo*. The regeneration of anhydro-II through sodium borohydride reduction of the corresponding ketone, a reaction which parallels the lithium aluminum hydride reduction of camphor to isoborneol,[22] also implies, in the simplest interpretation, the *exo* configuration. However, the case is again weakened by the same equilibrium consideration. A secure stereochemical assignment is made possible by reference to the hydrogenation results already detailed. Both anhydro compounds yield the same tetrahydro isomer, which is no longer epimerizable at C-2; since the hydrogenation conditions used are not likely to effect inversion at some intermediary stage,[23] oxygen attachment is *exo* (XXX) in anhydro-II, as in -I. Corollarially, the aldo-type equilibrium (1) considered above cannot intervene to the extent that any detectable amount of the more stable *endo* isomer of anhydro-II accumulates. Further, the hydride reduction of the ketones in this series must then, as in the camphor case, provide the less stable of the possible diastereoisomeric alcohols.

Associated with the structural clarification of anhydro-I is the more fundamental problem of its formation, a change involving a seemingly random reshuffling of non-skeletal atoms. Some order can be gained by considering, first of all, a series of Wagner–Meerwein shifts initiated by attachment of a proton to the nitro group of the starting material (XXXI). Nitrous acid, or its equivalent, is expelled and may remain associated with the cation, although its sphere of activity in these early stages is obscure. Production of the isocamphane skeleton involves a migration of methyl (XXXII → XXXIII) followed by elimination of a proton to give 4-bromocamphene (XXXIV). ω-Nitrosation ensues, yielding XXXV or XXXVI, and this recombination is followed by a second skeletal rearrangement, as expressed by the formulas (XXVI → XXVII). Closure (XXVII) of the isoxazoline ring (which one would anticipate to give the stabler form (*exo*) of I) completes the sequence.[24]



XXXI XXXII XXXIII XXXIV

Earlier it was noted that both I and II are optically inactive. This property can be best accounted for by assuming 2,6-hydrogen transfer at the stage XXXVII, resulting in racemization, either through simple enantiomer production (XXXVII → XXXVIII) or by way of a symmetrical cation.[25,26]

It is possible that reactions in the terpene series similar to those described above have been carried out but gone unrecognized. For example, Konovalov,[27] in 1902, recorded the conversion of camphene by dilute nitric acid at 100° to an oxidation product $C_{10}H_{15}NO$ (m.p. 266–267°). The substance was said to be stable in the bromine and permanganate tests but susceptible to the action of sodium and alcohol. More drastic acid conditions effected transformation to tricyclenic acid (XXXIX). These data, admittedly scanty, are interpretable

(21) Borneol (*endo*) is more stable than isoborneol (*exo*); J. L. Simonsen, "The Terpenes," Vol. II, Cambridge University Press, Cambridge, 1949, pp. 351–353.

(22) W. G. Brown, "Organic Reactions," Vol. VI, John Wiley and Sons, Inc., New York, N. Y., 1951, p. 475.

(23) This same reaction cannot, in fact, be operative since the same aminoalcohol is secured from anhydro-II tetrahydropyranyl ether (XVII), which is not susceptible to the heavy-metal catalyzed, oxidation–reduction equilibrium necessary for inversion under these conditions.

(24) Certain features of this over-all change find analogy in, *e.g.*, the formation of β-camphor dichloride (J. Houben and E. Pfankuch, *Ann.*, **501**, 219 (1933)) and camphor-10-sulfonic acid (E. Wedekind, D. Schenk and R. Stusser, *Ber.*, **56**, 633 (1923)) from camphor.

(25) J. D. Roberts, C. C. Lee and W. H. Saunders, Jr., This Journal, **76**, 4501 (1954).

(26) The most recent publication[5] dealing with anhydro-I or -II describes the action of methylmagnesium iodide on -I. The intermediate ($C_{11}H_{18}ONBr$) was reported to undergo hydrolysis with alkali, affording 1,2,2-trimethyl-3-acetylcyclopentanecarboxylic acid. However, the final product was not compared with authentic material, nor was an analysis reported; consequently, we do not believe that this claim need be reconciled with the findings and conclusions reported in this contribution.

(27) K. Konovalov, *J. Russ. Phys. Chem. Soc.*, **34**, II, 43 (1902).

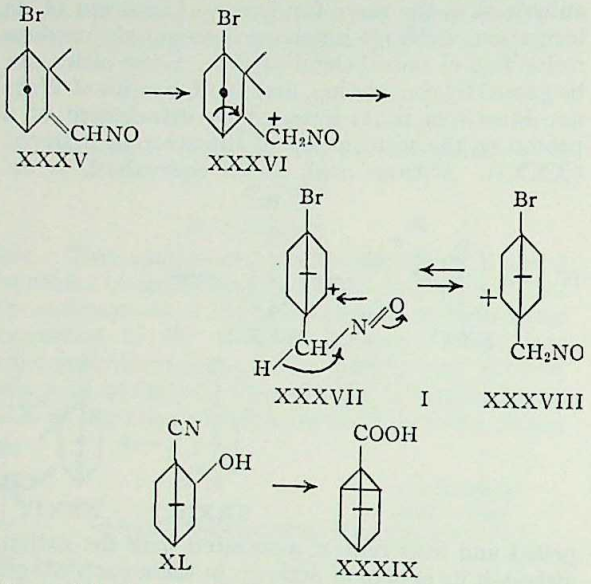
in terms of the structure XL, arising along lines considered above. Konovalov further states that, on treatment with fuming nitric acid, the $C_{10}H_{15}NO$ compound gave rise to a product $C_{10}H_{14}N_2O_3$, which regenerates the starting material on reduction with



tin and hydrochloric acid. A similar pair of reactions characterizes anhydrobromonitrocamphane-II,[2] and the infrared behavior indicates that the nitro derivative is merely the O-nitrate. This explanation is of course equally applicable to the Konovalov case.

Experimental[28]

Anhydrobromonitrocamphane-I.—A solution of 43 g. (0.16 mole) of bromonitrocamphane in 100 ml. of petroleum ether was dropped slowly into a vigorously stirred mixture of 300 g. of concentrated sulfuric acid and 50 ml. of petroleum ether held at −5°. After the addition was complete, the mixture was stirred an additional 0.5 hr., then poured on crushed ice. In order to obtain even fairly good crude material, it was found necessary to wash the precipitated product with dilute ammonia as it was being filtered, since it turned dark brown otherwise. This is in contrast to the experience of Ginnings and Noyes,[5] who state that the product precipitates "as a slightly yellow flocculent solid in nearly quantitative yield, pure enough for most purposes." Recrystallization from ethanol gave in general 18–25 g. of crude product (46–60%).

Anhydrobromonitrocamphane-II.—Refluxing a solution of 10 g. of anhydro-I in 30 ml. of 95% ethanol containing 5 ml. of 12 *N* hydrochloric acid gave anhydro-II essentially quantitatively; m.p., after recrystallization from ethanol–water, 244–245°.[2]

Treatment of II with methanesulfonyl chloride in dry pyridine gave a mesylate as needles from benzene–petroleum ether, m.p. 101–102°.

Anal. Calcd. for $C_{11}H_{16}O_3NSBr$: C, 41.00; H, 5.01. Found: C, 41.06; H, 4.75.

Heating II with fuming nitric acid for 10 minutes on the steam-bath gave a nitrate ester as needles from ethanol, m.p. 99–100°. Infrared bands at 6.07, 7.80 and 11.5 μ could be assigned to the nitrate grouping.

Anal. Calcd. for $C_{10}H_{13}O_3N_2Br$: C, 41.54; H, 4.53. Found: C, 41.59; H, 4.49.

Anhydro-II Ketone.—Anhydro-II (2.4 g., 0.01 mole) was dissolved in 50 ml. of glacial acetic acid and was added with stirring to a cooled mixture of 1.0 g. (0.01 mole) of chromium trioxide in 100 ml. of glacial acetic acid. The mixture was stirred 2 hr. at room temperature; it was then poured into cold water, and the product was collected by filtration and recrystallized from 95% ethanol (prisms). The yield in several runs was 2.1–2.3 g. (85–95%), m.p. 237°. A carbonyl band at 5.71 μ indicated a five-membered ring ketone.

Anal. Calcd. for $C_{10}H_{12}ONBr$: C, 49.55; H, 4.99. Found: C, 49.83; H, 5.20.

Treatment of 120 mg. (0.5 mmole) of the ketone with a slurry of excess sodium borohydride in a mixture of ethanol–ether for 1 hr. gave a solid, m.p. 235–238°, after decomposition of the excess hydride with dilute hydrochloric acid and the usual work-up. One recrystallization from ethanol gave 110 mg. (92%) of solid, m.p. and mixed m.p. with authentic anhydro-II 244–245°. About 4% starting material was recovered from the mother liquors, m.p. 235–237° (no depression on admixture with authentic ketone).

2,2-Dimethyl-3-methylenecyclopentanecarbonitrile (X).—When either anhydro-I or anhydro-II was treated with excess 30% sodium hydroxide at reflux temperature for 1 to 2 hr., steam distillation of the reaction mixture and extraction of the distillate with ether followed by the usual drying and distillation afforded *ca.* 40% of a sweet-smelling, mobile oil, b.p. 81° (16 mm.), $n^{25}D$ 1.4620.[2]

Ozonolysis of X.—A moderate excess of ozone was passed into a solution of 1.1 g. of nitrile X (0.00815 mole) in 50 ml. of cooled glacial acetic acid. Half this solution was poured into a 250-ml. flask containing 50 ml. of water and 2 g. of zinc dust; the mixture was steam distilled under nitrogen until 110 ml. of distillate was collected. Half of this was refluxed for 10 minutes with 1.0 g. of dimedon, 20 ml. of ethanol and 3 drops of pyridine and allowed to stand overnight in the cold. The other half was treated with 50 ml. of dimedon reagent, neutralized with 5 ml. of 5% hydrochloric acid and also allowed to stand in the ice-box overnight. The combined yield of adduct was 0.365 g., 25% of theory, m.p. and mixed m.p. with an authentic sample of dimedon–formaldehyde 189–191°.[29] To characterize the other fragment of the ozonolysis, a solution of 1.1 g. of X in glacial acetic acid was prepared and ozonized as above. The solution was then refluxed with 100 ml. of water and 4 g. of zinc dust for 15 minutes. Cooling, extraction with ether and the usual workup gave about 650 mg. of an oil whose infrared spectrum indicated a five-membered ring ketonitrile. This oil was refluxed with 20 ml. of 25% sodium hydroxide until the oil disappeared. The solution was cooled, acidified and extracted repeatedly with ether. Drying and evaporation of the ether yielded about 200 mg. of a glass which solidified on rubbing with cold methanol. It sublimed readily at 0.3 mm. on the steam-bath to give XII, m.p. 104–105°.

Anal. Calcd. for $C_8H_{12}O_3$: C, 61.52; H, 7.75. Found: C, 61.95; H, 7.93.

The material was characterized by the preparation of an oxime, m.p. 195°, and a semicarbazone, m.p. 219–220°. Perkin and Thorpe[30] gave the following melting points for 2,2-dimethyl-3-ketocyclopentanecarboxylic acid: acid, 108–109°; oxime, 198°; semicarbazone, 215°. A mixed melting point of our material with authentic ketoacid XII was undepressed.[31] The infrared spectra were identical.

Anhydrobromonitrocamphane-III.—When anhydro-II was allowed to stand three days at room temperature in concentrated sulfuric acid, a product was obtained on pouring the sulfuric acid solution into cold water and recrystallizing the precipitate from ethanol. A sample recrystallized from ethanol for analysis melted at 201–202° (prisms).

Anal. Calcd. for $C_{10}H_{14}ONBr$: C, 49.18; H, 5.74. Found: C, 49.32; H, 5.81.

This material was further characterized as follows: treatment of a solution of the amide in dry chloroform in the presence of anhydrous sodium carbonate with nitrogen dioxide,[32] followed by acidification, drying and evaporation of the solvent, gave an acid. This acid was quantitatively

(28) Infrared spectra were taken on a Baird recording infrared spectrophotometer. Ultraviolet spectra were measured with a Cary spectrophotometer, on samples dissolved in ethanol.

esterified with diazomethane in ether solution to give a methyl ester, m.p. 69° (sublimed).

Anal. Calcd. for $C_{11}H_{15}O_2Br$: C, 50.98; H, 5.84. Found: C, 50.64; H, 5.80.

This methyl ester was converted to the alcohol by treatment with excess lithium aluminum hydride in dry ether in the usual manner. The product (feathery needles from ethanol) melted sharply at 160° (87% yield). Conversion to a 3,5-dinitrobenzoate by treatment with the corresponding chloride in dry pyridine gave material, m.p. 124–125° (leaflets from ethanol–water).

Anal. Calcd. for $C_{17}H_{17}O_6N_2Br$: C, 48.01; H, 4.03. Found: C, 48.46; H, 4.19.

Conversion of Anhydro-II to 2-Hydroxy-10-aminocamphane (XVIII).—Anhydro-II, 2.0 g. (0.0082 mole), was dissolved in 20 ml. of alcohol-free chloroform. To this was added 1.0 g. of dry, redistilled dihydropyran followed by four drops of concentrated hydrochloric acid and approximately 1 g. of anhydrous sodium sulfate.[12] The mixture was stirred 3 hr. at room temperature, then shaken with two 10-ml. portions of 30% sodium hydroxide. Ether was added and the organic layer washed with water. The usual work-up gave 2.3 g. of tetrahydropyranyl ether (XVII), m.p. 120–130°, star-shaped clusters of needles from hexane (89% yield).

The ether (1.76 g., 0.0054 mole) was dissolved in 75 ml. of refluxing absolute ethanol and 5 g. of sodium added in small pieces over a period of 2 hr. The solution was made acid to congo red with concentrated hydrochloric acid in ethanol (cooling), concentrated *in vacuo* on the steam-bath; the residue was taken up in water and extracted with ether. The aqueous layer was made basic with 10% sodium hydroxide and thoroughly extracted with ether. Drying and evaporation of the ether gave about 350 mg. of a slightly greenish oil. The yield is 39%. The material readily was converted with tosyl chloride in pyridine (or with 20% sodium hydroxide) to a sulfonamide (XIX), m.p. 165–166°, leaflets from ethanol–water. A sample was recrystallized from ethyl acetate for analysis (prisms).

Anal. Calcd. for $C_{17}H_{25}O_3NS$: C, 63.14; H, 7.79. Found: C, 63.45; H, 7.56.

Oxidation of XIX.—The sulfonamide (140 mg., 0.41 mmole) was dissolved in 10 ml. of glacial acetic acid, and 50 mg. (0.5 mmole) of chromic anhydride was added in small portions. The mixture was stirred magnetically at room temperature for an hour, then poured onto ice and extracted with ether. The usual workup gave 86 mg. of ketone, m.p. 130–133° (62% yield). After recrystallization from ethanol–water and then ethyl acetate, it melted at 144–146° (short rods).

Anal. Calcd. for $C_{17}H_{23}O_3NS$: C, 63.53; H, 7.21. Found: C, 63.66; H, 7.31.

Conversion of Ketopinic Acid to XVIII.—Ketopinamide was prepared by treatment of an ether solution of the acid chloride with a stream of anhydrous ammonia.[33] After evaporation of the ether and excess ammonia, the residue was treated with hot ethyl acetate. Inorganic material was removed by filtration, and the solution was evaporated to dryness, taken up in benzene and evaporated to dryness again. On trituration with petroleum ether, a nicely crystalline product was obtained, m.p. 190–194°, 4.6 g., 92% from 5.0 g. of acid. The amide is extremely soluble in cold water. Ketopinamide (1.50 g., 0.00825 mole) was dissolved in 25 ml. of dry tetrahydrofuran and added to a slurry of 2 g. of lithium aluminum hydride in 50 ml. of tetrahydrofuran. The mixture was refluxed with stirring under nitrogen for 2 hr. The usual workup gave about 1.2 g. of a slightly yellow oil. This was not purified but treated immediately with 25 ml. of 20% sodium hydroxide and 2 g. of tosyl chloride. The originally oily mixture solidified, on warming, after 10 minutes. After all excess tosyl chloride had decomposed, the precipitate was filtered, washed and dried to yield 2.25 g. of crude tosylamide, m.p. 153–156° (85%). On recrystallization from ethanol–water and then ethyl acetate, the m.p. was raised to 165–166°, and a mixed melting point with II gave no depression. The infrared spectra of the compounds were identical.

Anal. Calcd. for $C_{17}H_{25}O_3NS$: C, 63.14; H, 7.79. Found: C, 62.94; H, 7.86.

(33) E. Wedekind, *Ber.*, **57**, 664 (1924).

Oxidation with chromic anhydride in glacial acetic acid yielded a ketone, m.p. 144–145° after recrystallization from ethanol–water, identical (mixed m.p., infrared) with the corresponding ketone prepared from authentic XIX (see above).

Tetrahydroanhydro-II (XXII).—Anhydro-II (1.076 g., 0.00441 mole) was hydrogenated at atmospheric pressure in the presence of *ca.* 0.2 g. of prereduced platinum oxide in 95% ethanol; 93% of 2 moles of hydrogen was absorbed in 11 hr. (For no apparent reason, the reaction was sometimes complete, on approximately the same amounts of material, in 5 hr.) Workup yielded 980 mg. of an amine, m.p. after recrystallization from ethyl acetate–petroleum ether, 183–184°.

Anal. Calcd. for $C_{10}H_{18}ONBr$: C, 48.39; H, 7.31. Found: C, 48.15; H, 7.22.

The compound was characterized by the formation of a benzamide (with benzoyl chloride in dry pyridine) which crystallized as thin, rectangular plates from ethyl acetate–petroleum ether, m.p. 219–220°.

Anal. Calcd. for $C_{17}H_{22}O_2NBr$: C, 57.96; H, 6.29. Found: C, 57.70; H, 6.37.

Reduction of Anhydro-II with Lithium Aluminum Hydride.—When anhydro-II (1.5 g.) was reduced with an excess of lithium aluminum hydride in dry ether in the usual manner, it yielded 1.44 g. (95%) of an amine, m.p. 184° (plates from ethyl acetate–petroleum ether), identical in all respects with XXII.

Tetrahydroanhydro-II Sulfate from Anhydro-I.—When 900 mg. (0.0037 mole) of anhydro-I was dissolved in 95% ethanol containing an equimolar amount of sulfuric acid and the mixture hydrogenated as above (cooling), 2 moles of hydrogen were absorbed in 1 hr. The crude amorphous product crystallized as small plates from a mixture of ethanol and water containing a little sulfuric acid, m.p. *ca.* 318° (with vigorous decomposition).

Anal. Calcd. for $C_{20}H_{38}O_6N_2Br_2S$: C, 40.42; H, 6.44. Found: C, 40.35; H, 6.40.

To check the possibility that anhydro-I might have isomerized under the conditions of the reduction, 244 mg. (1 mmole) was stirred with 1 mmole of sulfuric acid in 25 ml. of 95% ethanol containing 50 mg. of platinum oxide for 3 hr. at room temperature. The usual workup and one recrystallization from ethanol gave material which was apparently pure anhydro-I according to its infrared. It showed characteristic anhydro-I behavior on melting.

Treatment of Anhydro-I with Lithium Aluminum Hydride.—Reduction of 2.03 g. of anhydro-I with excess lithium aluminum hydride in ether yielded, after the usual workup, 1.91 g. of crude amorphous product, m.p. 110–130°. This was chromatographed with chloroform on silicic acid to yield 75% of XXII and 25% of another compound, which was neutral and analyzed as a *dihydro derivative*, m.p., after several recrystallizations from ethyl acetate, 185–187°.

Anal. Calcd. for $C_{10}H_{18}ONBr$: C, 48.79; H, 6.55. Found: C, 48.90; H, 6.79; infrared spectrum (KBr disk), 3.03, 3.24 sharp, 6.18, 6.40 μ.

Conversion of Tetrahydroanhydro-II to XVIII.—Tetrahydroanhydro-II (160 mg., 0.65 mmole) was treated with tosyl chloride in pyridine; the usual workup gave 180 mg. of tosylamide, m.p. 163–165°, needles from ethanol–water (68% yield). The tetrahydropyranyl ether of this material was prepared by stirring the above with 42 mg. of dihydropyran (0.5 mmole, 0.05 ml.) in 10 ml. of alcohol-free chloroform containing two drops of concentrated hydrochloric acid and a little anhydrous sodium sulfate. After 1 hr., the mixture was poured into cold 10% sodium hydroxide and shaken thoroughly to remove all traces of acid. The crude ether weighed 100 mg., after recrystallization from ethanol. It was then dissolved in absolute ethanol and treated with sodium as previously described. Acidification and the usual workup gave about 50 mg. (80%) of material which, after passage through a silicic acid column and two recrystallizations from benzene–petroleum ether, melted at 165–166° and did not depress the melting point of an authentic sample of XIX. The infrared spectra in chloroform were essentially identical.

Lithium Aluminum Hydride Reduction of 3-Methyl-Δ^2-isoxazoline.—The isoxazoline (6.5 g.) was dissolved in 25 ml. of dry tetrahydrofuran and added to a magnetically-stirred slurry of 1.0 g. of lithium aluminum hydride in 50 ml.

of tetrahydrofuran under nitrogen. The mixture was held at 65° for 0.5 hr., then allowed to stand at room temperature for another hour. Ethyl acetate was added to decompose the excess hydride, followed by saturated sodium potassium tartrate. The solvents were separated from sludge by decantation, the latter extracted with hot alcohol, combined with the former, dried and distilled to give 18% of crude starting material (b.p. 48–53° (8 mm.), $n^{25}D$ 1.4435) and 2.48 g. of 3-amino-1-butanol, b.p. 73–74° (7 mm.) (reported[34] b.p. 82–85° (19 mm.)), $n^{25}D$ 1.4532–1.4543, 48% yield (based on unrecovered isoxazoline). A sample was distilled twice for analysis, precautions being taken to exclude water vapor and carbon dioxide.

Anal. Calcd. for $C_4H_{11}NO$: C, 53.89; H, 12.44. Found: C, 54.15; H, 11.97.

Reduction of Ethyl *dl*-β-Aminobutyrate.—Ethyl β-aminobutyrate (5.0 g., 0.0038 mole), prepared from 3-acetamidocrotonic ester[35] by reduction of the latter according to Skita with platinum oxide in ethanol containing a few drops of concentrated hydrochloric acid, followed by hydrolysis and re-esterification,[36] was reduced with lithium aluminum hydride in ether for 15 minutes according to Karrer.[37] Workup yielded an oil which was rectified in vacuum to give 2.11 g. of an aminoalcohol, b.p. 73° (7 mm.), $n^{25}D$ 1.4534–1.4543 (62%). The infrared of this material (neat) and that from isoxazoline showed little resolution but were superimposable, broad bands centered at 3.15, 6.29, 9.05, 9.40 μ. Samples of both amino alcohols were converted to identical bis-*p*-nitrobenzoyl derivatives, m.p. 155–156°, separately and on admixture. An analytical sample was recrystallized from ethanol (balls of tiny needles, m.p. 157°).

Anal. Calcd. for $C_{18}H_{17}N_3O_7$: C, 55.81; H, 4.42. Found: C, 55.91; H, 4.56.

The aminoalcohol was further characterized as the bis-benzoyl derivative, leaflets from ethanol–water, m.p. 112–112.5°.

Anal. Calcd. for $C_{18}H_{19}NO_3$: C, 72.70; H, 6.40. Found: C, 72.36; H, 6.37.

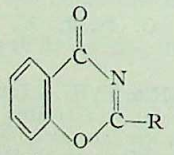
Experiments with 2-Aryl-1,3-benzoxaz-4-ones and with 2-Phenyl-2,3-dihydro-1,3-benzoxaz-4-one. A New Type of Thermochromic Compounds

BY AHMED MUSTAFA AND ALAA ELDIN ABDEL AZIZ HASSAN

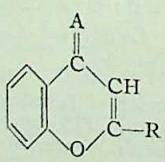
RECEIVED FEBRUARY 5, 1957

A number of new thermochromic di-(2-aryl)-1,3-benzoxaz-4-ylidenes (IVa-c) now have been prepared. Fission of the central ethylene linkage in IVa-c is brought about by the action of sulfur at 250° to yield the corresponding benzoxaz-4-thione derivatives (Va-c), respectively, and by the action of thionyl chloride followed by water in the case of IVa to give 2-phenyl-1,3-benzoxaz-4-one (Ia). The two new benzoxaz-4-one derivatives (Ib-c), needed in this investigation, have been synthesized. Whereas Ia, Ic, Va and/or Vc react with hydroxylamine hydrochloride in the presence of pyridine to give the corresponding oxime derivatives, they react with hydrazine hydrate to yield the corresponding 1,2,4-triazole derivatives (VIa-b), respectively. Treatment with organomagnesium compounds brought about addition to the carbonyl group in the case of Ic and cleavage of the hetero ring in the case of 2-phenyl-2,3-dihydro-1,3-benzoxaz-4-one (X).

2-Aryl-1,3-benzoxaz-4-ones (Ia-c) bear a structural resemblance to flavone (IIa), the former having in the hetero ring the system —CR=N— in place of CR=CH— in the latter. This has stimulated us to investigate the analogy between I and II in their chemical reactions.

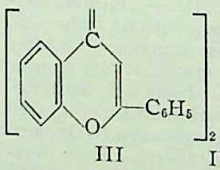


Ia, R = C_6H_5
b, R = $C_6H_4CH_3$-*p*
c, R = $C_6H_4OCH_3$-*p*

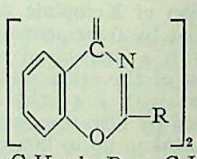


IIa, A = O; R = C_6H_5
b, A = S; R = C_6H_5

Diflavylene (III) shows remarkable physical and chemical properties; it forms light yellow crystals at the temperature of liquid air, at room temperature they are yellow, the melt is ruby-red and the color of the hot solutions varies from orange-red to deep red depending on concentrations.[1] Under pressure, it shows piezochromic properties,[2] changing from yellow to dark red. We now have found that di-(2-aryl)-1,3-benzoxaz-4-ylidenes (IVa-c) show thermochromic properties: dilute solutions of IVa in ethyl benzoate and/or in diphenyl ether are yellow at 0° and orange-red at the boiling point of the solvent; the phenomenon is reversible. Strong thermochromic effects also were observed with powdered solid IVa (yellow at 0° ⟷ deep red at 260°).



III



IVa, R = C_6H_5; b, R = $C_6H_4CH_3$-*p*;
c, R = $C_6H_4OCH_3$-*p*

III shows remarkable behavior toward thionyl chloride, followed by the action of water[3] and toward the action of elementary sulfur[4]; fission of the central ethylene bond occurs and IIa and IIb are formed, respectively. We now have found that IVa behaved analogously; fission of the central ethylene linkage in IVa-c is brought about by the action of sulfur at 250° to yield the corresponding benzoxaz-4-thione derivatives (Va-c), respectively, and by the action of thionyl chloride followed by the action of water in the case of IVa to give Ia.

Whereas IIa reacts with hydroxylamine hydrochloride to give the corresponding oxazole deriva-

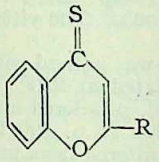
tive,[5] Ia and Ic react readily with the same reagent, under the same conditions, to give the corresponding oxime derivatives. The latter are also formed by the action of the same reagent on the thione derivatives (Va and Vc, respectively).[6]

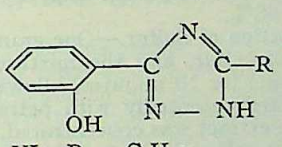
Phenylhydrazine reacts with flavone to form the pyrazole derivative,[5] but 2,4-dinitrophenylhydrazine reacts with flavone in acid solution to give the corresponding hydrazone derivative.[7] We now have found that Ia reacts readily with phenylhydrazine to give the hydrazone derivative.

It has been established that the action of hydrazine on 2-methylchromone[8] and on chromone itself[5b] leads to the formation of pyrazole derivatives and not hydrazones of the chromones in question as previously described.

We now have investigated the action of hydrazine hydrate on Ia and on Va and believe, by analogy, that the reaction product is the 1,2,4-triazole derivative VIa. Similarly, VIb is obtained upon treatment of Ic with the same reagent. VIa-b are colorless compounds, soluble in aqueous sodium hydroxide solution and give violet color with ferric chloride.

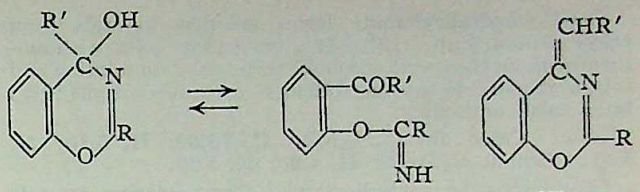


Va, R = C_6H_5;
b, R = $C_6H_4CH_3$-*p*;
c, R = $C_6H_4OCH_3$-*p*



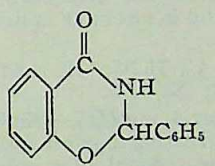
VIa, R = C_6H_5;
b, R = $C_6H_4OCH_3$-*p*

Recently, Mustafa and co-workers[9] have shown that in contrast to 2-phenyl-3,1-benzoxaz-4-one, which underwent hetero ring opening with phenylmagnesium bromide, Ia reacted with the same reagent to yield 2,4-diphenyl-4-hydroxy-1,3-benzoxazine (VIIa) which could also be present in equilibrium with the open form VIIIa. 2-Phenyl-4-benzal-1,3-benzoxazine (IXa) was obtained when Ia was treated with benzylmagnesium chloride. Similar results now have been obtained when 2-(*p*-methoxyphenyl)-1,3-benzoxaz-4-one (Ic) was allowed to react with phenylmagnesium bromide and with benzylmagnesium chloride, followed by hydrolysis, yielding 2-(*p*-methoxyphenyl)-4-phenyl-4-hydroxy-1,3-benzoxazine (VIIb), which could also be present in equilibrium with the open form VIIIb, and 2-(*p*-methoxyphenyl)-4-benzal-1,3-benzoxazine (IXb), respectively. That VIIb and IXb are not identical in structure is indicated by the analytical results; furthermore, VIIb is colorless and contains an active hydrogen atom, while IXb is yellow and contains no active hydrogen atom. The behavior of Ia and Ic toward Grignard reagents is comparable to that of flavone.[10]

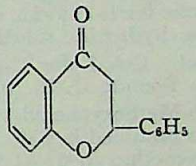


VIIa, R = R′ = C_6H_5 VIII IX
b, R = $C_6H_4OCH_3$-*p*; R′ = C_6H_5

In this connection, we have also investigated the behavior of 2-phenyl-2,3-dihydro-1,3-benzoxaz-4-one (X), which bears structural resemblance to flavanone (XI), toward the action of organomagnesium compounds. Thus, whereas XI reacts with both aliphatic[11] and aromatic Grignard reagents[12] to form chromanols which can be dehydrated to α-chromenes, X undergoes hetero ring

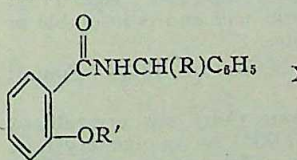


X



XI

opening with phenylmagnesium bromide and with methylmagnesium iodide to yield colorless products, believed to have structures like XIIa-b, respectively. XIIa-b are soluble in aqueous sodium hydroxide solution and give violet color with alcoholic ferric chloride. They form insoluble acetyl derivatives (XIIc-d) in aqueous sodium hydroxide solution when allowed to react with acetic anhydride. When an acetic acid solution of XIIa is boiled with hydrochloric acid, salicylamide was obtained.



XIIa, R = C_6H_5; R′ = H
b, R = CH_3; R′ = H
c, R = C_6H_5; R′ = $COCH_3$
d, R = CH_3; R′ = $COCH_3$

Methods of Preparation.—The new 2-aryl-1,3-benzoxaz-4-ones (Ib-c) now have been obtained after the procedure of Titherley[13] by treatment of O-*p*-methylbenzoyl- and O-*p*-methoxybenzoylsalicylamides, respectively, with hydrogen chloride gas in boiling anisole.

IVa-c have been obtained by the action of copper bronze on the corresponding 2-aryl-1,3-benzoxaz-4-thiones[14] (Va-c), respectively, which may be prepared by treating Ia-c with phosphorus pentasulfide.[15] IVa also has been obtained by the action of copper bronze[14] on the product resulting by treatment of Ia with thionyl chloride.

Experimental

2-Aryl-1,3-benzoxaz-4-ones (Ib-c). O-Aroylsalicylamides.—O-*p*-Toluoyl- and O-*p*-methoxybenzoylsalicylamides were obtained by treating a solution of 5 g. of salicylamide in 20 ml. of dry pyridine with 5.5 g. of *p*-toluoyl chloride and with 6 g. of *p*-methoxybenzoyl chloride, respectively. The reaction mixture was heated on a steam-bath for 1 hr., poured into ice-cold water and the resulting solids (yield 85, 89%, respectively) collected and worked up as follows:

O-*p*-Toluoylsalicylamide forms colorless crystals from ethyl alcohol, m.p. 213°. It gives yellow color with sulfuric acid, no color with alcoholic ferric chloride solution and is insoluble in cold aqueous sodium hydroxide solution (10%) but soluble on boiling.

Anal. Calcd. for $C_{15}H_{13}NO_3$: C, 70.59; H, 5.10; N, 5.48. Found: C, 70.32; H, 4.90; N, 5.60.

O-*p*-Methoxybenzoylsalicylamide forms colorless crystals from dilute ethyl alcohol, m.p. 198°. It gives greenish-yellow color with sulfuric acid and behaves similarly toward ferric chloride and sodium hydroxide solutions.

Anal. Calcd. for $C_{15}H_{13}NO_4$: C, 66.42; H, 4.80; N, 5.17. Found: C, 66.23; H, 4.72; N, 5.15.

2-*p*-Tolyl-1,3-benzoxaz-4-one (Ib) was obtained in 72% yield by treating a clear solution of 5 g. of O-*p*-toluoylsalicylamide in 30 ml. of freshly distilled anisole with a stream of dry hydrogen chloride for a few minutes after the procedure described by Titherley[13] for the preparation of Ia. Ib forms colorless crystals from a mixture of petroleum ether (b.p. 80–100°), m.p. 113°. It does not give color with alcoholic ferric chloride solution and is insoluble in aqueous sodium hydroxide solution.

Anal. Calcd. for $C_{15}H_{11}NO_2$: C, 75.95; H, 4.64; N, 5.90. Found: C, 76.10; H, 4.52; N, 5.56.

2-*p*-Methoxyphenyl-1,3-benzoxaz-4-one (Ic).—Similarly, Ic was obtained in 68% yield by treating a solution of 5 g. of O-*p*-methoxybenzoylsalicylamide in 40 ml. of anisole with a stream of hydrogen chloride as described above. Ic forms colorless crystals from ethyl alcohol, m.p. 168°. It is insoluble in aqueous sodium hydroxide solution and gives no color with alcoholic ferric chloride solution.

Anal. Calcd. for $C_{15}H_{11}NO_3$: C, 71.14; H, 4.35; N, 5.53. Found: C, 70.88; H, 4.14; N, 5.41.

2-Aryl-1,3-benzoxaz-4-thiones (Va-c). General Procedure.—The thiones were prepared by refluxing a benzene solution of 1 g. of each of Ia-c with 1 g. of phosphorus pentasulfide for 3 hr. The reaction mixture was filtered while hot, the benzene was evaporated and the oily residue was washed several times with cold light petroleum (b.p. 40–60°). The solidified mass was then worked up as follows: 2-phenyl-1,3-benzoxaz-4-thione (Va) was crystallized from petroleum ether as orange crystals, m.p. 128°, yield 71%. It gives orange color with sulfuric acid and is insoluble in aqueous sodium hydroxide solution.

Anal. Calcd. for $C_{14}H_9NOS$: N, 5.81; S, 13.38. Found: N, 5.72; S, 13.58.

2-*p*-Tolyl-1,3-benzoxaz-4-thione (Vb) was crystallized from petroleum ether (b.p. 60–90°) as orange crystals, m.p. 155°, yield 78%. It gives yellow color with sulfuric acid.

Anal. Calcd. for $C_{15}H_{11}NOS$: C, 71.14; H, 4.35; N, 5.53; S, 12.65. Found: C, 70.78; H, 4.15; N, 4.92; S, 12.34.

2-*p*-Methoxyphenyl-1,3-benzoxaz-4-thione (Vc) formed orange crystals from petroleum ether (b.p. 60–90°), m.p. 148°, yield 62%. It gives orange-red color with sulfuric acid.

Anal. Calcd. for $C_{15}H_{11}NO_2S$: N, 5.20; S, 11.90. Found: N, 4.99; S, 11.72.

Di-(2-aryl)-1,3-benzoxaz-4-ylidenes (IVa-c). General Procedure.—These were obtained by refluxing a solution of 1 g. of each of Va-c in 40 ml. of dry xylene with 1 g. of copper bronze for 6 hr. The reaction mixture was filtered off, concentrated and cooled. The crystals that separated out were collected. No molecular weight determination could be carried as the compounds (IVa-c) are difficultly soluble. Di-2-phenyl-1,3-benzoxaz-4-ylidene (IVa) was crystallized from xylene, as yellow crystals, m.p. 269°, yield *ca.* 68%. It gives yellow color with sulfuric acid.

Anal. Calcd. for $C_{28}H_{18}N_2O_2$: C, 81.16; H, 4.35; N, 6.76. Found: C, 80.92; H, 4.16; N, 6.95.

Di-2-(*p*-tolyl)-1,3-benzoxaz-4-ylidene (IVb) formed yellow-orange crystals, m.p. 288°, yield *ca.* 71%. It gives yellow color with sulfuric acid and is insoluble in aqueous sodium hydroxide solution.

Anal. Calcd. for $C_{30}H_{22}N_2O_2$: C, 81.45; H, 4.98; N, 6.33. Found: C, 81.24; H, 4.76; N, 6.25.

Di-2-(*p*-methoxyphenyl)-1,3-benzoxaz-4-ylidene (IVc) was crystallized from xylene as orange-yellow crystals, m.p. 282°, yield *ca.* 61%. It gives yellow color changing to violet with sulfuric acid.

Anal. Calcd. for $C_{30}H_{22}N_2O_4$: C, 75.94; H, 4.64; N, 5.91. Found: C, 75.74; H, 4.26; N, 5.67.

IVa also was obtained by the following procedure: one gram of Ia was treated with 15 ml. of freshly distilled thionyl chloride on a steam-bath for 20 hr.; the excess of thionyl chloride was distilled off. The residue was dissolved in 30 ml. of dry xylene and refluxed with 1 g. of copper bronze for 6 hr. The xylene solution was filtered hot and concentrated; on cooling IVa (*ca.* 0.42 g.) separated out. It was filtered off and recrystallized from xylene, m.p. 269°; identified as IVa (m.p. and mixed m.p.).

Experiments with Thermochromic Substances.—The color changes, which are all reversible, were obtained in layers of solution 1 cm. in depth. The solutions were heated nearly to the boiling point (heating lasted only for a few seconds) and then cooled immediately. The expansion of the volume of the solutions with temperature was taken into consideration.

Ethyl benzoate (Schering–Kahlbaum) was purified by shaking it with sodium carbonate for 24 hr., followed by filtration and distillation.

Action of Thionyl Chloride.—One gram of IVa was refluxed with 30 ml. of thionyl chloride for 6 hr.; the excess of thionyl chloride was distilled off completely (pump) and the residual oil was dissolved in benzene and shaken with water at 30° for 30 minutes. The benzene layer was evaporated and the residual oil was solidified on scratching and crystallized from petroleum ether, m.p. 106°; identified as Ia (m.p. and m.p. determination). The yield was *ca.* 68%.

Action of Sulfur.—One gram of IVa was ground with 0.5 g. of sulfur, and the mixture was heated at 250° (bath-temp.) for 10 minutes, allowed to cool, powdered and extracted repeatedly with petroleum ether (b.p. 100–120°). The extract was concentrated, cooled, filtered from precipitated sulfur and was concentrated further and cooled. Va was obtained; identification was carried out by m.p. and m.p. determination with an authentic specimen (see above).

Behavior of 2-Aryl-1,3-benzoxaz-4-ones toward: (a) Hydroxylamine Hydrochloride.—A solution of 1 g. of each of Ia and Ic in 40 ml. of ethyl alcohol was treated with 0.3 g. of hydroxylamine hydrochloride and five drops of freshly distilled pyridine for 4 hr. (steam-bath). The cooled reaction mixture was poured into ice-cold water, acidified with dilute hydrochloric acid; the deposit formed was filtered (*ca.* 0.75 g., 0.64 g., respectively), and crystallized from alcohol as colorless crystals.

2-Phenyl-1,3-benzoxaz-4-one oxime melts at 135°, gives no color with alcoholic ferric chloride and is soluble in aqueous sodium hydroxide solution.

Anal. Calcd. for $C_{14}H_{10}N_2O_2$: C, 70.58; H, 4.20; N, 11.76. Found: C, 70.26; H, 4.05; N, 11.92.

The above oxime derivative was similarly prepared by the action of hydroxylamine hydrochloride on Va, as described above, in almost quantitative yield. Identification was carried out by m.p. and mixed m.p. determination.

2-(*p*-Methoxyphenyl)-1,3-benzoxaz-4-one oxime formed colorless crystals (*ca.* 0.73 g.), m.p. 140°. Its behavior toward ferric chloride and sodium hydroxide simulates that of the oxime of Ia.

Anal. Calcd. for $C_{15}H_{12}N_2O_3$: C, 67.16; H, 4.47; N, 10.45. Found: C, 66.92; H, 4.31; N, 10.55.

(b) Phenylhydrazine.—A mixture of 1 g. of Ia and 1 g. of phenylhydrazine and 40 ml. of absolute ethyl alcohol was refluxed for 3 hr. Working up the reaction mixture gave colorless crystals from ethyl alcohol (*ca.* 0.67 g.) of 2-phenyl-1,3-benzoxaz-4-one phenylhydrazone derivative, m.p. 130°. It is insoluble in aqueous sodium hydroxide solution and gives no color with alcoholic ferric chloride solution.

Anal. Calcd. for $C_{20}H_{15}N_3O$: C, 76.69; H, 4.79; N, 13.42. Found: C, 76.36; H, 4.38; N, 13.21.

(c) Hydrazine Hydrate.—A solution of 1 g. of each of Ia and Ic in 50 ml. of absolute ethyl alcohol was treated with 0.30 g. of hydrazine hydrate. The reaction mixture was heated (steam-bath) for 15 minutes and kept aside overnight at room temperature. It was diluted with water and the colorless crystals, so obtained, were collected.

3-(*o*-Hydroxyphenyl)-5-phenyl-1,2,4-triazole (VIa) formed colorless crystals from benzene, m.p. 204°, yield *ca.* 82%. VIa is soluble in aqueous sodium hydroxide solution and gives violet color with alcoholic ferric chloride solution.

Anal. Calcd. for $C_{14}H_{11}N_3O$: C, 70.88; H, 4.64; N, 17.72. Found: C, 70.61; H, 4.42; N, 17.90.

VIa was similarly prepared by the action of hydrazine hydrate on 1 g. of Va, as described above, in an almost quantitative yield. Identification was carried out by m.p. and mixed m.p. determination.

3-(*o*-Hydroxyphenyl)-5-(*p*-methoxyphenyl)-1,2,4-triazole (VIb) formed colorless crystals from ethyl alcohol, m.p. 186°, yield *ca.* 79%. It behaves in a similar manner to VIa toward ferric chloride and sodium hydroxide solutions.

Anal. Calcd. for $C_{15}H_{13}N_3O_2$: C, 67.41; H, 4.87; N, 15.73. Found: C, 67.52; H, 4.65; N, 15.80.

Action of Grignard Reagents on Ic. (a) Phenylmagnesium Bromide.—To a solution of phenylmagnesium bromide (prepared from 0.9 g. of magnesium and 9 g. of bromobenzene in 50 ml. of dry ether) was added a solution of 1.5 g. of Ic in 50 ml. of dry benzene. The ether was evaporated and the reaction mixture heated for 3 hr. on a steam-bath. After the mixture had stood overnight at room temperature, it was poured slowly into 100 ml. of saturated aqueous ammonium chloride solution and extracted with ether. The precipitate which separated from the ether–benzene mixture was crystallized from benzene–light petroleum as colorless crystals, m.p. 122°, yield *ca.* 0.89 g.

Anal. Calcd. for $C_{21}H_{17}NO_3$: C, 76.13; H, 5.13; N, 4.23; active H, 0.30. Found: C, 75.68; H, 4.96; N, 4.15; active H, 0.27.

2-(*p*-Methoxyphenyl)-4-phenyl-1,3-benzoxazine (VIIa) is easily soluble in benzene and hot ethyl alcohol, difficultly soluble in light petroleum and insoluble in cold aqueous sodium hydroxide solution. It gives red color with sulfuric acid. The alcoholic solution of VIIb does not become colored when treated with alcoholic ferric chloride solution.

(b) Benzylmagnesium Chloride.—To a Grignard solution of benzylmagnesium chloride (prepared from 0.8 g. of magnesium, 5.5 g. of benzyl chloride and 50 ml. of dry ether) was added a solution of 1 g. of Ic in 40 ml. of benzene. The reaction mixture was worked up in the usual manner. The oily product, obtained upon evaporation of the ethereal extract, solidified after working with light petroleum. 2-(*p*-Methoxyphenyl)-4-benzal-1,3-benzoxazine (IXb) was obtained as yellow crystals from petroleum ether, yield 0.68 g., m.p. 126°.

Anal. Calcd. for $C_{22}H_{17}NO_2$: C, 80.73; H, 5.20; N, 4.28. Found: C, 80.62; H, 4.91; N, 4.05.

IXb is easily soluble in chloroform and benzene, difficultly soluble in cold petroleum ether and insoluble in cold aqueous sodium hydroxide solution; it gives an orange red color with sulfuric acid.

Action of Grignard Reagents on X. (a) Phenylmagnesium Bromide.—To a solution of phenylmagnesium bromide was added 1 g. of X[13] in 30 ml. of dry benzene. The reaction mixture was worked up as described above. The oily residue, obtained on evaporation of the ethereal extract, solidified on scratching and cooling. N-Benzohydrylsalicylamide (XIIa) was crystallized from petroleum ether (b.p. 100–120°) as colorless crystals, m.p. 140°, yield 0.64 g.

Anal. Calcd. for $C_{20}H_{17}NO_2$: C, 79.21; H, 5.61; N, 4.62. Found: C, 79.20; H, 5.46; N, 4.32.

XIIa is easily soluble in benzene and hot alcohol, difficultly soluble in light petroleum and soluble in cold aqueous sodium hydroxide; it gives an orange-red color with alcoholic ferric chloride solution.

Acetylation.—A solution of 0.5 g. of XIIa in 30 ml. of acetic anhydride was refluxed for 2 hr. The reaction mixture was poured into cold water, and the solid, so obtained after cooling, was filtered off, washed thoroughly with water and crystallized from alcohol as colorless crystals (*ca.* 0.39 g.), m.p. 148°. The acetyl derivative XIIc is insoluble in cold aqueous sodium hydroxide solution and gives no color with ferric chloride. It gives an orange-red color with sulfuric acid.

Anal. Calcd. for $C_{22}H_{19}NO_3$: C, 76.52; H, 5.51; N, 4.06. Found: C, 76.50; H, 5.34; N, 3.82.

Action of Hydrochloric Acid on XIIa.—A solution of 1 g. of XIIa in 40 ml. of glacial acetic acid was treated with 5 ml. of concentrated hydrochloric acid. The reaction mixture was refluxed for 3 hr., cooled, poured into ice-cold water and neutralized with sodium carbonate. It was extracted with ether, dried and evaporated. The solid residue was crystallized from ethyl alcohol as colorless crystals (*ca.* 0.41 g.), m.p. 136°; identified as salicylamide (m.p. and mixed m.p.).

Anal. Calcd. for $C_7H_7NO_2$: C, 61.31; H, 5.10; N, 10.21. Found: C, 61.42; H, 4.96; N, 10.12.

(b) Methylmagnesium Iodide.—A solution of 1 g. of XIIa in 40 ml. of dry benzene was added to methylmagnesium iodide (prepared from 0.9 g. of magnesium, 3.6 g. of methyl iodide and 50 ml. of dry ether); the reaction mixture was refluxed on a steam-bath for 3 hr., allowed to stand overnight at 25° and worked out as usual. N-(α-Phenylethyl)-salicylamide (XIIb) was crystallized from light petroleum as colorless crystals, m.p. 103°, yield 0.51 g.

Anal. Calcd. for $C_{15}H_{15}NO_2$: C, 74.68; H, 6.22; N, 5.81. Found: C, 74.46; H, 5.98; N, 5.85.

XIIb is easily soluble in benzene and hot alcohol, difficultly soluble in light petroleum and soluble in cold aqueous sodium hydroxide solution; it gives yellow color with sulfuric acid. The alcoholic solution of XIIb gives violet color with alcoholic ferric chloride solution.

Acetylation.—The acetyl derivative XIId was similarly prepared as previously described in the case of XIIc. It was obtained in colorless crystals from chloroform–light petroleum mixture, m.p. 98°, yield 82%. It was insoluble in aqueous sodium hydroxide solution and gives no color with alcoholic ferric chloride solution.

Anal. Calcd. for $C_{17}H_{17}NO_3$: C, 72.08; H, 6.00; N, 4.94. Found: C, 71.78; H, 5.82; N, 5.00.

Relative Reactivities of Polynuclear Aromatic Systems. The Solvolysis of α-Arylethyl Chlorides[1]

BY ERNST BERLINER AND NAN SHIEH

RECEIVED FEBRUARY 18, 1957

The rates of reaction, activation energies and entropies were determined for the SN1 solvolysis of 13 different α-arylethyl chlorides, $ArCHClCH_3$, in 80% or 90% aqueous acetone. The relative reactivities, referred to 25° and 80% aqueous acetone, correlate satisfactorily with various theoretical parameters, but compounds with an "α-naphthalene-like" structure react slower than predicted.

Although polynuclear aromatic hydrocarbons have played an important part in organic chemical theories, an experimental knowledge of the relative reactivities of polycyclic aromatic systems is very scanty. This is in contrast to the theoretical treatment accorded these systems, particularly in

[a] $T = 32.13°$. [b] $T = 39.70°$. [c] Values of 9.04 (titrimetric) and 10.0 (polarimetric) are reported by E. D. Hughes, C. K. Ingold and A. D. Scott, ref. 8.

the last decades. Various parameters arising out of modern theories, such as free valences, atom- and bond-localization energies, charge densities, molecular diagrams and others, have made it possible to predict relative reactivities at various positions within the same molecule, as well as differences among different molecules.[2]

Two lines of approach suggest themselves for a collection of data by which relative reactivities of polynuclear aromatic systems can be ascertained. One is a kinetic study of an electrophilic substitution reaction, the other a study of a suitable side-chain reaction. The latter was chosen for a preliminary survey because a definite position in the polynuclear aromatic compound can be studied without the complicating factor of isomer distribution or polysubstitution.

Most of the older quantitative data refer to various side-chain reactions and dissociation constants in the benzene and naphthalene series, but some extend to biphenyl, anthracene and phenanthrene.[3] In direct electrophilic substitution, there is abundant qualitative information, based usually on preparative ease of substitution, that the reactivity is anthracene > phenanthrene > naphthalene > benzene for the most reactive positions.[4] Systematic quantitative data were practically completely missing, until Dewar, Mole and Warford recently demonstrated an excellent correlation between theoretical parameters and relative rates of nitration for polynuclear aromatic hydrocarbons.[5]

Relative reactivites in free radical reactions (methyl or trichloromethyl affinities and others)[6] correlate well with free valence numbers or the atom localization energies.[6,7] Since the point of attack in these reactions is not known with certainty, the assumption is always made that the attack occurs at the position predicted to be the most reactive.

The side-chain reaction chosen for the present study is the SN1 solvolysis of α-arylethyl chlorides, $ArCHClCH_3$, in aqueous acetone, partly because the mechanism of the reaction and the nature of the transition state are fairly well understood[8] and partly because of the similarity of the transition state, as far as electronic effects are concerned, to the transition state in aromatic substitution. Since this work was initiated, two very similar studies on the solvolysis of arylmethyl chlorides, $ArCH_2Cl$, have been reported by Fierens, *et al.*,[9] and by Dewar and Sampson.[10] The aim of these papers was the same as the present one, and the results are very similar. A study has also been reported on the reaction of polynuclear amines with 2,4-dinitrochlorobenzene.[11]

Results and Discussion

The kinetic data for the solvolysis of 13 compounds, most of them studied at four different temperatures, are collected in Table I. Because of a considerable spread in reactivity and solubility it was not possible to compare all compounds in the same solvent mixture or at the same temperature. Four compounds were studied in 90% aqueous acetone and all the others in 80% acetone. Two compounds, 2-fluorenyl and 2-chrysenyl, were investigated in both solvents, and the results obtained were used to refer all compounds to 80% aqueous acetone. This was not wholly satisfactory, because, as expected, the factors thus obtained differed for the two standard compounds, but the uncertainty introduced by taking an average value was probably not too serious, and in no case was a reactivity order inverted. Where necessary, rate constants were extrapolated to 25° by means of the Arrhenius equation. The only kinetic complication was experienced with the 9-anthryl compound. The first-order rate constants fell within one run, and the data could be analyzed very well for two concurrent first-order reactions by the method of Brown and Fletcher.[12] But neither the crystalline solid starting material nor the products revealed the presence of two compounds. A more likely explanation is that this compound, the fastest of all, is subject to a mass law effect by the chloride ion.[13] When analyzed on this assumption, a smooth curve was obtained on plotting the apparent k_1 against time, which was extrapolated to zero time, to give the rate constants recorded in Table I.

In Table II are listed all rate constants referred to 80% by volume aqueous acetone at 25°. A number of relevant theoretical parameters are also listed. In Fig. 1 the logarithms of the rate constants ($\log k/k_0$) are plotted against the atom-localization energies ($E_0 - E$), where k_0 and E_0 refer to benzene. The atom-localization energies (in units of β) are those obtained by Dewar by a simplified molecular orbital treatment.[14] These values were used rather than those obtained by the more rigorous method[15] because they easily can be extended to a wide variety of alternant hydrocarbons;[16] the results of the plots are identical. Although atom-localization energies refer strictly to the π-electron energy difference between the initial and the transition state in aromatic substitution, *i.e.*, for a direct attack on the nucleus, rather than the side-chain, they were chosen as the most general ones for a possible future comparison. Also, the various parameters are interrelated, and from a general knowledge of carbonium ion stability, one would expect a relation between the power of conjugation of Ar– with a carbonium ion, and hence the stabilizing effect of Ar–, and some of the

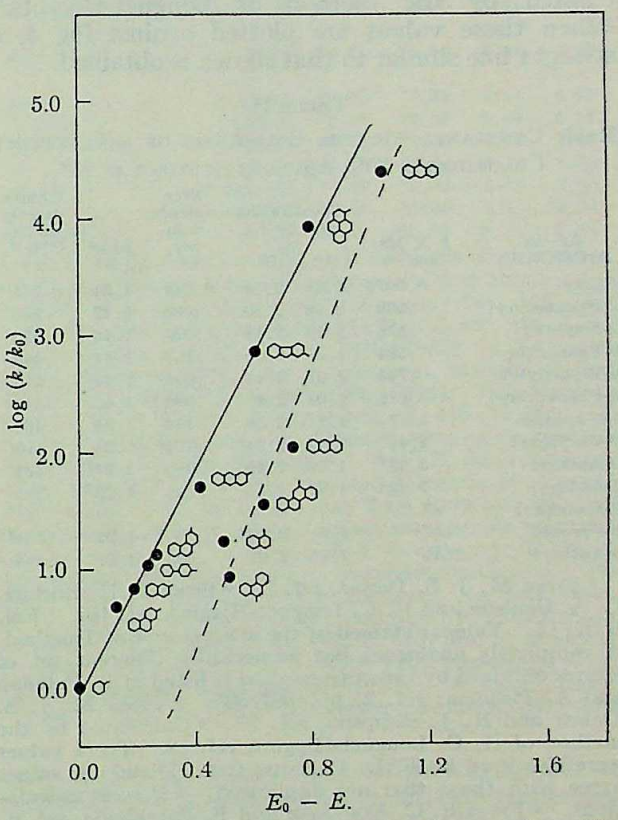

Fig. 1.—A plot of log k against localization energies. The point corresponding to the 2-fluorenyl compound was obtained from the line.

parameters referring to ArH.[17] In their more strict treatment, Dewar and Sampson[10] have plotted rate constants against the parameters $2a_{or}$, which are related to the energy difference between $ArCH_2X$ and $ArCH_2^+$. When our data were plotted against these quantities, a plot similar to Fig. 1 is obtained. Another readily available quantity is the charge density on the exocyclic carbon atom in the carbonium ion, which can be calculated by the method of Longuet-Higgins.[18] When these values are plotted against log k, a straight line similar to that shown is obtained.

A completely analogous but numerically different set of figures obtained by the same method is listed in B. Pullman and A. Pullman, ref. 2, pp. 587–589. [d] From M. J. S. Dewar and R. J. Sampson, ref. 10. [e] Calculated by the method of H. C. Longuet-Higgins, ref. 18. These values were also used by F. L. J. Sixma (ref. 11) and our values agree with those that are duplicated. [f] Present calculations. [g] From E. C. Kooyman and E. Farenhorst, ref. 6. [h] G. Berthier, C. A. Coulson, H. H. Greenwood and A. Pullman, *Compt. rend.*, 226, 1906 (1948). [i] Value extrapolated from kinetic data in 90% aqueous acetone.

In general, high reactivity corresponds to low values for the localization energies, the $2a_{or}$ parameters and the charge densities, and high values for the maximum free valence numbers.[9] On a more quantitative comparison, a very satisfactory agreement and a good linear relation is obtained when the compounds are classed in two groups. The lower curve in Fig. 1, which defines a line of lower reactivity than predicted and which is practically parallel to the first line, contains without exception compounds which have the substituent in an α-naphthalene-like structure, next to a *peri*-hydrogen. The same was observed by the other two groups of workers ("α-naphthalene effect") and has been ascribed by them to a steric effect.[9,10] This is the most reasonable explanation that can be offered, and it shows that the SN1 solvolysis of α-arylethyl chlorides is subject to steric hindrance toward either coplanarity or solvation, even by the somewhat remote *peri* grouping. That the lower reactivity might be due to a theoretical value which is uniformly too high for just these compounds is unlikely and can be ruled out by the observation that it is not observed in cases where no hindrance might be expected, such as in direct nitration[5] or free radical attack.[6,7]

The slope of the straight line in Fig. 1, which is measured in terms of the resonance integral β, has a least square value of 4.82 ± 0.16. It has a meaning similar to Hammett's ρ-value,[19] and the magnitude of the slope should make it possible to draw conclusions about the susceptibility of various reactions to changes in hydrocarbon structure. Particularly, in direct aromatic substitution it should be related to the activity of the substituting agent.[20] A more detailed discussion of the significance of the slopes in both side-chain and substitution reactions has been given by Dewar, *et al.*,[5,7,10] who has pointed out that β, obtained from the slope,[21] should not be considered the usual universal constant, but a variable parameter dependent on the particular reaction. In a plot of our rate constants (log k_1) against $2a_{or}$ the slope has the value 12.6 ± 0.31, and β is 17.1 kcal. as compared to 30 kcal. obtained for β in the SN1 solvolysis of arylmethyl chlorides, $ArCH_2Cl$, in moist formic acid.[10] In the interpretation of Dewar and Sampson, this means that the transition state of α-arylethyl chloride solvolysis in 80% aqueous acetone has not progressed as far in free carbonium ion character as that of arylmethyl chloride solvolysis in moist formic acid. Viewed differently, the carbonium ion formed from $ArCHClCH_3$ is more stable than that formed from $ArCH_2Cl$ and therefore the reaction less "selective,"[20] giving rise to a smaller slope.

If it is accepted that the results group themselves into two classes of compounds and if each class is considered separately, only one pair of compounds shows an inverted order: 9-phenanthryl should be faster than 1-naphthyl but is slower. Both are less reactive than predicted, and an additional steric effect may possibly be operative in the 9-position of phenanthrene. Such an additional effect should then also be operative in 9-anthryl, where it is not observed, but the value for 9-anthryl is probably the least accurate because it was obtained by several extrapolations. Also, the 3-pyrenyl compound should by analogy fall on the low reactivity line but does not. It is gratifying that certain observed orders of reactivity, which could not easily have been predicted on the basis of preparative reactivities, agree with the theory. For instance, the 4-biphenylyl and 2-naphthyl compounds fall within the 2- and 3-phenanthryl derivatives. Other orders, found and predicted by the various theoretical parameters are, for instance, 9-anthryl > 3-pyrenyl > 1-anthryl > 2-anthryl, or 2-chrysenyl > 1-naphthyl > 2-naphthyl, etc. To the extent to which the deviations from the least square lines can be taken as a measure of agreement between theoretical and ex-

perimental values, the experimental values agree almost equally well with any of the theoretical parameters. The localization energies (A and B), the $2a_{or}$ constants and the charge densities (Table II) give straight lines with probable errors of 3.3, 4.5, 2.5 and 2.4%, respectively, but the error is larger (12.4%) when the maximum free valence numbers are plotted.[22]

No theoretical value is available for 2-fluorenyl, but it is very reactive, and the effect of the 5-membered ring and the methylene group raises the reactivity greatly over that of 4-biphenylyl. Forced coplanarity and hyperconjugation may be a contributing factor.

The most desirable situation would obtain if the localization energies could be compared directly with the experimental activation energies. Although the errors obtained for the activation energies are small, and logarithms of rate constants at four different temperatures fall virtually on a straight line when plotted against $1/T$, the differences among the activation energies for the various compounds are not sufficiently large or regular to be usable in place of the rate constants.[23] In a very approximate way, rate differences appear to be determined by differences in activation energies. The log A factors are of the same order of magnitude for reaction in the same solvent, and the activation entropies are, as expected, negative. Some of the deviations from the straight line may be due to variations in activation entropy, because one of the assumptions made in calculating the theoretical parameters is that the entropies remain constant. It is also noted that the differences in rate on going from the more to the less aqueous solvent is due almost exclusively to a lowering of the activation entropies in the less aqueous solvent. This is expected for reactions where ions are formed from neutral molecules.[24]

(22) Not only is the error small when the parameters $2a_{or}$ are plotted, but the "low reactivity" line is almost exactly parallel; the slopes of the two lines are 12.61 and 12.21, respectively, and 4.82 and 6.05 when the localization energies are used. In either case, however, the low reactivity line contains rate constants that were obtained by several extrapolations and are probably not as accurate as those of the other line.

(23) See also ref. 9, and the relevant discussion in ref. 10.

Experimental

Materials.—All chlorides were prepared by passing a stream of HCl gas, in the presence of calcium chloride, into the cold ethereal solutions of the carbinols[25]; yields of crude product were 80–90%. For the phenyl and the two naphthyl compounds, thionyl chloride was used.[26] After evaporation of the solvent, the chlorides were repeatedly recrystallized from 60–70° ligroin (petroleum ether in the case of 9-anthryl), until the melting point remained constant. The phenyl and the two naphthyl compounds were distilled *in vacuo*. The carbinols were made by aluminum isopro-

poxide reduction of the corresponding ketones (yields of crude product usually 80–90%); lithium aluminum hydride was used for the reduction of 2- and of 9-anthryl methyl ketone (87 and 85%), as well as of 2-chrysenyl methyl ketone (85%). The 1-anthryl methyl ketone was reduced by both reagents, but aluminum isopropoxide proved superior (70%). All the ketones were made by methods described in the literature, usually involving a Friedel and Crafts acylation of hydrocarbons, which had been purified by recommended procedures. The physical properties of all compounds and the carbon, hydrogen analyses of the new compounds are listed in Table III.[27]

Kinetic Runs.—Purified acetone[28] and boiled-out distilled water were thermostated at 25° and the necessary volumes, measured in 2-l. volumetric flasks (for instance 8 l. of acetone and 2 l. of water), were mixed in a 5 gal. Pyrex bottle. Enough of the 80 and the 90% aqueous acetone was prepared to last throughout the entire investigation. Kinetic runs below 25°, and some at 25°, were conducted in a 100-ml. volumetric flask, and 10-ml. samples were withdrawn at appropriate time intervals. Most runs at 25°, and all runs above 25°, were run in sealed tubes, prepared from 15-mm. Pyrex tubing. For these runs, an exactly weighed amount of chloride was made up to volume in a 100-ml. volumetric flask at room temperature, the mixture was cooled and eight approximately 12-ml. samples were pipetted into the ampules, sealed at ice-bath temperature and placed in the thermostat. When the tubes had reached the temperature of the thermostat, one ampule was opened and a 10-ml. sample was withdrawn and titrated for the zero titer. The contents of one sealed tube were allowed to react for at least 10 half-life times, in order to get the infinity reading. All samples, including the one for the infinity reading, were withdrawn at the reaction temperatures, which were maintained at ±0.02°. The 10-ml. samples were allowed to run into 60–80 ml. of ice-cold acetone and were titrated with a NaOH solution contained in a 5-ml. microburet graduated in hundredths; a 0.5% alcoholic lacmoid solution was used as an indicator. Initial concentrations of chloride were usually around 0.01 *M*, except for the less soluble 2-anthryl (0.006–0.007 *M*) and 2-chrysenyl (0.005 *M* in 80% acetone) compounds. A check with the 2-fluorenyl compound at a 0.01 and 0.005 *M* concentration showed that the rates were not affected by the initial concentrations. Reactions were conducted to at least 60% completion, and usually more. Isolation runs were conducted with all compounds, except the phenyl, 1-naphthyl and 4-biphenylyl compounds, and the only products that were isolated were the corresponding carbinols, whose identity was checked by mixed melting points. The purity of the chlorides was obtained from infinity readings at 25°; all titrated for 99–100% purity except for the 1-naphthyl compound which was only 84% pure. This was undoubtedly due to some decomposition which was noticeable during vacuum distillation, but runs conducted with samples of various chloride content (60–84%) gave identical results.

Rate constants were calculated from the integrated form of the first-order rate equation. All runs were conducted at least in duplicate, all runs being listed in Table I. The average deviations within one run were 1–2%; some runs had a slight upward drift. The errors quoted for the activation energies and log *A* factors are probable errors obtained from least square calculations, rounded off to the values shown in Table I. The results of two typical runs are recorded in Table IV.

On Some *cis*-Forms of Phenylundecapentaenal

BY CH. GANSSER AND L. ZECHMEISTER

RECEIVED FEBRUARY 4, 1957

All-*trans*-11-phenyl-2,4,6,8,10-undecapentaenal (I) can be rearranged to give four *cis* isomers, termed I–IV. The pertinent experimental conditions, relative thermo- and photostabilities and certain interconversions are described. Some connected spectroscopic phenomena are discussed and tentative configurational assignments are made.

While the stereoisomerization of some α,ω-diphenylpolyenes,[1] $C_6H_5(CH{=}CH)_nC_6H_5$, and symmetrical azines,[2] $C_6H_5(CH{=}CH)_nCH{=}N{-}N{=}CH(CH{=}CH)_nC_6H_5$, was studied earlier, *cis* forms of phenylpolyene aldehydes, $C_6H_5(CH{=}CH)_nCHO$, containing a rather high number of conjugated double bonds in an unbranched chain, do not seem to be known.

All-*trans*-11-phenylundecapentaenal ($n = 5$) was first obtained by Kuhn and Wallenfels,[3] then by Schmitt[4] who used a modified procedure. Theoretically, the molecules of this unsymmetrically built compound may assume 32 spatial configurations, the all-*trans* form included.[1e] We find

that when the all-*trans* aldehyde is submitted to some thermic or photochemical treatments, upon subsequent chromatographic resolution of the stereoisomeric mixture, four *cis* zones appear, all located below the *trans* zone. They were termed *cises* I-IV, in the sequence of decreasing adsorption affinities. As will be indicated in the Experimental Part, this resolution is successful only on a specially prepared adsorbent, because of the rather difficult separation of the isomers and the sensitivity of the aldehyde group.[5]

In all experiments, regardless of the method, the main product of the *trans* → *cis* rearrangement was *cis*-II, while IV appeared only in traces. The *cises* II and III have been obtained as crystals but I and IV only as chromatographically homogeneous solutions. Each *cis* form yielded, upon iodine catalysis, (in part) the all-*trans* compound that was chromatographically inseparable from, and spectroscopically identical[6] with, the synthetic product.

With reference to relative stabilities the following observations were made (Tables I–II).

TABLE I

RATIO OF STEREOISOMERS OBTAINED BY TREATMENT OF ALL-*trans*-PHENYLUNDECAPENTAENAL AND OF ITS *cis*-II AND III FORMS

Treatment	Ratio, all-*trans*:*cis*-I:*cis*-II:*cis*-III (in the recovered substance)	Irreversible loss (% of starting material)[g]
(A) Starting material, all-*trans*:		
(Mostly 15 mg. substance were dissolved in 15 ml. of benzene. The ratios are based on observed extinction of the iodine catalyzed eluates of the respective zones.)		
Refluxing in darkness (30 min.)[a]	100:0:0:0	7
Standing in diffuse daylight (2 hr.)[b]	61:3:32:4	5
Insolation (2 hr.)[c]	62:6:25:7	25
Irradiation (2 hr.)[d]	58:6:32:4	10
Iodine catalysis, in light (30 min.)[e]	84:1:5:10	6
Melting crystals (90 sec.)[f]	72:1:27:0	31
(B) Starting material, *cis*-II:		
(Mostly 0.5 mg. substance in 5 ml. of benzene)		
Refluxing in darkness (30 min.)[a]	1:0:99:0	2
Standing in diffuse light (2.5 mg. in 50 ml.) (2 hr.)[b]	47:3:45:5	10
Insolation (2 hr.)[c]	61:5:27:7	39
Irradiation (2 hr.)[d]	54:2:39:5	22
Iodine catalysis, in light (30 min.)[e]	82:3:5:10	15
Melting crystals (90 sec.)[f]	69:3:28:0	40
(C) Starting material, *cis*-III:		
Refluxing in darkness (1 mg. in 50 ml.) (30 min.)[a]	10: trace:1:89	4
Standing in darkness (1 mg. in 5 ml.). (75 min.)[a]	0.5:trace:0:99.5	1
Insolation (5 mg. in 5 ml.) (20 sec.)[c]	9:0:4:87 (and traces of *cis*-IV)	1
Iodine catalysis, in light (4 min.)[e]	48:1:13:38	1

[a] A slow stream of nitrogen is recommended. [b] Intense diffuse light in the open (shade). [c] Intense morning sunshine (summer); end temp., 35°. [d] Three Photoflood bulbs from 10 cm. distance; end temp., 35–40°. [e] At 60 cm. distance from the light source. [f] 1–2 mg. substance in an evacuated capillary tube at about 190°, then cooled in iced water, extracted, and chromatographed. [g] These figures are based on the loss in extinction of iodine-catalyzed mixtures obtained from aliquots before and after the treatment but preceding chromatographic resolution.

TABLE II

RATIOS OF STEREOISOMERIC PHENYLUNDECAPENTAENALS OBTAINED UPON EXPOSURE TO WEAK DIFFUSE LIGHT[a] AT 20–25° FOR 4 MIN. (2.5 MG. IN 5 ML. BENZENE)

The ratios are based on observed extinctions of the iodine catalyzed eluates of the respective zones.

Isomer treated	Ratio, all-*trans*:*cis*-I:*cis*-II:*cis*-III (in recovered substance)	Irreversible loss (% of starting material)[b]
all-*trans*	95:1:3:1	1
cis-II	12:traces:76:12	1
cis-III	48:1:13:38	1

[a] Light intensity corresponding to f/5.6–1/100 sec.; (10 ASA) (Metraphot photometer). [b] *Cf.* footnote g to Table I.

When benzene solutions were refluxed in darkness for 0.5 hr., the all-*trans* compound remained sterically unaltered, while, respectively, 1 and 10% of the *cis* forms II and III were converted into the all-*trans* form.[7]

Like the diphenylbutadienes, the stereoisomeric phenylundecapentaenals show marked stereolability when exposed to intense scattered daylight. Under the conditions defined in Table I, roughly half of the all-*trans* and *cis*-II molecules were thus rearranged, while the *cis*-III configuration practically disappeared. Upon short exposure to weak daylight the data given in Table II were obtained. Likewise, in direct intense sunshine the photolability of the *cis*-III configuration surpasses that of the other isomers.

Under the usual conditions of the iodine catalysis (in light, in quartz cells) the rearrangement rates in this set are not significantly higher than in the absence of the catalyst (*cf.* the similar behavior of C=N bonds in azines).[2]

The spectral curves of the individual isomers, taken in the visible and ultraviolet regions,[8] appear in Figs. 1–3. The Figs. 1 and 2 also demonstrate the strong dependence of the fine structure on the solvent. Furthermore, while *trans* → *cis* rearrangements depressed the extinction values at λ_{max} con-

(5) *Cf.* J. F. Thomas and G. Branch, *J. Org. Chem.*, **18**, 1753 (1953).

(6) However, for some reason, our *trans ex cis* preparations showed a moderate band at 5.8 μ that was missing or present with much lower intensity in the spectra of synthetic all-*trans* samples.

(7) No reliable data are available for *cis*-I, since this isomer undergoes, while being rechromatographed, a partial structural alteration, whereby a beige-colored new zone appears on the column, much above the *cis*-I zone. The adsorption affinity of this pigment surpasses that of all-*trans*-phenylundecapentaenal; λ_{max} in benzene at 421 mμ, *versus* 425 mμ for all-*trans*-phenyltridecahexaenal.[5] Considering these observations, the spectral data listed in the Experimental Part and represented for this isomer in Fig. 4 are given with some reservation.

(8) Considering the photosensitivity of our substances, the unchanged steric homogeneity of the solutions was checked chromatographically each time after ultraviolet or infrared spectra had been taken. Qualitative curves of (probably not chromatographed) all-*trans*-phenylundecapentaenal samples had been given earlier by Thomas and Branch.[5] Quantitative spectrum of the all-*trans*-*p*- [illegible] and M. C. Whiting, *J. Chem. Soc.*, 4082 (1956).

siderably, the position of the latter on the wave length scale was shifted by a few millimicrons only (Table III). In the *cis*-peak region the all-*trans*, *cis*-I and *cis*-IV curves are flat, while those of II and III do show some peaks. The shape of the latter is comparable with that of some *cis*-peaks observed in the lycopene[14] and methylbixin[9] sets.

As demonstrated in Fig. 4 the infrared spectra show a significant influence of the spatial configuration mainly in two regions: (a) in the 7.5–9.0 μ region that had been found by Lunde, *et al.*,[10] to be stereochemically sensitive in diphenylpolyene sets, without the possibility of a clear interpretation; and (b) in the 10.0–10.6 μ region where the presence of a conjugated *cis-trans* diene group[11,12]

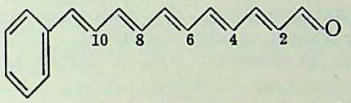
TABLE III

SOME SPECTRAL CHARACTERISTICS OF STEREOISOMERIC PHENYLUNDECAPENTAENALS IN HEXANE SOLUTION

	Main band			
Steric form	Fine structure	Position of λ_{max} (mμ)	Diff. from all-*trans* form at λ_{max} (mμ)	*cis*-Peak
all-*trans*	Very extensive	392	0	none
cis-I	Extensive	389	3	none
cis-II	Extensive	390	2	moderate, peak at 290 mμ
cis-III	Extensive	390	2	moderate, peak at 290 mμ
cis-IV	Very moderate	387	5	none

causes a splitting of the main band (located at 10.02 μ in the case of our all-*trans* compound). This doublet formation became strongly manifest in the curve of *cis*-II-undecapentaenal (new band at 10.19 μ), although only a small shoulder appeared in the *cis*-III curve, at 10.13 μ.



all-*trans*-phenylundecapentaenal

Considering the available experimental data, only tentative configurational assignments can be made at the present time (*cf.* ref. 13 and 14). The condensation product must represent the all-*trans* compound (*cf.* the formula) showing the greatest stability, the deepest color, the highest extinction values and by far the highest melting point. On the basis of observations made in comparable stereoisomeric sets, it is very probable that the *cis*es I-III represent mono*cis* forms.

The *cis*-I isomer, because of its strongest adsorption affinity among the *cis* forms and the absence of a *cis*-peak in its spectral curve, may well possess the 2-*cis* configuration, and hence an essentially straight molecular shape. In the case of *cis*es II and III the 2-*cis* position is excluded because of the presence of marked *cis*-peaks, and the centrally located 6-position is excluded because of the moderate height of these peaks as compared with the maximum values observed in the diphenyloctatetraene and diphenylhexatriene sets. Consequently, we assign the 8-mono*cis* configuration to *cis*-II and the 4-mono*cis* configuration to *cis*-III (or perhaps *vice versa*). The minor isomer IV seems to be a di*cis* compound, although, considering the flatness of its spectral curve in the *cis*-peak region and the small extent of fine structure in the main band, the sterically "hindered" 10-mono*cis* configuration cannot be excluded.[14,1b,c] Either of these assignments would explain the very weak adsorption affinity.

Acknowledgment.—We are indebted to Dr. Eugene F. Magoon for valuable discussions.

Experimental

Materials and Methods.—As adsorbent zinc carbonate (Merck Reagent Gr., precip.) was used. On zinc carbonate Harshaw (Techn. Gr.) and a number of other adsorbents, the stereoisomeric mixtures could not be resolved. The adsorbent was activated by heating, with occasional shaking, in large erlenmeyer flasks, in a drying oven at 120° for 3.5 hr. The powder should remain colorless and appear violet in ultraviolet light; it should be kept in sealed bottles and shaken before use. Overactivation results in too low migration rates on the chromatographic column. All operations should be carried out in quasi-darkness and the chromatographic tubes should be wrapped in black cloth, otherwise the orange colored zones might turn pink on the side facing the window. Benzene (Reagent Gr.) was used as the developer and ethanol as the eluent. Washing of benzene solutions was effected according to LeRosen.[15] Evaporations were carried out *in vacuo*, at near-room temperature. Melting points (cor.) were taken in a Fisher–Johns apparatus. For microanalyses we are indebted to Dr. A. Elek (Los Angeles, Calif.).

All photometric treatments refer to Pyrex volumetric flasks. A Photoflood bulb (Gen. Electric, No. 1) with attached Corning light filter No. 5840 served as the ultraviolet light source; and for irradiations the same bulb was used without the filter. Iodine catalyses (I_2 = 2% of the substance) were carried out in the light of two 120-cm. Mazda lamps (3500°, 40 watt, white and yellowish) at 60 cm. distance. Instruments: Beckman spectrophotometer model DU (quartz cells); Cary recording ultraviolet spectrophotometer model 11 M (quartz cells); and Perkin–Elmer infrared double beam spectrophotometer model 21 (NaCl prism). The extinction coefficients given represent averages of at least two independent experiments. When direct weighing of the substance was impossible, the mol. extinction coefficient of the iodine-equilibrium mixture was used in the calculations as determined by iodine-catalyzing a weighed all-*trans* sample.

All-*trans*-phenylundecapentaenal was prepared by condensing cinnamaldehyde with crotonaldehyde[4] and was freed from its 7-phenylheptatrienal content by extraction with 70% ethanol.[16] After recrystallization from acetone the aldehyde was purified chromatographically (instead of the usual sublimation) as follows. A benzene solution of 17 mg. substance was developed on a 27 × 4.4 cm. column for about 90 min.[17] Above the orange-yellow main zone several other colored zones appeared, evidently containing some higher condensation products (these had been eliminated by Kuhn and Wallenfels[3] by fractional crystallization). The main zone was cut out; its eluate was washed with water, the benzene solution dried with sodium sulfate, evaporated to a few milliliters and crystallized by cautious, dropwise addition, with stirring, of hexane. Brownish-orange prisms with pointed ends, m.p. 185–186°, yield 12 mg. $E^{mol.}_{1\,cm.}$ 9.98 × 10^4 at λ_{max} 392 mμ (in hexane); 7.98 × 10^4 at λ_{max} 403 mμ (in benzene); 8.2 × 10^4 at λ_{max} 406 mμ (in methanol).

Anal. Calcd. for $C_{17}H_{16}O$: C, 86.93; H, 6.83. Found: C, 87.13; H, 7.22.

By chromatographing as described crude all-*trans*-phenylundecapentaenal samples on a much weaker, unactivated adsorbent, such as zinc carbonate Harshaw (Techn. Gr.), the presence of some higher condensation products could be demonstrated in a simple way. (The figures on the left designate thickness of zones, in mm.; the parentheses refer to fluorescence in ultraviolet light; and the spectral data to λ_{max} in benzene):

30 three minor pink zones and interzones
30 pink (dull red): 15-phenylpentadecaheptaenal,[3] 444, 470 mμ
25 empty interzone
40 beige (weak dull red): 13-phenyltridecahexaenal[5] (?), 423 mμ
10 empty interzone
50 orange-yellow (golden-yellow): 11-phenylundecapentaenal, 403 mμ (96% of the recovered pigment)
90 empty section

(16) M. Korach and W. Bergmann, *J. Org. Chem.*, **14**, 1118 (1949).
(17) A chromatographic treatment of relatively more substance on a longer column (*e.g.*, 100 mg.; 40 × 4.4 cm.) should be avoided, because of structural changes causing dark-violet colorations of the zones. Such all-*trans*-zones yielded crimson, rod-like crystals, m.p. 197–200°, λ_{max} at 421 mμ in benzene, *versus* 210–213° and 425 mμ observed for phenyltridecahexaenal). Likewise, some chemical processes (liberation of aldehydes) took place when benzene or hexane solutions of some polyene aldehyde anils, $C_6H_5(CH{=}CH)_nCH{=}N{\cdot}C_6H_5$ (n = 2, 3 or 5) were developed on zinc carbonate, calcium carbonate even sugar. For this reason a planned stereochemical study of the anils was unsuccessful.

cis-I-Phenylundecapentaenal was obtained from the chromatogram described in the next Section. Since it could not be rechromatographed unchanged, the following data were determined upon iodine catalysis. $E^{mol.}_{1cm.}$ 8.08 × 10^4 at λ_{max} 389 mμ (in hexane); 7.30 × 10^4 at λ_{max} 401 mμ (in benzene).

cis-II-Phenylundecapentaenal.—Seventeen milligrams of pure all-*trans* crystals was dissolved in 15 ml. of benzene on a water-bath and, after cooling to 20°, exposed to intense diffuse daylight on a window sill. After 2 hr. the solution was developed on a 22 × 3.5 cm. column:

20	orange-yellow (golden-yellow): unchanged all-*trans*
5	pale yellow (dull dark brown): *cis*-I
5	empty interzone
23	yellow (golden light yellow): *cis*-II
7	pale yellow (dull brown): *cis*-III
160	empty section

The eluate of the 23-mm. zone was transferred to benzene, dried, concentrated and rechromatographed as described on a 18 × 2 cm. column. The developing process was continued until a narrow but clear interzone appeared between the *cis*-II and *cis*-III zones. The benzene solution obtained from the former was evaporated completely, the crystalline residue dissolved at 25° in the minimum amount of benzene and crystallized by cautious addition of hexane; yield 4 mg. (in all, 20 mg. were prepared). Fine, orange-yellow needles grouped in sheaves or fan-like forms, m.p. 103–105°, or short needles, m.p. 108–110°; $E^{mol.}_{1cm.}$ 7.49 × 10^4 at λ_{max} 390 mμ (in hexane); 6.2 × 10^4 at λ_{max} 401 mμ (in benzene).

Anal. Calcd. for $C_{17}H_{16}O$: C, 86.93; H, 6.83. Found: C, 87.25; H, 7.39.

cis-III-Phenylundecapentaenal.—The 7-mm. zone of the above chromatogram was treated as described for *cis*-II and combined with seven similar zones originating from parallel experiments. After rechromatographing (column, 22 × 3.5 cm.) the benzene solution (50 ml.) was evaporated to 1 ml. at 10° (oil pump, receiver in acetone–Dry Ice). Upon cautious addition of hexane at 20°, this concentrate deposited crystals. Recrystallization in the same manner yielded 3 mg. of small, sturdy, yellow spears. The sample sintered at about 103° and melted at 176–178°, *i.e.*, somewhat below the m.p. of the all-*trans* isomer; evidently, this determination was disturbed by spatial changes in the fused state. The following values were obtained upon iodine catalysis: $E^{mol.}_{1cm.}$ 6.91 × 10^4 at λ_{max} 390 mμ (in hexane); 5.90 × 10^4 at λ_{max} 401 mμ (in benzene).

cis-IV-Phenylundecapentaenal was formed, when a solution of 5 mg. of *cis*-III in 5 ml. of benzene was exposed to sunshine (*cf.* Table IC). In the chromatogram, the thin, pale yellow *cis*-IV zone was located just below *cis*-III. After rechromatographing, the following data were obtained by the iodine catalysis method: $E^{mol.}_{1cm.}$ 6.64 × 10^4 at λ_{max} 387 mμ (in hexane); 5.67 × 10^4 at λ_{max} 394 mμ (in benzene).

Structure of Corn Hull Hemicellulose. Part VI. The Synthesis of 5-O-β-D-Galactopyranosyl-L-arabinose[1,2]

BY IRWIN J. GOLDSTEIN, F. SMITH AND H. C. SRIVASTAVA

RECEIVED FEBRUARY 27, 1957

The synthesis of 5-*O*-β-D-galactopyranosyl-L-arabinose is described.

In a previous paper[3] of this series there was discussed the isolation and characterization of 5-*O*-β-D-galactopyranosyl-L-arabinofuranose, a disaccharide formed amongst others when corn hull hemicellulose[4] is subjected to graded hydrolysis with dilute mineral acid.[3]

The formulation of the disaccharide as 5-*O*-β-D-galactopyranosyl-L-arabinose was based upon these observations: Acid hydrolysis showed the presence of galactose and arabinose, while hydrolysis of the phenylosazone of the disaccharide gave galactose, but no arabinose. Hydrolysis of the fully methylated disaccharide furnished 2,3,4,6-tetra-*O*-methyl-D-galactopyranose and 2,3-di-*O*-methyl-L-arabinose. The decision to assign a β-configuration to the galactose residue and a furanose conformation to the arabinose moiety was based upon the rules of isorotation.[3,5]

This communication is concerned with the synthesis of 5-*O*-β-D-galactopyranosyl-L-arabinose in order to confirm the structure assigned to the disaccharide from the corn hull hemicellulose. The synthesis was accomplished as follows: interaction of ethyl 2,3-di-*O*-acetyl-α-L-arabinofuranoside with 2,3,4,6-tetra-*O*-acetyl-α-D-galactosyl bromide in the presence of silver oxide gave a sirup which, when deacetylated and subjected to controlled hydrolysis, afforded 5-*O*-β-D-galactopyranosyl-L-arabinofuranose. This was purified by chromatography on a carbon:Celite column[6] taking care to avoid washing with water to remove monosaccharides, since this leads to imperfect separations.[7] In this manner two isomeric galactose–arabinose disaccharides were obtained. Methylation of the one whose rotation corresponded to that of the galactose–arabinose disaccharide isolated from the corn hull hemicellulose, first with methyl sulfate and 40% potassium hydroxide solution in the absence of air, and then with methyl iodide and silver oxide, gave methyl 5-*O*-(2,3,4,6-tetra-*O*-methyl-β-D-galactopyranosyl)-2,3-di-*O*-methyl-L-arabinofuranoside, a non-reducing sirup which showed $[\alpha]^{24}D$ −45° in methanol. Acid hydrolysis of the latter followed by paper chromatographic analysis afforded two cleavage products, namely, 2,3,4,6-

tetra-*O*-methyl-D-galactopyranose and 2,3-di-*O*-methyl-L-arabinose.

Separation of these components was effected by sheet paper chromatography in the usual way using butanone:water azeotrope. The 2,3-di-*O*-methyl-L-arabinose was identified as its crystalline 1,4-di-*p*-nitrobenzoate[3] while the 2,3,4,6-tetra-*O*-methyl-D-galactopyranose afforded the characteristic crystalline aniline derivative.[8]

The characterization[3] of the *O*-D-galactosyl → L-arabinoise disaccharide from the corn hull hemicellulose as 5-*O*-β-D-galactopyranosyl-L-arabinose is therefore correct.

Experimental

The following solvents were used for partition chromatography: A, pyridine:ethyl acetate:water (1:2.5:3.5)[9]; B, 1-butanol:pyridine:water (6:4:3)[10]; C, 1-butanol:acetic acid:water (2:1:1)[11]; and D, butanone–water azeotrope.[12] The sugars were detected on the paper chromatogram by spraying with *p*-anisidine trichloroacetate[13] and/or ammoniacal silver nitrate.[14]

All evaporations were carried out under reduced pressure at 30–40°. R_x represents the rate of movement of sugars with respect to D-xylose.

Ethyl 2,3-Di-*O*-acetyl-5-*O*-trityl-α-L-arabinofuranoside.—Ethyl α-L-arabinofuranoside[15] (1.15 g., m.p. 48–49°) was suspended in dry pyridine (5 ml.) and after the addition of triphenylmethyl chloride (1.8 g.) the mixture was shaken. The reaction mixture which became clear after 10 hr. was kept at room temperature for 20 days. To the reaction mixture, acetic anhydride (5 ml.) was added and the solution kept at room temperature for 20 hr. The mixture was poured with stirring into cold water when a viscous sirup separated. The sirup was extracted with chloroform and the extract washed successively with a dilute aqueous solution of sodium bicarbonate and water. After drying (Na_2SO_4), the chloroform solution was evaporated to give a viscous sirup (3.2 g.) which did not crystallize.

Ethyl 2,3-Di-*O*-acetyl-α-L-araboinfuranoside.—The compound (3.2 g.) obtained in the previous experiment was detritylated by dissolving it in glacial acetic acid (30 ml.) and adding to the cooled solution a saturated solution (2.5 ml.) of hydrogen bromide in acetic acid. The precipitated triphenylmethyl bromide was filtered, the residue washed with acetic acid and the combined filtrates poured into a mixture of cold water and chloroform. The chloroform layer was separated and the aqueous layer extracted twice with chloroform. The combined chloroform extracts were washed with a solution of sodium bicarbonate and then with water. The chloroform solution was dried (Na_2SO_4) and evaporated to give a light colored sirup (1.4 g.) which showed $[\alpha]^{25}D$ −30° in chloroform (*c* 1.7).

2,3,4,6-Tetra-*O*-acetyl-α-D-galactosyl Bromide.—1,2,3,-4,6-Penta-*O*-acetyl-β-D-galactose (7 g.), transformed into the glycosyl bromide in the usual way, was obtained as a liquid (6.5 g.) which showed $[\alpha]^{19}D$ +211° in benzene (*c* 6); lit.[16] $[\alpha]D$ +234°. This product was used directly.

Interaction of Ethyl 2,3-Di-*O*-acetyl-α-L-arabinofuranoside with 2,3,4,6-Tetra-*O*-acetyl-α-D-galactosyl Bromide.—The reagents (chloroform, silver oxide and Drierite) for the condensation reaction were prepared according to the procedure of Reynolds and Evans.[17] The reactants were dried *in vacuo* at 50–60° for 4 hr.

Sirupy ethyl 2,3-di-*O*-acetyl-α-L-arabinofuranoside (1.1 g.) was dissolved in chloroform (7 ml.) and after the addition of Drierite (5 g.) and silver oxide (2.0 g.), the mixture was shaken for 0.5 hr. A solution of iodine (0.2 g.) in chloroform (10 ml.) was added to the mixture and then 2,3,-4,6-tetra-*O*-acetyl-α-D-glactosyl bromide (1.7 g.) in chloroform (7 ml.) was added in small portions during 0.5 hr. The mixture was shaken for 36 hr., filtered and the residue washed with chloroform. The combined filtrate and washings were evaporated to give a sirup (2.2 g.).

The sirup was deacetylated by dissolving it in ethanol (50 ml.), adding 0.1 *N* potassium hydroxide (20 ml.) and heating at 60° for 1 hr. The reaction mixture was evaporated to a sirup which was dissolved in 0.01 *N* sulfuric acid (20 ml.) and the solution heated on a steam-bath for 2 hr. The inorganic ions were removed by passing the solution successively through columns of Duolite A-4[18] and Amberlite IR-100,[19] and the effluent was evaporated to a sirup (1.0 g.). Upon chromatographic analysis using solvent A the sirup was found to contain arabinose (R_x 0.84), galactose (R_x 0.62) and a third component with R_x 0.52. This component was indistinguishable on paper chromatograms using solvents A, B and C from 5-*O*-β-D-galactopyranosyl-L-arabinose[3] isolated by graded hydrolysis of corn hull hemicellulose.

Isolation of 5-*O*-β-D-Galactopyranosyl-L-arabinose.—The sirupy mixture (1.0 g.) containing the galactose–arabinose disaccharide, galactose and arabinose, was dissolved in 2.5% aqueous ethanol and the solution put on a charcoal:Celite column[6] previously washed with 2.5% aqueous ethanol. The column was washed first with 2.5% aqueous ethanol[7] (750 ml.) to displace the monosaccharides and then with 10% aqueous ethanol (900 ml.), collected in six fractions of 150 ml. each, to elute the disaccharide. Fractions 1 and 2 were found to contain negligible amounts of carbohydrate material. Fraction 3, when evaporated, yielded a sirup (181 mg.) which had $[\alpha]^{25}D$ −18° in water (*c* 1). In solvents A, B and C it had the same R_f as that of 5-*O*-galactopyranosyl-L-arabinose obtained from the corn hull hemicellulose. The disaccharide (10 mg.) was hydrolyzed with 0.7 *N* sulfuric acid (3 ml.) for 4 hr. on a steam-bath, neutralized ($BaCO_3$), filtered and evaporated to give a sirup which, upon chromatographic analysis, was found to contain galactose and arabinose.

Fractions 4 and 5 were combined and then evaporated to yield a sirup (217 mg.) which had the same R_f as 5-*O*-β-D-galactopyranosyl-L-arabinose and showed $[\alpha]^{25}D$ −76° in water (*c* 5). Upon acid hydrolysis with 0.7 *N* sulfuric acid it also afforded galactose and arabinose. The structure of this disaccharide will form the subject of a later communication.

Fraction 6, upon evaporation, gave a sirup (6.7 mg.) which was shown to be a mixture of galactosylarabinose and higher oligosaccharides and was not further examined.

Proof of Structure of 5-*O*-β-D-Galactopyranosyl-L-arabinose. Methyl 5-*O*-(2,3,4,6-Tetra-*O*-methyl-D-galactopyranosyl)-2,3-di-*O*-methyl-L-arabinofuranoside.—The galactose–arabinose disaccharide (90 mg., $[\alpha]D$ −18° in H_2O) was methylated in an atmosphere of nitrogen with 40% potassium hydroxide (24 ml.) and methyl sulfate (8 ml.), the reagents being added in eight portions with vigorous stirring at 0° during 1.5 hr.[3] The reaction mixture was stirred for another hour and after it had attained room temperature it was methylated with 40% potassium hydroxide (9 ml.) and methyl sulfate (3 ml.) in the previous manner. The mixture was stirred for 2 hr. and after warming it to 50–60° it was methylated again with methyl sulfate (2 ml.) and 40% potassium hydroxide (6 ml.). The reaction mixture was stirred for 1.5 hr. and then heated at 80–90° for 1.5 hr. The mixture was cooled, stirred with chloroform (50 ml.), filtered and the residue washed with chloroform. The chloroform solution was separated and the remaining aqueous layer extracted twice more with chloroform. The combined chloroform extracts were washed with a saturated solution of sodium sulfate, dried (Na_2SO_4) and evaporated to give a sirup (52.7 mg.). This was dissolved in methyl iodide (10 ml.) and silver oxide (3 g.) added in small portions. The mixture was refluxed for 12 hr. After the reaction, the mixture was filtered, washed with chloro-

form, and the combined filtrates evaporated to give a sirup which was methylated twice more with methyl iodide and silver oxide in the previous manner.

After distilling the methyl iodide, the silver oxide residue was extracted with ether (five 20-ml. portions). Concentration of the ethereal extract gave methyl 5-*O*-(2,3,4,6-tetra-*O*-methyl-D-galactopyranosyl)-2,3-di-*O*-methyl-L-arabinofuranoside as a yellow, non-reducing sirup (48.5 mg.) which showed $[\alpha]^{24}D$ −45° in methanol (*c* 1.6).[3]

Hydrolysis of Methyl 5-*O*-(2,3,4,6-Tetra-*O*-methyl-D-galactopyranosyl)-2,3-di-*O*-methyl-L-arabinofuranoside.—A solution of the methylated disaccharide (48.5 mg.) in 0.3 *N* sulfuric acid (3 ml.) was heated at 100° for 9 hr. The reaction mixture was neutralized ($BaCO_3$) and filtered, the salts being washed thoroughly first with water, then ethanol. Concentration of the filtrate gave a yellow sirup (38 mg.) which showed $[\alpha]^{26}D$ +32° in methanol (*c* 1.3).

Analysis of the sirup by paper chromatography, using solvent D, showed the presence of two components upon spraying either with ammoniacal silver nitrate or with *p*-anisidine, namely, 2,3-di-*O*-methyl-arabinose (R_f 0.43) and 2,3,4,6-tetra-*O*-methylgalactose (R_f 0.68).

Separation of the methylated components was achieved by sheet paper chromatography (Whatman No. 1) using solvent D. In addition to the two components noted, a small amount of the reducing unhydrolyzed methylated disaccharide was obtained, R_f 0.79.

Identification of 2,3,4,6-Tetra-*O*-methyl-D-galactose.—The component corresponding to 2,3,4,6-tetra-*O*-methyl-D-galactose was eluted from the filter paper and concentrated to give a chromatographically pure sirup (13 mg.) which showed $[\alpha]^{25}D$ +58° in ethanol (*c* 0.4). It was converted in the usual manner to N-phenyl-D-galactopyranosylamine 2,3,4,6-tetramethyl ether, m.p. and mixed m.p. 196–197°, $[\alpha]^{27}D$ −78° in acetone (*c* 0.4), after recrystallization from ethanol; lit.[8] m.p. 192°, $[\alpha]D$ −77° (acetone).

Identification of 2,3-Di-*O*-methyl-L-arabinose.—2,3-Di-*O*-methyl-L-arabinose was obtained as a colorless sirup (6.5 mg.) which showed $[\alpha]^{25}D$ +92° in water (*c* 0.3). It was characterized as its 1,4-di-*p*-nitrobenzoate, m.p. and mixed m.p. 149–152°.[3]

Acknowledgment.—The authors thank Professor Eugene Pacsu of Princeton University for a nucleus of ethyl α-L-arabinofuranoside.

Starch Formate

BY I. A. WOLFF, D. W. OLDS AND G. E. HILBERT

RECEIVED MARCH 9, 1957

Formylation of starch under the conditions investigated is a reversible reaction; the extent of substitution is dependent upon the ratio of formic acid to starch and on the water content of the system. Appreciation of this fact is required by workers who use formylation of cellulose for accessibility studies and refer to amylaceous materials as standards for comparison, assuming the latter to be 100% accessible. Maximum degree of substitution of starch achieved was 2.3 acyl groups per anhydroglucose unit.

As part of a program at this Laboratory on the preparation of starch esters,[2] formyl derivatives were desired.

Gottlieb, Moe, Nickerson and their co-workers[3–5] esterified starch, using 90% formic acid at room temperature and obtained esters having a degree of substitution approximating, but slightly greater than, one formyl group per anhydroglucose unit. Tarkow and Stamm,[6] using 99% formic acid at 55° also report formation of essentially a monoformate, but in their studies a relatively low ratio of formic acid to carbohydrate was used. All of these authors indicate either exclusive reaction of the formic acid with primary hydroxyl groups or at least preferential, rapid formylation of this grouping. Browning and Sell[7] state that their work "suggests formylation of secondary hydroxyl groups," though more slowly than primary hydroxyl groups. These authors conducted their experiments with 99.3% formic acid at 51° and demonstrated increased formylation of starch at higher formic acid to starch ratios. Their conclusions are based on analytical data alone. Reaction products were not isolated. The use of data on the formylation of cellulose as a measure of its accessibility, with reference to amylaceous materials as standards,[4–6] makes an understanding of the formylation of starch particularly pertinent.

In the studies reported here, starch was esterified at ambient temperature in excess formic acid containing different amounts of water. Formyl esters were isolated by alcohol precipitation at varying time intervals and analyzed for acyl content. Our results indicate that the formylation of starch under the conditions used is best depicted as a reversible reaction

$$\underset{\text{Starch}}{R(OH)_3} + n\text{HCOOH} \rightleftarrows \underset{\text{Starch formate}}{R(OCHO)_n(OH)_{3-n}} + n\text{H}_2\text{O}$$

in which equilibrium is reached in about 8 hr. Fortuitous choice of reaction conditions was apparently responsible for isolation of a monoformate by many earlier workers.

Anhydrous formic acid reacts with starch to give a monoformate in only one-fourth of the time needed with the 90% acid (Fig. 1). The final product obtained with this more concentrated acid approximates a diformate. Use of anhydrous starch, of higher proportions of formic acid relative to the starch or reformylation of an isolated "diformate" all raise the degree of formylation still further. The equilibrium nature of the reaction was demonstrated as follows: Sufficient water was added to the reaction mixture of dry starch with

anhydrous formic acid after maximum reaction was obtained to lower the acid strength to 90%. The product then isolated corresponded to that expected if 90% formic acid had been used initially.

It was not possible to prepare starch triformate by removal of water with anhydrous calcium sulfate or azeotropically with benzene. The highest degree of substitution attained was 2.3 formyls per C_6 unit. However, failure to achieve preparation of the triester may still be simply a question of equilibrium, with the conditions employed being inadequate for removal of the last traces of water from the system. The large effects of small quantities of water in displacing the equilibrium toward the side of deacylation are demonstrated by the work of Hiller[8] on a comparable cellulose–acetic acid system. In studying equilibrium combined acetic acid content of cellulose acetate in homogeneous, uncatalyzed reactions, Hiller found that (at 94.2°) presence of 0.5% water resulted in equilibrium degree of substitution of 2.75 acetyl groups per C_6 unit; 2.8% water in the system gave equilibrium substitution of 1.9.

Our results agree with those of other investigators in indicating preferential reactivity of the 6-hydroxyl group, as deduced from periodate analysis of "mono-" and "di-" formates. Starch monoformate consumed approximately one mole of oxidant per mole of anhydrohexose present. The starch diformate was oxidized by the periodate only to the extent of 0.15 mole of oxidant consumed per anhydroglucose unit. This fact indicates a fair degree of homogeneity for the diformate, although the possibility exists that some monoformate, with compensating amounts of triformate ester, may be present. In other studies we have shown[9] that under conditions employed in the periodate oxidation analysis a minor, but definite and measurable, hydrolysis of formate esters can occur.

The free hydroxyl groups in starch formates can be esterified to give completely substituted mixed esters.

The solid starch esters developed a strong odor of formic acid within several days when left exposed to the laboratory atmosphere.

Experimental

Materials.—High grade commercial corn starch served as the carbohydrate raw material. Eastman Kodak Co. anhydrous formic acid (98–100%) and Merck and Co., Inc., reagent (approximately 90%) formic acid were used in the esterifications.

Analytical Procedures.—Formyl analysis on the starch esters was carried out by saponification at room temperature for 48 hr. with 0.25 *N* potassium hydroxide in aldehyde-free absolute ethanol. An excess of 0.25 *N* hydrochloric acid was added at the end of the saponification period and after several hours the samples were titrated to a phenolphthalein end-point with 0.1 *N* aqueous sodium hydroxide.

Esterification Methods.—Esterifications of the starch were carried out by adding the required amount of starch to formic acid which was being rapidly stirred mechanically at room temperature. Mechanical stirring was continued throughout the reaction period. Gelatinization always occurred in a short time. In about 2 hr. the mixture was practically homogeneous and free from gelled particles. From then on the mixture gradually became clearer and less viscous. At the end of the reaction period the esters were precipitated in absolute ethanol (Waring Blendor), washed three times in the Blendor with this solvent and finally dried *in vacuo* at 25 and 70°. The esters were all white powders.

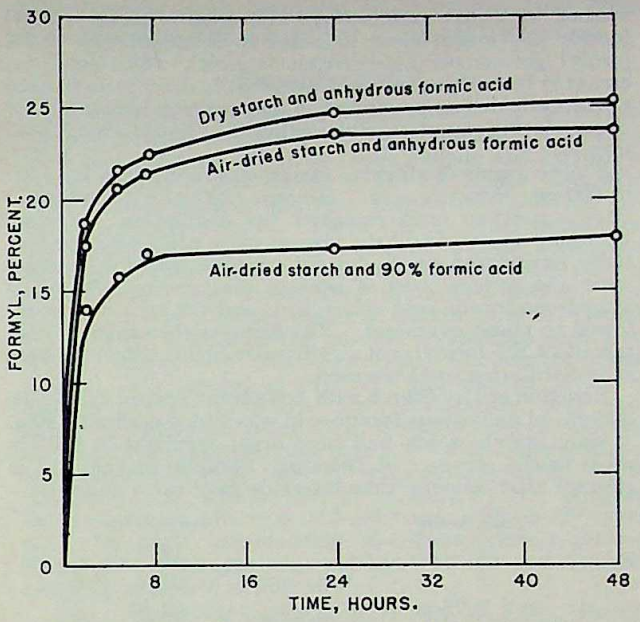

Fig. 1.—Esterification of starch with formic acid.

Reaction of Air-dried Starch with 90% Formic Acid.—Thirty grams of air-dried starch was treated with 300 ml. of 90% formic acid. Samples were withdrawn at various time intervals, precipitated and analyzed:

Reaction time, hours	Formyl, %[a]
2	14.0
5	15.7
7.5	17.0
24	17.3
48	17.9

[a] Calcd. for starch monoformate, $C_7H_{10}O_6$: 15.3% formyl.

Reaction of Air-dried Starch with Anhydrous Formic Acid.—Reaction of 30 g. of air-dried starch with 300 ml. of anhydrous formic acid and withdrawal of samples, as above, gave materials with the following analysis:

Reaction time, hours	Formyl, %[a]
2	17.75
5	20.6
7.5	21.4
24	23.65
72	24.2

[a] Calcd. for starch diformate, $C_8H_{10}O_7$: formyl, 26.6.

If Drierite is added initially to a reaction mixture such as the above, the product after 5 hr. has 20.7% formyl and 1.05% ash.

Twenty-five grams of vacuum oven-dried starch formate (18.8% formyl) prepared by 3 hr. reaction of air-dried starch with anhydrous formic acid was reformylated for 4.5 hr. with 300 ml. of anhydrous formic acid. The formyl content of the product was 24.4%.

To test the effect of concentration 30 g. of air-dried starch was formylated in 600 ml. of anhydrous formic acid. The course of the reaction was as shown:

Reaction time, hours	Formyl, %
2	20.1
5	23.2
7	24.3
24	27.3
48	28.0

The 24-hr. sample above (3.3 g. vac. oven dry wt.) was reformylated for 7.5 hr. with 80 ml. of anhydrous formic acid. The material was precipitated in diethyl Cellosolve,

Digitized by Arya Samaj Foundation Chennai and eGangotri

washed with that same solvent and dried *in vacuo;* formyl found: 29.5 (equivalent to a degree of substitution of 2.3 formyl groups per anhydroglucose unit). This small increase in formyl content indicates that in other formylations ethanolysis during precipitation and washing is not a factor in preventing complete substitution of hydroxyl groups with formyl.

Thirty grams of air-dried starch was formylated for 4 hr. in 300 ml. of formic acid. Benzene (200 ml.) was added in 50-ml. portions and removed by distillation *in vacuo*. Bumping occurred and the viscous paste containing the partially formylated starch did not mix well with the benzene. After the surface layer of benzene disappeared, 150 ml. of anhydrous formic acid was added, and the mixture was allowed to stand overnight. The formate then isolated contained 24.8% formyl, not significantly higher than if no benzene distillation had been used.

Reaction of Dry Starch with Anhydrous Formic Acid.—To 300 ml. of anhydrous formic acid was added gradually 30 g. f corn starch which had been dried overnight at 110° *in vacuo* in the presence of Drierite. Samples precipitated in ethanol after varying time intervals gave these analyses:

Time, hours	Formyl, %
2	18.7
5	21.7
7.75	22.6
24	24.8
48	25.4

Thirty grams of corn starch was formylated as above. One hundred milliliters of the mixture was precipitated after 24 hr. To the remainder 25 ml. of water was added and reaction was continued for 27 hr. longer. The remainder was then precipitated. The analysis of these products was: 24-hr. product, 26.1% formyl; 51-hr. product, 18.9% formyl.

The starch formates are soluble in pyridine and in formic acid but not in the other common organic solvents tested.

Optical Rotation of Starch Formates.—The rotation of a formyl ester with 1.3 formyl groups per C_6 (19.0% formyl) was $[\alpha]^{25}D$ +180.6° (pyridine, c = 1). A formate containing 2.1 formyl per C_6 (27.7% formyl) had $[\alpha]^{25}D$ +166.5° (pyridine, c 1).

Oxidation of Starch Formate with Periodate.—Samples of starch formate were treated with an excess of sodium periodate. After 24 hr., analysis for excess periodate was carried out.[10] Data are summarized below.

		Starch formate	
Formyl/C_6 unit	Wt. sample, g.	Periodate consumed (millimole)	Millimoles periodate per millimole repeating unit
2.10	0.3050	0.21	0.15
1.16	.1449	.80	1.08

Carbanilation of Starch Formate.—To 19.0 g. of oven-dried starch formate (18.8% formyl, 1.28 formyl per C_6) in 125 ml. of dry pyridine was added 35 g. of phenyl isocyanate, and the mixture was heated for 6 hr. at 100°. The ester, isolated by precipitation with ethanol, had 5.99% N; calcd. 5.94% N. Similar preparation of other mixed esters from starch formates indicates that formyl esters are produced and that the formic acid is not held merely by sorption or solvation onto the carbohydrate.

Acknowledgment.—The authors are indebted to T. A. McGuire and C. H. Van Etten for assistance with the formyl analyses. The use of trade names in this paper does not necessarily constitute endorsement of these products or of the manufacturers thereof.

1,2 :3,5-Di-*O*-benzylidene-α-D-glucose

By Harry B. Wood, Jr., Harry W. Diehl and Hewitt G. Fletcher, Jr.

Received January 31, 1957

Condensation of D-glucose with benzaldehyde in the presence of zinc chloride–acetic acid gives a di-*O*-benzylidene-D-glucose identical with a substance which earlier authors obtained through successive benzylidenation and debenzoylation of 6-*O*-benzoyl-D-glucose diethyl dithioacetal. Evidence is presented showing the acetal to be 1,2:3,5-di-*O*-benzylidene-α-D-glucose.

In 1937, Papadakis[1] published a study of the behavior of 6-*O*-benzoyl-D-glucose diethyl dithioacetal with benzaldehyde in the presence of zinc chloride. Under the conditions which this author employed, the thioethyl groups were lost and a non-reducing *O*-benzoyl-di-*O*-benzylidene-D-glucose was obtained as the sole reaction product. Deacylation of the latter compound afforded a di-*O*-benzylidene-D-glucose, m.p. 163°, which was oxidized to a di-*O*-benzylidene-D-glucuronic acid, thus demonstrating that the di-*O*-benzylidene-D-glucose was unsubstituted at C_6 and that the benzoyl group in the starting material had not wandered in the process of cyclic acetal formation.[2]

In the same year Wolfrom and Tanghe[3] reported a more extensive study of the benzylidenation of 6-*O*-benzoyl-D-glucose diethyl dithioacetal. These authors were able to isolate a 6-*O*-benzoyl-di-*O*-benzylidene-D-glucose diethyl dithioacetal as an intermediate which, on further treatment with benzaldehyde and zinc chloride, afforded a non-reducing *O*-benzoyl-di-*O*-benzylidene-D-glucose melting at 160–160.5°. Debenzoylation gave a di-*O*-benzylidene-D-glucose melting at 163–165°. That Wolfrom and Tanghe's di-*O*-benzylidene-D-glucose and its benzoate were identical with the corresponding compounds prepared by Papadakis seems quite certain although the latter author unfortunately failed to report the rotations of his substances.

Recent investigations in this Laboratory have demonstrated, through experiments in the D-ribose

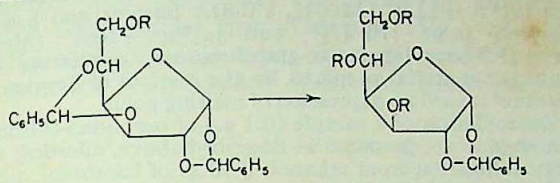
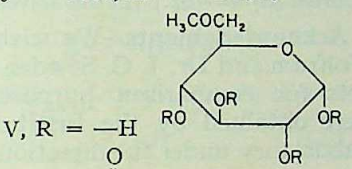
series,[4,5] that condensations of sugars with benzaldehyde in the presence of zinc chloride–acetic acid may give somewhat different results from those obtained when zinc chloride alone is the condensing



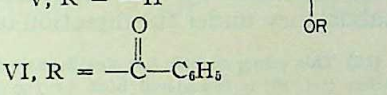
I, R = —H VII, R = —H

II, R = —CCH_3 VIII, R = —CC_6H_5

III, R = —CC_6H_5
IV, R = —CH_3



V, R = —H



VI, R = —$C—C_6H_5$

agent.[6] In the D-glucose series we have shown[7] that benzylidenation with zinc chloride alone affords, in addition to the previously known substances 4,6-*O*-benzylidene-D-glucose[8] and 1,2-*O*-benzylidene-α-D-glucofuranose,[9] 1,2:4,6-di-*O*-benzylidene-α-D-glucose. It was of interest, therefore, to examine the behavior of D-glucose with benzaldehyde in the presence of zinc chloride–acetic acid. Under the conditions employed only two crystalline products, the known 1,2-*O*-benzylidene-α-D-glucofuranose and a di-*O*-benzylidene-D-glucose, were obtained—both in relatively low yield. Comparison of our di-*O*-benzylidene-D-glucose and its benzoate with the corresponding substances kindly provided by Professor Wolfrom showed identity in both cases.

The structure of the di-*O*-benzylidene-D-glucose has now been elucidated in the following simple manner. Methylation afforded a crystalline methyl ether (IV); hydrogenolysis of the latter furnished 6-*O*-methyl-D-glucose (V) which was further characterized as its tetrabenzoate VI. Carbon six in the starting material is, therefore, unsubstituted. Partial hydrogenolysis, facilitated by use of a solvent in which a mono-*O*-benzylidenehexose is sparingly soluble,[7] led to the isolation of the known[9] 1,2-*O*-benzylidene-α-D-glucofuranose (VII). It is apparent, then, that the diacetal is 1,2:3,5-di-*O*-benzylidene-α-D-glucose (I), a furanose derivative in contrast to the isomeric di-*O*-benzylidene-D-glucopyranose reported earlier.[7]

In passing, we would like to observe that the apparent marked variability in catalytic activity of zinc chloride in benzylidenations[3] may actually be due to variations in the benzoic acid content of benzaldehyde since one would expect a zinc chloride–benzoic acid complex to resemble zinc chloride–acetic acid as a catalyst in acetal formation.

Experimental[10]

1,2:3,5-Di-*O*-benzylidene-α-D-glucose (I).—A mixture of 10 g. of powdered, anhydrous D-glucose, 20 g. of freshly fused zinc chloride, 60 ml. of benzaldehyde and 7.7 ml. of glacial acetic acid was shaken at 26° for 17 hr. The light straw-colored solution was then poured with stirring into 200 ml. of ice and water. Three 100-ml. ether extractions of the resulting mixture were combined, washed with water and sodium bicarbonate solution, dried over sodium sulfate, treated with 1 g. of decolorizing carbon and filtered. The filtrate was concentrated, finally at 0.5 mm. and 60° (bath). From 20 ml. of ethanol the product crystallized and, after several days at −5°, was filtered off. The minute prisms (3.1 g., 16%) melted at 141–147° and showed $[\alpha]^{20}D$ + 34.0 in pyridine (*c* 0.85). Recrystallization, first from 25 ml. of hot ethanol using 0.5 g. of decolorizing carbon, and then from ethyl acetate, gave pure 1,2:3,5-di-*O*-benzylidene-α-D-glucose melting at 160–161° and rotating $[\alpha]^{20}D$ +34.8° (pyridine, *c* 1.07) and $[\alpha]^{20}D$ +40° ($CHCl_3$, *c* 1.0). Wolfrom and Tanghe[3] recorded m.p. 163–165° and $[\alpha]^{24}D$ + 35° (pyridine) for their non-reducing di-*O*-benzylidene-D-glucose. Mixed with a sample prepared by Wolfrom and Tanghe, our product melted at 161–164°.

Anal. Calcd. for $C_{20}H_{20}O_6$: C, 67.40; H, 5.66. Found: C, 67.13; H, 5.71.

From the original mother liquor there was obtained, in addition to a small quantity of 1,2:3,5-di-*O*-benzylidene-α-D-glucose, 0.51 g. of **1,2-*O*-benzylidene-α-D-glucofuranose**, m.p. 174–175°, $[\alpha]^{20}D$ +11.5° (*c* 1, MeOH) and $[\alpha]^{20}D$ +27.9° (*c* 1.05, pyridine).

6-*O*-Acetyl-1,2:3,5-di-*O*-benzylidene-α-D-glucose (II).—One-half gram of 1,2:3,5-di-*O*-benzylidene-α-D-glucose was acetylated with acetic anhydride in pyridine in the usual fashion to yield, from ethanol, needles (0.4 g., 72%) melting at 144–145° and rotating $[\alpha]^{20}D$ +28.6° ($CHCl_3$, *c* 0.86).

Anal. Calcd. for $C_{22}H_{22}O_7$: C, 66.32; H, 5.57. Found: C, 66.23; H, 5.85.

6-*O*-Benzoyl-1,2:3,5-di-*O*-benzylidene-α-D-glucose (III).—One-half gram of 1,2:3,5-di-*O*-benzylidene-α-D-glucose was benzoylated in normal fashion using benzoyl chloride in pyridine to give a crude crystalline product which, recrystallized from 35 ml. of hot absolute ethanol, weighed 0.47 g. (73%), melted at 157–158° and rotated $[\alpha]^{20}D$ +12.9° ($CHCl_3$, *c* 1.1).

Anal. Calcd. for $C_{27}H_{24}O_7$: C, 70.42; H, 5.25. Found: C, 70.60; H, 5.33.

Papadakis[1] reported m.p. 156° while Wolfrom and Tanghe[3] reported m.p. 160–160.5° and $[\alpha]^{-6}D$ +15° ($CHCl_3$) for this substance. Mixed with a sample of the product of these latter authors, our material melted at 158–161°.

1,2:3,5-Di-*O*-benzylidene-6-*O*-methyl-α-D-glucose (IV).—Two grams of 1,2:3,5-di-*O*-benzylidene-α-D-glucose was dissolved in a mixture of 20 ml. of methyl iodide and 10 ml. of dioxane. To the boiling, well-stirred solution 1-g. portions of silver oxide were added at half-hour intervals until 6 g. had been used. After a further hour of stirring and boiling, the solution was cooled, filtered and then concentrated *in vacuo*, the temperature of the material not exceeding 40° at any time. Crystallization was spontaneous: 2.06 g. The product was dissolved in ethanol, decolorized with carbon and crystallized by the addition of pentane. A second recrystallization from cold ether afforded pure material (1.2 g., 58%) melting at 98–100° and rotating $[\alpha]^{20}D$ +25.2° in chloroform (*c* 1).

Anal. Calcd. for $C_{21}H_{22}O_6$: C, 68.09; H, 5.99. Found: C, 67.81; H, 5.93.

6-*O*-Methyl-α-D-glucose (V).—One gram of 1,2:3,5-di-*O*-benzylidene-6-*O*-methyl-α-D-glucose (IV) was hydrogenolyzed in the customary fashion using 0.5 g. of palladium black suspended in 25 ml. of absolute ethanol. After removal of the catalyst and the solvent the product crystallized: 0.45 g. (86%), m.p. 137–144°. Two recrystallizations from hot absolute ethanol gave pure material (0.22 g.) which was chromatographically homogeneous: m.p. 142–143°, $[\alpha]^{20}D$ +99° (2 min.) → +56° (19 hr., equil.)

(10) Melting points are corrected.

(c 0.94, water). For 6-*O*-methyl-α-D-glucose Bell[11] reported m.p. 145° and $[\alpha]^{16}D$ +110° → 55° (H_2O). Addition of 90 mg. of this material to a mixture of benzoyl chloride and pyridine which previously had been cooled to 0° led, after the usual manipulations, to the isolation, from ethanol–pentane, of 220 mg. of crystalline material. Recrystallization from hot pentane afforded, with little loss, a product melting at 157–159° and rotating $[\alpha]^{20}D$ +126.5° (c 1.1, $CHCl_3$).

Anal. Calcd. for $C_{35}H_{30}O_{10}$: C, 68.84; H, 4.95. Found: C, 68.81; H, 4.81.

Ohle and Tessmar[12] recorded m.p. 154° and $[\alpha]D$ +120.6° ($CHCl_3$) for 1,2,3,4-tetra-*O*-benzoyl-6-*O*-methyl-α-D-glucose (VI).

1,2-*O*-Benzylidene-α-D-glucofuranose (VII) from 1,2:3,5-Di-*O*-benzylidene-α-D-glucose (I).—A sample (0.5 g.) of palladium black catalyst was suspended in 50 ml. of ethyl acetate and saturated with hydrogen at room temperature and a pressure very slightly in excess of atmospheric. The ethyl acetate was then decanted and a solution of 2.0 g. of 1,2:3,5-di-*O*-benzylidene-α-D-glucose in 30 ml. of warm ethyl acetate added. The reduction was carried out in normal fashion and halted after 17 hr. when approximately two molar equivalents of hydrogen had been consumed. The product, which had precipitated in the course of the reaction, was removed with the catalyst and then extracted from the latter with 10 ml. of hot dioxane. Concentration of the dioxane solution gave a crystalline mass which was washed with a little water (to remove D-glucose) and dried: 0.65 g. (43%), m.p. 172–174°. Recrystallized successively from methyl ethyl ketone and from hot ethyl acetate (carbon treatment) the cyclic acetal (0.3 g.) was obtained as needles, m.p. 176–177°, $[\alpha]^{20}D$ +27.9° ($CHCl_3$, c 1) and $[\alpha]^{20}D$ +11.9° (MeOH, c 0.8). Sowden and Kuenne[9] reported m.p. 176–177° and $[\alpha]^{20}D$ +10.5° (MeOH) for 1,2-*O*-benzylidene-α-D-glucofuranose; admixture with authentic material prepared by the method of Sowden and Kuenne[9] caused no depression of melting point.

Benzoylation of a sample (0.1 g.) of our mono-*O*-benzylidene-D-glucose, prepared as described above, afforded, after recrystallization from ethanol, 0.13 g. of handsome needles melting at 112–114° either alone or in admixture with a sample of 3,5,6-tri-*O*-benzoyl-1,2-*O*-benzylidene-α-D-glucose (VIII) kindly provided by Dr. Sowden.[13] In chloroform (c 1) we found a rotation of −62.7°; the earlier authors reported $[\alpha]^{25}D$ −62.7° in this solvent.

Acknowledgments.—We wish to thank Dr. M. L. Wolfrom and Dr. J. C. Sowden for samples of products for comparison purposes. Analytical data were obtained by the Institutes' Microanalytical Laboratory under the direction of Dr. W. C. Alford.

Structure of 5-Aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose[1]

BY ROBERT SCHAFFER AND HORACE S. ISBELL

RECEIVED MARCH 6, 1957

Crystalline dimeric 5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose was shown to be bis-(5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose) 5,5′:3′,5-cyclic acetal. The following crystalline derivatives were prepared: 5′-*O*-acetyl-[bis-(5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose) 5,5′:3′,5-cyclic acetal], 3,5′-di-*O*-acetyl-[bis-(5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose) 5,5′:3′,5-cyclic acetal] and 5′-*O*-acetyl-3-*O*-mesyl-[bis-(5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose) 5,5′:3′,5-cyclic acetal]. The parent compound and the derivatives have an acetal structure at carbon 5 and a hemiacetal structure at carbon 5′. Both carbon 5 and carbon 5′ are asymmetric and four modifications of each substance are possible. The diacetate differs from the somewhat analogous diacetyl derivatives of Späth and co-workers in that it does not undergo hydrogenolysis with elimination of the hemiacetal acetate group. The two acetyl groups, however, differ in stability, in agreement with the two types of acetyl groups shown in the assigned structure.

Crystalline 5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose was prepared in this Laboratory as a raw material for the synthesis of D-glucose-6-C^{14}.[2] The substance was crystallized in the form of a hydrate from water and in the anhydrous form from benzene. The anhydrous product appears to be the same as a crystalline substance reported by Brocca and Dansi,[3] who concluded that the substance was a monomer. Molecular weight determinations reported by the present authors showed that both the hydrate and the anhydrous compound are dimers.[2] The importance of the 5-aldo-derivative for synthetic purposes and the existence of unusual chemical properties to be reported later led us to undertake a more detailed study of its structure.

By acetylation with acetic anhydride and pyridine at low temperature, Brocca and Dansi obtained from their product an amorphous material that was assumed to be 3-*O*-acetyl-5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose. In the present study a crystalline acetate was obtained by the same method. The molecular weight and analysis of this product show that it is a dimer having two acetyl groups.

The monomeric form of 5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose (I) would have a free aldehyde group. The infrared spectrum[4] of the crystalline substance, however, showed no absorption corresponding to a free aldehyde group. Hence the aldehyde group must be masked, presumably by formation of a dimer. Structures IIa and IIIa fulfill the requirements that the aldehyde groups be masked and that two hydroxyls be available for acetylation.

The 8-membered ring structure IIa is like one

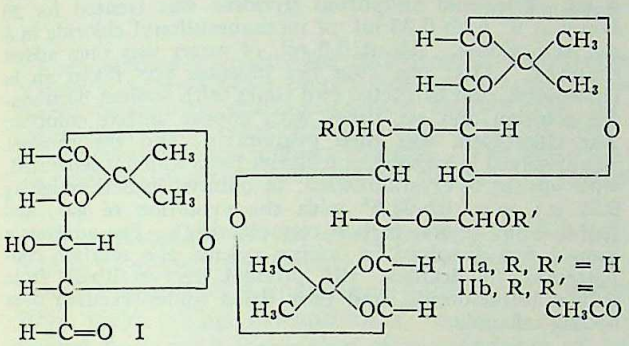
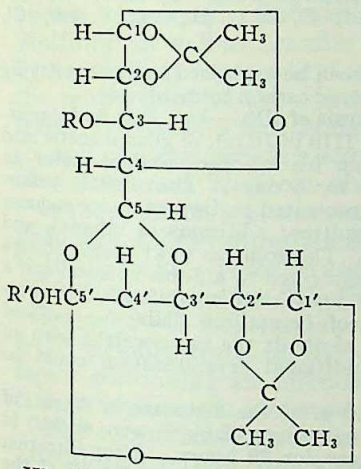
proposed by Bergmann and co-workers[5,6] for certain dimers of β-hydroxy-aldehydes. Subsequent work by Späth and co-workers,[7-9] however, established that β-hydroxy-aldehydes in general have the 6-membered ring structure IVa. Structure IIIa is of the same type, but is more restricted on account of the presence of several fused rings.

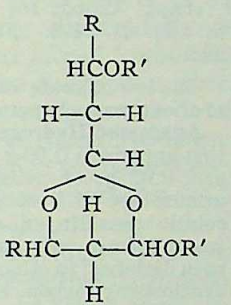


I

IIa, R, R′ = H
IIb, R, R′ = CH_3CO



IIIa, R,R′ = H
IIIb, R,R′ = CH_3CO
IIIc, R = H; R′ = CH_3CO
IIId, R = Ms; R′ = CH_3CO



IVa, R = alkyl; R′ = H
IVb, R = alkyl; R′ = CH_3CO

Späth and co-workers established structure IVa for the dimeric β-hydroxy-aldehydes by showing that the diacetyl derivatives IVb undergo hydrogenolysis with elimination of the hemiacetal acetate group to give the corresponding 1,3-dioxane derivatives in which hydrogen has been substituted for OR′ at carbon 4 of the ring.

Application of the hydrogenolysis procedure in the present case was not successful with either palladium black catalyst[10] in acetic acid or "S-palladium black."[11] It seems possible that the furanose ring fused to the 1,3-dioxane ring in IIIb, a structural feature not present in the acetylated 4-hydroxy-1,3-dioxane derivatives that undergo hydrogenolysis, constitutes a sufficient structural alteration to preclude hydrogenolysis under the conditions used.

Since the structure could not be determined by hydrogenolysis, attention was directed to other methods. Substance IIa has two hemiacetal hydroxyls and no alcoholic hydroxyl, but IIIa has one hemiacetal hydroxyl and one alcoholic hydroxyl. Aside from differences that might arise from the conformation of the 8-membered ring, the two hemiacetal hydroxyls of IIa are alike, and one would not expect the two groups to react at widely different rates, or the corresponding acetyl groups to have widely different properties.

To ascertain whether there was a difference in the reaction rates for the two hydroxyls, a sample of dimeric 5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose was acetylated for a short reaction time, and a crystalline product was isolated. The analysis and molecular weight showed that the compound is a dimer substituted with one acetyl group. Its infrared spectrum showed no aldehydic carbonyl absorption[4] and it did not react with phenylhydrazine. Hence all aldehyde groups must be blocked. With methanesulfonyl chloride the monoacetate gave a crystalline mesyl derivative. The analysis showed that the material corresponds to a dimer with one mesyl and one acetyl group. Its infrared spectrum showed no carbonyl absorption.[4] The method of preparation and the stability of the mesyl group in aqueous and alcoholic solution lead to the assignment of the mesyl group to a carbon in the alcoholic state of oxidation rather than in the hemiacetal state. This requires that the substance be IIId and the parent monoacetate be IIIc. The diacetate would then be IIIb.

To confirm the structure of the diacetate, the rate of hydrolysis of the acetyl groups was studied. The results given in the semi-log plot of Fig. 1

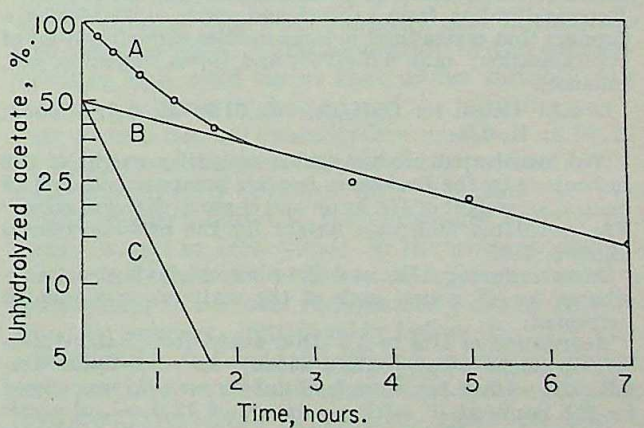

Fig. 1.—Hydrolysis of IIIb in 0.05 *N* hydrochloric acid at 80°: A, experimental curve; B, extrapolated curve for less reactive acetyl group; C, calculated curve for more reactive acetyl group.

clearly show the presence of two types of acetyl groups. The graphical analysis of the data shows that the half-time for the hydrolysis of one acetyl group is 7 or 8 times that for the other. This difference in stability is consistent with structure IIIb but is not in accord with structure IIb. Thus IIa is clearly eliminated as a possibility, and IIIa can be considered the structure of the anhydrous dimer.

Official nomenclature rules[12] are inadequate for naming the compounds but for the present the following names are suggested: IIIa is bis-(5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose) 5,5′:3′,5-cyclic acetal, IIIb is 3,5′-di-*O*-acetyl-[bis-(5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose) 5,5′:3′,5-cyclic acetal], IIIc is 5′-*O*-acetyl-[bis-(5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose) 5,5′:3′,5-cyclic acetal] and IIId is 5′-*O*-acetyl-3-*O*-mesyl-[bis-(5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose) 5,5′:3′,5-cyclic acetal].

Different configurations for carbons 5 and 5′ would give rise to four isomers. Consideration of the configuration of the present compound and the conformation of the cyclic acetal ring will be deferred for inclusion in a study of the infrared spectra now in progress.[4]

Experimental

Bis-(5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose) 5,5′:3′,5-Cyclic Acetal (IIIa).—This substance, previously called 1,2-*O*-isopropylidene-D-*xylo*-dialdo-pentofuranose, was obtained by oxidation of 1,2-*O*-isopropylidene-D-glucofuranose with sodium metaperiodate, and crystallization of the product by the method described previously.[2] The hydrate (crystallized first) was converted to the anhydrous form by crystallization from benzene.

Acetylation of IIIa to 5′-*O*-Acetyl-[bis-(5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose) 5,5′:3′,5-Cyclic Acetal] (IIIc).—One gram of finely powdered anhydrous IIIa was stirred vigorously at 0° with a mixture consisting of 5 ml. of acetic anhydride and 7 ml. of pyridine. After 8 to 10 minutes the reaction mixture was poured into 200 ml. of cracked ice. The product was extracted with chloroform. Then the chloroform solution was extracted twice with aqueous sodium bicarbonate and six times with copper sulfate solution. Finally the chloroform was evaporated, and subsequently the product was crystallized from carbon tetrachloride. The crystals, fine elongated prisms, weighed 0.54 g. and contained approximately 1.5 moles of carbon tetrachloride per mole of the product. They melted at 96–98°, solidified at 102°, and melted again at 175–176°. Recrystallization from ethanol and water (1:2) yielded a product that crystallized in large needles without solvent of crystallization; m.p. 175–176°, and $[\alpha]^{25}D$ +37.8° (*c* 0.7, ethanol).

Anal. Calcd. for $C_{18}H_{26}O_{11}$: C, 51.7; H, 6.3. Found: C, 51.3; H, 6.5.

The unsolvated product had a molecular weight of 393 in benzene by the Beckmann freezing point method, and an equivalent weight of 418 by an acetyl-group determination.[13] The calculated molecular weight for the mono-acetylated dimer is 418.

After refluxing IIIc and 2,4-dinitrophenylhydrazine in ethanol for 17 hours, each of the materials was isolated unreacted.

Acetylation of IIIa to 3,5′-Di-*O*-acetyl-[bis-(5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose) 5,5′:3′,5-Cyclic Acetal] (IIIb).—A 2.5-g. sample of anhydrous IIIa was stirred for 2.5 hours at 0° with a mixture of 12.5 ml. of acetic anhydride and 17 ml. of pyridine. The reaction mixture was poured into ice-water and extracted as described above. The chloroform was evaporated, and the residue was crystallized from ethanol. The crystals weighed 3 g. They contained 0.5 mole of ethanol per mole of dimer, and melted at 113.5–115° with the evolution of gas; $[\alpha]^{20}D$ +44.2° (*c* 2, ethanol).

Anal. Calcd. for $C_{26}H_{38}O_{12}\cdot{}^1/_2C_2H_5OH$: C, 52.1; H, 6.4. Found: C, 51.7; H, 6.4.

The molecular weight in benzene by the Beckmann freezing point method was 321. For the diacetylated dimer with one-half mole of ethanol of solvation the calculated value is 322. The equivalent weight by acetyl analysis was 251, and the calculated value is 242.

The product crystallized from carbon tetrachloride with approximately 0.5 mole of solvent per mole of dimer; m.p. 122–125°.

The unreacted diacetate was recovered unchanged after refluxing 18 hours with phenylhydrazine and with 2,4-dinitrophenylhydrazine.

Mesylation of IIIc to 5′-*O*-Acetyl-3-*O*-mesyl-[bis-(5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose) 5,5′:3′,5-Cyclic Acetal] (IIId).—A solution of 0.209 g. of IIIc and 5 ml. of ice-cold anhydrous pyridine was treated for 20 hours at 0° with 0.35 ml. of methanesulfonyl chloride in 5 ml. of pyridine. About 0.5 ml. of water was then added dropwise. After one hour the mixture was taken up in chloroform, and extracted two times with sodium bicarbonate solution and six times with copper sulfate solution. The chloroform was then evaporated, and the product was dissolved in carbon tetrachloride from which it separated, with solvent of crystallization, in pointed leaflets weighing 0.27 g.; m.p. 92–93.5° with the evolution of gas, and $[\alpha]^{20}D$ +35° (*c* 0.4, carbon tetrachloride). For analysis a sample was dissolved in boiling xylene, the solution concentrated to dryness, the product recrystallized from carbon tetrachloride, and then dried under vacuum over boiling ethanol.

Anal. Calcd. for $C_{19}H_{28}O_{13}S\cdot CCl_4$: C, 36.9; H, 4.3; S, 4.9; Cl, 21.8. Found: C, 37.1; H, 4.4; S, 4.9; Cl, 20.2.

The low chloride value can be explained by loss on drying of about ten mole per cent. of carbon tetrachloride.

Attempted Hydrogenolysis of IIIb.—In a Parr hydrogenation apparatus 0.59 g. of IIIb in 10 ml. of glacial acetic acid and 0.62 g. of palladium black[10] were shaken under an atmosphere of hydrogen for 5 days. The slightly yellow solution was filtered, concentrated to dryness under vacuum several times with intermittent additions of ethanol, and then dissolved in ethanol. This solution was filtered through decolorizing carbon, concentrated to a 2-ml. volume, and a few drops of water and some seed crystals of IIIb were added. About 0.27 g. of crystalline IIIb was isolated leaving a sirupy residue of about the same weight with an $[\alpha]^{20}D$ of +30°. No additional crystallization could be induced.

In another attempt 1.0 g. of the diacetate in 60 ml. of ethanol, and 1 g. of "S-palladium black"[11] were shaken in an atmosphere of hydrogen for 20 hours. After filtration and concentration of the solution, substantially all of the diacetate was recovered unchanged. Glacial acetic acid also was employed as solvent with the "S-palladium black" catalyst, but with the same result.

Acid Hydrolysis of the Diacetate IIIb.—Aliquots of 2 ml. of a stock solution of 0.497 g. of IIIb in 25 ml. of peroxide-free distilled dioxane were transferred to each of several test-tubes. The tubes were placed in a bath at 80 ± 1°, and 2-ml. portions of aqueous 0.1 *N* hydrochloric acid (previously heated to 80°) were added. The tubes were then fitted with reflux condensers. A series of blank samples were set up similarly using 2-ml. aliquots of a solution of 0.388 g. of IIIa in 25 ml. of dioxane and of the aqueous hydrochloric acid. Periodically a sample, or a blank, was removed, cooled in ice-water, and titrated to the phenolphthalein end-point with standard sodium hydroxide. In the blank runs acid formation in excess of the hydrochloric acid initially introduced increased uniformly with time, and amounted after three hours to about the equivalent of one-twentieth of the total hydrolyzable acetate, and to about one-tenth after seven hours. This correction served to reduce the net titers for the liberated acetyl groups at those times by only 3 and 6%, respectively. The results of the experiment are given in Fig. 1, where the curve representing the unsaponified acetate plotted against time was graphically analyzed into two linear curves showing the rates of hydrolysis for the two acetyl groups. The half-time for the rapidly split acetyl group is approximately 0.5 hour and for the slower approximate 3.5 to 4 hours.

The authors express their appreciation to R. A. Paulson and L. Tregoning of the Bureau for the microanalyses.

Reaction of Dimeric 5-Aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose with Cyanide and the Preparation of Calcium 1,2-*O*-Isopropylidene-L-idofururonate-6-C^{14} Dihydrate[1]

BY ROBERT SCHAFFER AND HORACE S. ISBELL

RECEIVED MARCH 6, 1957

A new method is reported for the separation of 1,2-*O*-isopropylidene-L-idofururonic-6-C^{14} acid from the reaction product of dimeric 5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose and C^{14}-labeled cyanide. After separation of barium 1,2-*O*-isopropylidene-D-glucofururonate-6-C^{14} hydrate from the reaction mixture, crystalline calcium 1,2-*O*-isopropylidene-L-idofururonate-6-C^{14} dihydrate was obtained in 27% yield. The combined radiochemical yield of the L-iduronic-6-C^{14} and D-glucuronic-6-C^{14} acid epimers was 85%. The high yield shows that under the conditions used the dimeric 5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose is cleaved, and the resulting monomer gives a normal cyanohydrin reaction.

By application of the cyanohydrin synthesis to 5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose, Sowden[2] obtained D-glucuronic-6-C^{14} acid in about 20% yield. The cyanohydrin reaction mixture turned dark with formation of by-products of unknown character. Subsequently Shafizadeh and Wolfrom[3] as well as Schaffer and Isbell[4] found that by controlling the acidity of the reaction mixture the proportions of the epimeric acids could be altered.[5] By use of a bicarbonate–carbon dioxide buffer and chromatographic separation of the lactones, Shafizadeh and Wolfrom obtained crystalline 1,2-*O*-isopropylidene-D-glucurono-γ-lactone in 15.5% yield and 1,2-*O*-isopropylidene-L-idurono-γ-lactone in 16.1% yield. From an acetate-buffered cyanohydrin reaction mixture Schaffer and Isbell separated barium 1,2-*O*-isopropylidene-D-glucufururonate-6-C^{14} monohydrate in 54% yield and a mother liquor containing an unknown amount of the 1,2-*O*-isopropylidene-L-idofururonic-6-C^{14} epimer.

The continued interest in this synthesis in this Laboratory derives from a program for the development of methods for the preparation of position-labeled radioactive carbohydrates,[6] and from interest in the structure and properties of the crystalline dimer of 5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose.

In the present study a crystalline salt of 1,2-*O*-isopropylidene-L-idofururonic acid was sought because this would provide not only a simple means for purifying this acid-sensitive material but would also provide a means for its quantitative determination by use of the isotope dilution technique.

It was shown previously,[4] by isotope dilution analysis, that the D-glucuronate epimer was produced in 58% yield by the cyanohydrin reaction with an acetate buffer and in 38% yield with a bisulfite buffer. In view of these results it seemed probable that with the bisulfite buffer a larger proportion of the product went to the L-iduronate epimer. For this reason a reaction product obtained from a cyanohydrin reaction buffered with sodium bisulfite was used in a search for a crystalline salt of the 1,2-*O*-isopropylidene-L-idofururonic acid. After removal of barium 1,2-*O*-isopropylidene-D-glucofururonate from the reaction mixture, crystalline calcium 1,2-*O*-isopropylidene-L-idofururonate dihydrate was prepared. The new salt crystallizes readily and provides a convenient means for separation of the iduronate epimer in a pure state. In order to utilize the salt for separation of the radioactive L-iduronate from the mother liquor of the preparation of barium 1,2-*O*-isopropylidene-D-glucofururonate-6-C^{14} hydrate it was necessary first to remove the barium acetate (by decationizing and freeze-drying), and the residual barium 1,2-*O*-isopropylidene-D-glucofururonate-6-C^{14} hydrate (by crystallization). Barium in the purified mother liquor was replaced by calcium, and calcium 1,2-*O*-isopropylidene-L-idofururonate-6-C^{14} dihydrate was separated in a radiochemical yield of 27%.[7] The combined yield of the D-glucuronate and L-iduronate epimers was 85%. The separation of the epimeric acids in high yield shows that under suitable conditions the dimer is cleaved and the resulting monomer gives a normal cyanohydrin reaction.

By isotope dilution analysis of the product from a bisulfite-buffered cyanohydrin reaction it was found earlier[4] that the D-glucuronate epimer had been formed in 38% yield; in the present study it was found that the L-iduronate epimer formed in 34% yield. The total radioactive yield of 72% for the two epimers, considerably below the 85% yield obtained in the acetate-buffered reaction, shows a substantial loss of labeled cyanide in the bisulfite-buffered reaction. A greater yield of the L-iduronate epimer (at the expense of the D-glucuronate) can be expected for more alkaline buffered systems, but the limit of alkalinity for an optimum yield of L-iduronate is restricted by the alkali-sensitivity of the 5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose. The behavior of this substance in alkaline solution is being studied and will be treated in a future publication.

Experimental Procedure

Calcium 1,2-*O*-Isopropylidene-L-idofururonate Dihydrate.—An aqueous solution of 12.54 g. of 5-aldo-1,2-*O*-isopropyli-

dene-D-*xylo*-pentofuranose, 12.65 g. of sodium pyrosulfite and 3.4 g. of sodium cyanide was prepared at 0°, and allowed to warm to room temperature. After three days the solution was heated at 90° for one hour, then treated with 7 g. of sodium carbonate, and refluxed for three hours. The solution was cooled in an ice-bath, and passed through a column containing 350 ml. of cation exchange resin[8] at ice temperature. The effluent, including washings, was delivered into a flask immersed in an ice-bath, containing 41.6 g. of barium hydroxide octahydrate. After removal of excess barium hydroxide by carbonation and filtration, one-tenth of the filtrate was set aside for analysis by an isotope dilution technique. The remainder of the solution was concentrated under vacuum to a sirup that yielded 7.77 g. of crude crystalline barium 1,2-*O*-isopropylidene-D-glucofururonate monohydrate. After removal of the barium salt, the mother liquor was passed through a column containing 75 ml. of cation exchange resin[8] at ice temperature. The effluent, including washings, was delivered into a flask containing 5 g. of calcium carbonate. The mixture was filtered, and the filtrate concentrated under vacuum. Calcium 1,2-*O*-isopropylidene-L-idofururonate-6-C^{14} dihydrate separated. The product, 4.2 g., was recrystallized from water with the addition of methanol.

Anal. Calcd. for Ca $C_{18}H_{26}O_{14}\cdot 2H_2O$: C, 39.8; H, 5.6; Ca, 7.4. Found: C, 39.8; H, 5.8; Ca, 7.2; $[\alpha]_D^{29}$ −11.8° (*c* 3, water).

Preparation of Calcium 1,2-*O*-Isopropylidene-L-idofururonate-6-C^{14} Dihydrate.—The original synthesis began with 0.005 mole of sodium cyanide-C^{14} (12.5 millicuries) and 1.11 g. of 5-aldo-1,2-*O*-isopropylidene-D-*xylo*-pentofuranose buffered with 0.005 mole of sodium hydroxide and 0.02 mole of acetic acid. The mother liquor that remained after separation of 6.75 millicuries of barium 1,2-*O*-isopropylidene-D-glucofururonate-6-C^{14} monohydrate from the cyanohydrin synthesis previously reported had been set aside for approximately two years before the work reported here was resumed.

The mother liquor was dissolved in 100 ml. of water, treated with 700 ml. of ethanol, and passed through a carbon-coated filter. Under vacuum the filtrate was concentrated to a 50-ml. volume. The concentrate was passed, ice-cold, into a column containing 30 ml. of cation exchange resin,[8] washed through with ice-water, and collected in a flask containing 0.3 g. of barium carbonate. The partially neutralized effluent was freeze-dried to remove the acetic acid present. Addition of methanol to an aqueous solution of the residue yielded 0.18 g. of crude barium 1,2-*O*-isopropylidene-D-glucuronate-6-C^{14} monohydrate.

The purified mother liquor was diluted with ice-water and passed through a column of 12 ml. of ice-cold cation exchange resin[8] into a flask containing 0.13 g. of calcium carbonate. Concentration of the solution under vacuum yielded calcium 1,2-*O*-isopropylidene-L-idofururonate-6-C^{14} dihydrate, which was separated and washed with a mixture of ethanol and water (6:1). Recrystallization from water and ethanol yielded 2.81 millicuries of the salt. By use of non-radioactive carrier, an additional 0.53 millicurie of this product was obtained. The radiochemical yield based on the 12.5 millicuries of cyanide-C^{14} originally used was 27%.

Yield of the L-Iduronate Epimer in a Bisulfite-buffered Cyanohydrin Reaction.—The portion of the solution from the preparation of non-radioactive calcium 1,2-*O*-isopropylidene-L-idofururonate dihydrate kept for the isotope dilution analysis was diluted with a tracer consisting of 95.2 microcuries of calcium 1,2-*O*-isopropylidene-L-idofururonate-6-C^{14} dihydrate (10.68 mg.). After separation of the D-glucuronate epimer as the barium salt, the solution was passed through 15 ml. of cation exchange resin[8] into a flask containing 0.75 g. of calcium carbonate. The excess calcium carbonate was removed, and the calcium salt was crystallized as already described. After two recrystallizations, the air-dried salt had a specific radioactivity of 0.151 μc./mg. This activity corresponds to dilution of the tracer by 620 mg. of calcium 1,2-*O*-isopropylidene-L-idofururonate dihydrate or a 34.3% yield of this substance from the cyanohydrin reaction.

Radioactivity Measurements.—Determinations of C^{14} were made by direct count of the materials in formamide or aqueous formamide solutions.[9] Samples were counted to a probable error of 1%, and the results converted to microcuries by a factor based on the C^{14}-standard issued by the National Bureau of Standards.

The authors express their appreciation to R. A. Paulson and L. Tregoning for the microanalyses.

Acyl Migration in the D-Galactose Structure

BY M. L. WOLFROM, A. THOMPSON[1] AND M. INATOME[1]

RECEIVED JANUARY 17, 1957

When 2,3,4-tri-*O*-acetyl-1,6-anhydro-β-D-galactose is treated successively with titanium tetrachloride and mercuric acetate, there are obtained two crystalline tetraacetates of D-galactose. The one (isomer A) is convertible to the other (isomer B) by traces of alkali. Both are convertible to β-D-galactopyranose pentaacetate on mild acetylation. Isomers A and B are resistant toward triphenylmethylation. Isomer A yields a *p*-toluenesulfonate which in turn forms a methyl tri-*O*-acetyl-*O*-*p*-toluenesulfonyl-β-D-galactopyranoside, both of which derivatives are different from known isomers believed to have the *p*-toluenesulfonyl group in the sixth position. Both isomers A and B yield tetra-*O*-acetyl-3-*O*-methyl-β-D-galactopyranose on methylation. Positions 2, 3 or 4 are assignable for the open hydroxyl group in each of the two D-galactopyranose tetraacetates, but the present evidence disallows definite allocations.

No tetraacetate of D-galactose is known in which the terminal primary hydroxyl group is unsubstituted. An attempt to prepare such a derivative by a procedure suitable for the synthesis of the analogous D-glucose structure, led to a crystalline D-galactose tetraacetate, m.p. 138–138.5°, $[\alpha]_D$ +37° (chloroform), herein designated isomer A.[2] This substance was considered to have its position six substituted by an acetate group since it was recovered unchanged on treatment with triphenylmethyl chloride and pyridine.[2] Isomer A had been prepared[2] by the successive action of titanium tetrachloride and mercuric acetate on 2,3,4-tri-*O*-acetyl-1,6-anhydro-β-D-galactopyranose. A second isomer has now been isolated, by chromatographic techniques, from the same reaction mixture. The substance, m.p. 140–141.5°, $[\alpha]_D$ +25.5° (chloroform), designated isomer B, possesses essentially the same melting point as isomer A but the mixed

melting point exhibits a marked depression; rotations and crystal X-ray powder diffraction data are different.

Isomer A is convertible to isomer B by traces of alkali, statements to the contrary[2] being in error. Mild acetylation of both isomers yielded β-D-galactopyranose pentaacetate. Methylation of either resulted in a crystalline monomethyl ether without acetyl loss, and this on deacetylation afforded 3-*O*-methyl-α-D-galactose[3] of established structure. Esterification of isomer B with *p*-toluenesulfonic acid failed to yield a crystalline product but like treatment of isomer A did. This tetra-*O*-acetyl-*O*-*p*-toluenesulfonyl-β-D-galactopyranose was converted to methyl tri-*O*-acetyl-*O*-*p*-toluenesulfonyl-β-D-galactopyranoside through its glycosyl bromide derivative.

While the complete structures of the isomeric D-galactose tetraacetates A and B cannot be established on the basis of the present evidence, some data may be advanced as to their partial structures. Their rotatory powers, method of synthesis and ease of conversion to β-D-galactopyranose pentaacetate would indicate that both contain the pyranose ring and possess an acetate group on carbon one in the β-D-anomeric form. Acyl migrations are catalyzed by both acids and bases and the direction of acyl movement is considered to favor a shift from a secondary to a primary hydroxyl group.[4,5]

Both isomers were resistant to etherification with triphenylmethyl chloride. It is accordingly probable that carbon six is acetylated in both tetraacetates. This conclusion is supported by the nature of the *p*-toluenesulfonate derivative of isomer A. This substance did not react with sodium iodide in acetonylacetone as a primary *p*-toluenesulfonate should, and it was not identical with either of the two known forms of tetra-*O*-acetyl-6-*O*-*p*-toluenesulfonyl-β-D-galactose recorded by Ohle and Thiel[6] (Table I). These workers acetylated the two anomeric forms of D-galactopyranose 6-*p*-toluenesulfonate, prepared in turn from 1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose. There is no established case of *p*-toluenesulfonyl migration, and it is believed that this group, possessing no function quite analogous to a carbonyl, does not migrate. In the case of the β-D-anomer, Ohle and Thiel obtained two products which they considered to be ring isomers. If the *p*-toluenesulfonate group in our isomer A was on position 6, it should have been identical with one of the two ring forms of the β-D-derivatives of Ohle and Thiel. Since this is not the case, position 6 must be occupied by an acetyl group in the *p*-toluenesulfonate ester of isomer A. This conclusion is supported by the fact that the methyl β-D-glycoside of the *p*-toluenesulfonate is not identical with the recorded anomeric forms of methyl tri-*O*-acetyl-6-*O*-*p*-toluenesulfonyl-D-galactopyranoside (Table II).

TABLE I

ISOMERIC FORMS OF TETRA-*O*-ACETYL-*O*-*p*-TOLUENESULFONYL-D-GALACTOSE

Tetra-*O*-acetyl-	M.p., °C.	$[\alpha]^{20\pm5}D$, $CHCl_3$, $c < 5$	Reference
O-*p*-Toluenesulfonyl-β-D-galactopyranose (from isomer A)	154–155	+43°	This work
6-*O*-*p*-Toluenesulfonyl-α-D-galactose	117	+89	6
6-*O*-*p*-Toluenesulfonyl-β-D-galactose, ring isomer 1	126–127	+ 9.3	6
6-*O*-*p*-Toluenesulfonyl-β-D-galactose, ring isomer 2	147	+16	6

TABLE II

ISOMERIC FORMS OF METHYL TRI-*O*-ACETYL-*O*-*p*-TOLUENESULFONYL-D-GALACTOPYRANOSIDE

Methyl tri-*O*-acetyl-	M.p., °C.	$[\alpha]^{20\pm5}D$, $CHCl_3$, $c < 5$	Reference
O-*p*-Toluenesulfonyl-β-D-galactopyranoside (from isomer A)	129–130	+25°	This work
6-*O*-*p*-Toluenesulfonyl-β-D-galactopyranoside	Sirup	*ca.* +2.5	7
	Sirup	−3	8
6-*O*-*p*-Toluenesulfonyl-α-D-galactopyranoside	128	+102	6

The *p*-toluenesulfonate ester of isomer B failed to crystallize but was obviously different from the corresponding derivative of isomer A. On the other hand, 3-*O*-methyl-α-D-galactose was obtained from both isomers on methylation and deacetylation.

The following reaction is established.

$$A \xrightarrow{\text{Base}} B$$

Thus, isomer B is the more stable form.

2,3,4-Tri-*O*-acetyl-α-D-galactopyranosyl chloride has been prepared in crystalline form by Zemplén, Gerecs and Flesch[9] and was utilized by them

in their synthesis of robinobiose, 6-*O*-β-L-rhamnopyranosyl-D-galactose. Thus, the *O*-acylglycosyl chloride must have its terminal primary hydroxyl group unsubstituted. Isomer A was obtained by us on reaction of this halide with mercuric acetate in acetic acid solution. It is then probable that an acetyl shift occurred in this replacement reaction.

The collective evidence then would appear to establish the presence of acetate groups on positions 1 and 6 of the β-D-galactopyranose ring structure, but an assignment of the remaining two acetate groups on positions 2, 3 and 4 in the two isomeric tetraacetates cannot be made on the basis of the present evidence.

Experimental[10]

Isomer A from 2,3,4-Tri-*O*-acetyl-α-D-galactopyranosyl Chloride.—An amount of 1.7 g. of 2,3,4-tri-*O*-acetyl-α-D-galactopyranosyl chloride[9] (m.p. 134°) was dissolved in 25 ml. of acetic acid containing 4 g. of mercuric acetate and allowed to stand for 1 hr. Isomer A was isolated from the reaction mixture by the procedure described previously[2]; yield 1.2 g., m.p. 133–135°. Pure material was obtained on crystallization from chloroform–ether; m.p. 140–140.5° undepressed on admixture with an authentic specimen of isomer A.

β-D-Galactopyranose Tetraacetate (Isomer B).—The sirup from the concentration of the mother liquors obtained in the preparation[2] of isomer A, from 7.8 g. of tri-*O*-acetyl-1,6-anhydro-β-D-galactopyranose, was chromatographed, following the general directions of McNeely, Binkley and Wolfrom.[11] The sirup (4.7 g.) was dissolved in a small amount of benzene and placed on a Magnesol[12]–Celite[13] (5:1 by wt.) column (250 × 75 mm., diam.) using 3500 ml. of benzene–*t*-butyl alcohol (100:1 by vol.) as the developer. After the column was extruded and streaked with indicator (1% potassium permanganate in 10% sodium hydroxide), two zones appeared. They were numbered from the bottom to the top of the column.

Zone I, located 125–155 mm. from the top, was eluted with acetone, evaporated to a sirup under reduced pressure and the residue was crystallized from an ether–petroleum ether (b.p. 30–60°) solution; yield 640 mg., m.p. 70–73°, unchanged on admixture with 2,3,4-tri-*O*-acetyl-1,6-anhydro-β-D-galactopyranose.

Zone II, located 24–75 mm. from the top, was eluted with acetone, the eluate evaporated to a sirup and crystallized from ether; yield 0.37 g., m.p. 138–141°. Pure β-D-galactopyranose tetraacetate (isomer B) was obtained on further recrystallization from ether; m.p. 140–141.5° depressed to 116–122° on admixture with isomer A of m.p. 138–138.5°, $[\alpha]^{32}D$ +25.5° (*c* 2.94, chloroform); X-ray powder diffraction data: 9.77[14] vs,[15] 7.76m, 5.55vw, 4.99vs, 4.60w, 4.36m, 4.21s, 3.82m, 3.69s, 3.56m, 3.40m, 3.27m.

Anal. Calcd. for $C_6H_8O_6(CH_3CO)_4$: C, 48.27; H, 5.79; CH_3CO, 11.48 ml. of 0.1 *N* NaOH per 100 mg. Found: C, 48.40; H, 5.76; CH_3CO, 11.65 ml.

The substance was recovered unchanged after treatment with pyridine and triphenylmethyl chloride.

Conversion of Isomer A to Isomer B by Alkali.—Following the general directions of Helferich and Klein,[16] 0.2 g. of isomer A was shaken for 1 hr. in 20 ml. of 0.001 *N* sodium hydroxide whereupon the solution was extracted with chloroform. The sirup obtained on solvent removal, under reduced pressure, from the dried chloroform extract, was dissolved in ether and crystallization ensued on seeding with isomer B; yield 10 mg., m.p. 138–141° unchanged on admixture with isomer B and depressed to 115–120° on admixture with isomer A, X-ray powder diffraction lines identical with those of isomer B.

The isomer B was obtained in better yield when 0.1 g. of isomer A was shaken for 3.5 hr. with 10 ml. of water and 0.2 g. of Amberlite IR-4B.[17] The resin was removed by filtration and the aqueous solution was extracted with chloroform. The sirup obtained on solvent removal, under reduced pressure, from the dried extract, was crystallized from ether; yield 70 mg., m.p. 140–141.5° unchanged on admixture with isomer B and depressed to 114–125° on admixture with isomer A.

Conversion of Isomers A and B to β-D-Galactopyranose Pentaacetate.—An amount of 100 mg. of isomer A was treated for 18 hr. at 0° with acetic anhydride (1 ml.) and pyridine (2 ml.). The reaction was completed on being maintained at room temperature for 12 hr. The crystalline product that formed on pouring the reaction mixture into ice and water was removed by filtration and recrystallized from ethanol; yield 100 mg., m.p. 137–139° unchanged on admixture with authentic β-D-galactopyranose pentaacetate; X-ray powder diffraction data[14,15] (identical with that of authentic material): 12.93vw, 8.10m, 6.93s, 6.18s, 5.62w, 5.06m, 4.28m, 4.00vs, 3.83s, 3.66vw, 3.42vw, 3.29vw, 3.17vw, 3.08w, 3.03w, 2.94vw, 2.87w, 2.81vw, 2.72vw.

β-D-Galactopyranose pentaacetate was likewise identified on the acetylation of isomer B effected in the same manner.

1,2,4,6-Tetra-*O*-acetyl-3-*O*-methyl-β-D-galactose.—The general procedure of Haworth, Hirst and Teece[18] was followed. An amount of 1.0 g. of isomer A, 50 ml. of methyl iodide and 7 g. of silver oxide was maintained at 50–60° under reflux for 5 hr. Ether was then added and the mixture was filtered. The filtrate was concentrated under reduced pressure and the resultant sirup was crystallized from ether; yield 400 mg., m.p. 118–120°. Recrystallization from ethanol gave pure 1,2,4,6-tetra-*O*-acetyl-3-*O*-methyl-β-D-galactose, m.p. 119–120°, mixed m.p. with isomer A 105–111°, $[\alpha]^{25}D$ +41° (*c* 3, chloroform); X-ray powder diffraction data[14,15]: 10.72s, 8.93m, 7.53m, 6.99m, 6.60vw, 6.23m, 5.53m, 5.13w, 4.93w, 4.44s, 3.97m, 3.90m, 3.69m, 3.46m.

Anal. Calcd. for $C_6H_7O_5(CH_3CO)_4(OCH_3)$: C, 49.71; H, 6.12; OCH_3, 8.57; CH_3CO, 11.00 ml. of 0.1 *N* NaOH per 100 mg. Found: C, 49.70; H, 6.01; OCH_3, 8.61; CH_3CO, 11.01 ml.

Methylation of Isomer B.—The general procedure of Richtmyer and Hudson[19] was followed. An amount of 400 mg. of isomer B, 5 g. of silver oxide and 25 ml. of methyl iodide were shaken in a closed flask for 3 hr. at room temperature. The product was processed in a manner similar to that described for the methylation of isomer A. Crystals were obtained from an ethanolic solution; yield 70 mg., m.p. 119–120° unchanged on admixture with 1,2,4,6-tetra-*O*-acetyl-3-*O*-methyl-β-D-galactoside, the methylation product of isomer A. The X-ray powder diffraction patterns of crystals from the two sources were identical.

3-*O*-Methyl-α-D-galactose.—The 1,2,4,6-tetra-*O*-acetyl-3-*O*-methyl-β-D-galactose was deacetylated by an adaptation of the method of Zemplén and Pacsu.[20] An amount of 500 mg. of the substance was dissolved, under exclusion of moisture, in 10 ml. of dry methanol, and 1.5 ml. of a sodium methoxide solution, prepared by treating 500 mg. of sodium with 100 ml. of methanol, was added. After 30 min., 50 ml. of water was added and the solution was passed successively over Amberlite IR-120[17] and Duolite A-4.[21] The neutral, aqueous solution was concentrated under reduced pressure, and the resultant sirup was crystallized from methanol by seeding with 3-*O*-methyl-α-D-galactose[22]; yield 100 mg., m.p. 146–148° (recorded[3] 144–147°) unchanged on admixture with an authentic specimen of 3-*O*-

methyl-α-D-galactose; X-ray powder diffraction data[14,15] (identical with those of authentic 3-*O*-methyl-α-D-galactose): 8.85m, 6.93s, 5.74s, 4.98w, 4.56vs, 3.90vw, 3.76s, 3.62vw, 3.49m, 3.39s, 3.31m, 2.88w, 2.83w, 2.66m, 2.41w, 2.32w, 2.26w.

Tetra-*O*-acetyl-*O*-*p*-toluenesulfonyl-β-D-galactopyranose from Isomer A.—The general experimental procedure followed was that of Helferich and Klein.[16] An amount of 500 mg. of isomer A was treated with 200 mg. of *p*-toluenesulfonyl chloride in 3 ml. of dry pyridine. After 24 hr., the mixture was poured into ice and water. The precipitate that formed was filtered and dissolved in ethanol. Crystals appeared upon concentration of the solution; yield 500 mg., m.p. 153–155°. The product was recrystallized from an acetone–ether–petroleum ether (b.p. 30–60°) mixture; m.p. 154–155°, $[\alpha]^{25}D$ +43° (*c* 3, chloroform); X-ray powder diffraction data[14,15]: 10.52s, 8.44vw, 5.72m, 5.31w, 4.76w, 4.48m, 4.19vw, 4.00vw, 3.53w, 3.45m, 3.14w.

Anal. Calcd. for $C_{21}H_{26}O_{12}S$: C, 50.19; H, 5.21; S, 6.38. Found: C, 50.10; H, 5.30; S, 6.33.

Similar treatment of isomer B with *p*-toluenesulfonyl chloride and pyridine failed to yield a crystalline product.

The *p*-toluenesulfonate (150 mg.) from isomer A yielded a negligible precipitate (5 mg.) of sodium *p*-toluenesulfonate on heating at 100° with 70 mg. (1.5 molar ratio) of sodium iodide in 3 ml. of acetonylacetone for 48 hr. A like experiment utilizing 400 mg. of tetra-*O*-acetyl-6-*O*-*p*-toluenesulfonyl-β-D-glucopyranose, 180 mg. of sodium iodide and 8 ml. of acetonylacetone yielded 141.2 mg. (88%) of sodium *p*-toluenesulfonate.

Methyl Tri-*O*-acetyl-*O*-*p*-toluenesulfonyl-β-D-galactopyranoside from Isomer A.—The general procedure of Haworth, Jackson and Smith[7] was followed. An amount of 500 mg. of tetra-*O*-acetyl-*O*-*p*-toluenesulfonyl-β-D-galactopyranose (from isomer A) was treated for 1 hr. with 5 ml. of a solution containing 30% hydrogen bromide in anhydrous acetic acid:acetic anhydride (1:1 by vol.). Chloroform was then added to the solution and the extract was washed four times with water and dried over sodium sulfate. The dried solution was concentrated under reduced pressure, and the resulting sirup was dissolved in 25 ml. of dry methanol, and 10 g. of freshly prepared silver carbonate was added. The mixture was shaken for 5.5 hr. whereupon it was filtered, and the filtrate was concentrated under reduced pressure. Crystals of the methyl tri-*O*-acetyl-*O*-*p*-toluenesulfonyl-β-D-galactopyranoside appeared during the concentration; yield 240 mg., m.p. 129–130°, $[\alpha]^{25}D$ +24° (*c* 3, chloroform); X-ray powder diffraction data[14,15]: 9.77vs, 6.20w, 5.84m, 5.24s, 4.88m, 4.46w, 4.23w, 4.01s, 3.79vw, 3.65m, 3.51m, 3.37m.

Anal. Calcd. for $C_{20}H_{26}O_{11}S$: C, 50.62; H, 5.52; S, 6.77. Found: C, 50.42; H, 5.71; S, 6.67.

Deuterium-isotope Effects in the Autoxidation of Aralkyl Hydrocarbons. Mechanism of the Interaction of Peroxy Radicals[1]

BY GLEN A. RUSSELL

RECEIVED FEBRUARY 1, 1957

α-Phenethylperoxy radicals interact to form non-radical products 1.9 times as readily as their α-deutero derivatives. This is taken as evidence that the termination reaction is $2C_6H_5CH(D)CH_3COO\cdot \rightarrow C_6H_5COCH_3 + C_6H_5CH(D)OH(D)-CH_3 + O_2$. Yields of hydroperoxide and acetophenone produced in the autoxidation of ethylbenzene at various kinetic chain lengths are consistent with the indicated termination reaction. Evidence is presented that this reaction involves a cyclic transition state and excluding an alternate process proceeding by the formation and disproportionation of alkoxy radicals. The deuterium-isotope effect in the reaction of a peroxy radical with cumene and α-*d*-cumene is $k_H/k_D = 5.5$. The magnitudes of deuterium-isotope effects in the reactions of atoms and radicals with carbon–hydrogen and carbon–deuterium bonds are considered. Reactivities of the attacking atoms or radicals and polar effects in the reaction are discussed.

Despite the fact that the autoxidation of hydrocarbons has been studied intensively,[2] evidence is lacking as to the mechanism and products of the reaction wherein two peroxy radicals are converted to non-radical products. We have, therefore, investigated the products of this termination reaction in the oxidation of ethylbenzene and have demonstrated its detailed mechanism by a study of deuterium-isotope effects. The deuterium-isotope effect in the reaction of a peroxy radical with α-*d*-cumene has been measured, and its magnitude confirms our earlier conclusions in regard to the extent of bond-breaking in the transition state for this reaction.

Results

Autoxidations of cumene, ethylbenzene and various deuterated derivatives were performed at 60° in the liquid phase in the presence of α,α′-azodiisobutyronitrile (AIBN). The rates of oxidation were independent of the oxygen pressure over the range 200–760 mm. indicating that only peroxy radicals were involved in the termination reaction.[2] The kinetics of the reaction under these conditions indicate that the following sequence of events is involved.

$$\text{AIBN} \xrightarrow{k_d} (CH_3)_2\dot{C}CN \xrightarrow{O_2} \text{ROO}\cdot \ (\text{Rate} = R_i)$$

$$\text{ROO}\cdot + \text{RH} \xrightarrow{k_3} \text{ROOH} + \text{R}\cdot$$

$$\text{R}\cdot + O_2 \xrightarrow{\text{fast}} \text{ROO}\cdot$$

$$2\text{ROO}\cdot \xrightarrow{k_6} \text{non-radical products} + O_2$$

Under steady-state conditions the rate of oxygen consumption is calculated to be

$$-d[O_2]/dt = k_3[RH](R_i)^{1/2}/(2k_6)^{1/2} + R_i/2 \quad (1)$$

The rate of initiation, R_i, is equal to $2k_d e[AIBN]^{1/2}$ where *e* represents the fraction of catalyst molecules that produce two free radicals. In Table I the rates of oxidation of cumene and ethylbenzene are presented as a function of hydrocarbon concentration, AIBN concentration and oxygen pressure. The data of column 6 indicate that (1) is obeyed and the rate of oxidation is independent of

the oxygen pressure and proportional to $k(R_i)^{1/2} + R_i/2$. The value of R_i used in the above calculations for 0.1 M AIBN has been taken as 1.38×10^{-6} mole l.$^{-1}$ sec.$^{-1}$ based on a value of 1.15×10^{-5} sec.$^{-1}$ for k_d at 60° and 0.60 for e. The value of k_d in an aromatic solvent was selected from a compilation of various literature references[3,4] while the value of e appears established from the work of Hammond, Sen and Boozer.[5]

Having thus established the course of the reaction, the deuterium-isotope effect in the slow propagation step (k_3) was investigated. α-Deuterocumene was prepared by the reaction of deuterium chloride with α,α-dimethylbenzylpotassium. Analysis by high resolution nuclear magnetic resonance spectroscopy indicated that 58.4% of the tertiary hydrogen atoms of cumene had been replaced by deuterium atoms. Aromatic deuterium atoms were present (0.24 atom/molecule) in the form of d_1-, d_2- and d_3-cumenes, but analysis by high resolution infrared absorption indicated that less than 3% of the molecules contained a β-deuterium atom.

This sample of α-d-cumene oxidized considerably less rapidly than cumene, even though 41.6% of the molecules had an α-hydrogen atom. Since, in the presence of 0.1 M AIBN, cumene was oxidized at a rate of 2.58×10^{-5} mole l.$^{-1}$ sec.$^{-1}$ and α-d-cumene (58.4% pure) at a rate of 1.38×10^{-5} mole l.$^{-1}$ sec.$^{-1}$, it can be calculated that in the slow propagation reaction the deuterium-isotope effect is $k_H/k_D = 5.5$. Based on possible errors in analysis, the isotope effect might be as low as 4.5 and as high as 7.2.

$$ROO\cdot + RH \xrightarrow{k_H} ROOH + R\cdot$$

$$ROO\cdot + RD \xrightarrow{k_D} ROOD + R\cdot$$

$$k_H/k_D = 5.5$$

There can be no deuterium-isotope effect in the termination reaction in the oxidation of α-d-cumene since both cumene and α-d-cumene yield the same α,α-dimethylbenzylperoxy radical.

The data of Table II demonstrate that the yields of hydroperoxide in the autoxidations of cumene and α-d-cumene were essentially quantitative irrespective of kinetic chain length (molecules oxidized per initiating fragment). This supports the conclusion of Boozer[6] that the interaction of cumylperoxy radicals should be formulated

$$2C_6H_5C(CH_3)_2OO\cdot \longrightarrow C_6H_5C(CH_3)_2OOH + C_6H_5CCH_3{=}CH_2 + O_2$$

The yield of hydroperoxide in the oxidation of ethylbenzene was neither quantitative nor independent of kinetic chain lengths (see Table II). The yield of hydroperoxide decreased with decreasing kinetic chain length suggesting that oxygen-containing non-peroxidic products were formed in the termination reaction. In the oxidation of ethylbenzene, under the conditions specified in Table II, an average of 4.2 molecules of oxygen were absorbed per initiating radical. If the termination reaction between two α-phenethylperoxy radical yields one molecule of oxygen and one molecule of oxygen combined in non-peroxidic products, the theoretical yield of hydroperoxide, based on oxygen absorbed, is 88%. The observed yield was 85%. In the oxidation of d_4-ethylbenzene (prepared by the addition of deuterium to phenylacetylene) the kinetic chain length was only 2.0 and the yield of hydroperoxide was 65%. The theoretical yield calculated on the basis of a termination reaction yielding a molecule of oxygen and a molecule of oxygen combined in non-peroxidic products is 75%.

A possible termination reaction, consistent with the above observations, is

$$2C_6H_5CHCH_3OO\cdot \longrightarrow C_6H_5COCH_3 + C_6H_5CHOHCH_3 + O_2$$

Hydroxylic and ketonic products are generally formed in small amounts in low-temperature autoxidations, but these products may represent only the decomposition of some of the initially formed hydroperoxide. However, the formation of exactly one mole of acetophenone per two kinetic chains would give considerable support to the above termination reaction. The oxidates of α-d_1-ethyl-

(3) The following data were used: F. M. Lewis and M. S. Matheson, THIS JOURNAL, **71**, 747 (1949); 80°, xylene, 1.53×10^{-4} sec.$^{-1}$; 70°, xylene, 4.16×10^{-5} (unpublished); 90°, xylene, 5.0×10^{-4} (unpublished); L. M. Arnett, *ibid.*, **74**, 2027 (1952), 77°, xylene, 9.5×10^{-5}; 82°, xylene, 1.45×10^{-4}; M. Talat-Erben and S. Bywater, *ibid.*, **77**, 3712 (1955), 70°, toluene, 4.0×10^{-5}; 80.4°, toluene, 1.55×10^{-4}; 90°, toluene, 4.86×10^{-4}; 100°, toluene, 1.6×10^{-3}; G. S. Hammond, J. N. Sen and C. E. Boozer, ref. 5, 62.5°, benzene, 1.42×10^{-5}; 62.5°, chlorobenzene, 1.54×10^{-5}; C. G. Overberger, M. T. O'Shaughnessy and H. Shalit, *ibid.*, **71**, 2661 (1949), 69.8°, toluene, 3.8×10^{-5}; 80.2°, toluene, 1.66×10^{-4}; G. A. Russell, *ibid.*, **78**, 1044 (1956), 80°, cumene, 1.67×10^{-4}; J. C. Roy, J. R. Nash, R. R. Williams, Jr., and W. H. Hamill, *ibid.*, **78**, 519 (1956), 80°, chlorobenzene, 1.50×10^{-4}; J. W. Breitenbach and A. Schindler, *Monatsh. Chem.*, **83**, 724 (1952), 50°, styrene, 2.97×10^{-5}; 70°, styrene, 4.72×10^{-5}. These data yield the expression $k_d = 1.78 \times 10^{15} \exp(-31,300/RT)$ with serious deviation for the 82° point of Arnett only. Interestingly, the decomposition rates of C. E. H. Bawn and S. H. Mellish [*Trans. Faraday Soc.*, **47**, 1216 (1951)], obtained by use of diphenylpicrylhydrazyl, which supposedly is a measure of $k_d e$,[4,5] are in excellent agreement with this rate expression over the range 40–70°. Decomposition rate constants in nitrobenzene solution are consistently higher. The data of Hammond, ref. 5, 1.79×10^{-5} sec.$^{-1}$ at 62.5°, and of K. Ziegler, W. Deparade and W. Meye [*Ann.*, **567**, 141 (1950)], 2.0×10^{-4} at 80°, 2.25×10^{-3} at 100°, give the expression $k_d = 4.9 \times 10^{15} \exp(-31,200/RT)$.

benzene and d_4-ethylbenzene were therefore analyzed for carbonyl content by infrared absorption. In the oxidation of d_4-ethylbenzene the kinetic chain length was only 2. Therefore, three molecules of hydroperoxide and one molecule each of acetophenone and α-phenethanol were expected per pair of initiating radicals formed. Of the total oxygen absorption of 0.64×10^{-3} mole, $^1/_8$ should be present as acetophenone if the suggested termination reaction occurs. By analysis 0.13×10^{-3} mole of acetophenone was found which is in fair agreement with the theoretical value of 0.16 $(2 \times 0.64/8) \times 10^{-3}$ mole. Based on a kinetic chain length of 3.4, 0.135×10^{-3} mole of acetophenone was expected in the oxidation of α-d_1-ethylbenzene wherein 0.915×10^{-3} mole of oxygen was consumed. The observation that 0.13×10^{-3} mole of acetophenone was formed lends strong support to the suggested termination reaction.

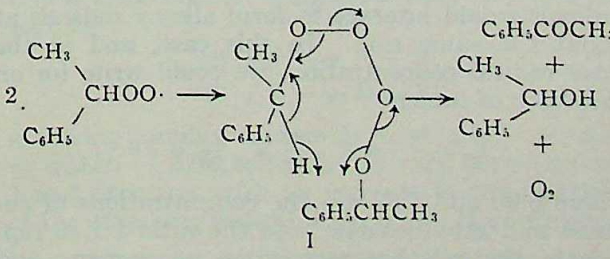
The mechanism of this termination reaction was investigated further by a study of deuterium-isotope effects in the oxidation of ethylbenzene. If there were no deuterium-isotope effect in the termination reaction of α-deutero-α-phenethylperoxy radicals, the ratio of $k_3/k_6^{1/2}$ for the oxidations of ethylbenzene and α-d_1-ethylbenzene[7] should be 1:0.60 provided that the deuterium-isotope effect in the propagation reaction is $k_H/k_D = 5.5$. The observed ratio was 1:0.78. This ratio would be consistent with a termination reaction involving no isotope effect only if the deuterium-isotope effect in the propagation reaction (k_3) was $k_H/k_D = 1.8$. This isotope effect is so inconsistent with the isotope effect of 5.5 determined in the oxidation of cumene that there must be a deuterium-isotope effect in the termination reaction of α-deutero-α-phenethylperoxy radicals.[8] Using an isotope effect in the propagation reaction of $k_H/k_D = 5.5$, it follows that α-phenethylperoxy radicals terminate 1.7 times as readily as the peroxy radicals formed in the oxidation of α-d_1-ethylbenzene. The peroxy radicals formed in the oxidation of α-d_1-ethylbenzene[7] should be 78.8% α-deutero-α-phenethylperoxy and 20.2% α-phenethylperoxy based on the magnitude of the isotope effect in the propagation reaction. If the crossed termination reaction (k_{HD}) is assumed to occur with a rate constant that is the geometric mean of the rate constants for the other two reactions,[9] $k_{HD} = (k_H k_D)^{1/2}$, it can be calculated that the deuterium-isotope effect in the termination reaction is $k_H/k_D = 1.9$. The magnitude of this deuterium-isotope effect, which occurs when a deuterium atom is substituted for an α-hydrogen

$$\left.\begin{array}{l} 2C_6H_5CHCH_3OO\cdot \xrightarrow{k_H} \\ C_6H_5CHCH_3OO\cdot + C_6H_5CDCH_3OO\cdot \xrightarrow{k_{HD}} \\ 2C_6H_5CDCH_3OO\cdot \xrightarrow{k_D} \end{array}\right\} \text{non-radical products}$$

atom in the α-phenethylperoxy radical, suggests that an α-carbon–hydrogen bond of the α-phenethylperoxy radical is broken in the rate-determining step of the termination reaction. This, of course, is in agreement with the termination reaction suggested wherein two α-phenethylperoxy radicals interact to form oxygen, acetophenone and α-phenethanol.

Discussion

Mechanism of Chain Termination.—The observation that α-phenethylperoxy radicals terminate more readily than their α-deutero derivatives allows the assignment of a detailed mechanism to this reaction. A reaction involving a cyclic transition state seems most likely.



I may actually be an intermediate that is formed rapidly and reversibly and which decomposes slowly in an irreversible manner. The reaction path illustrated is consistent with the yield of hydroperoxide and acetophenone observed in the oxidation of ethylbenzene and in view of the exothermicity of the reaction,[10,11] is consistent with a low

(7) Containing 1.1% ethylbenzene.

(8) Since a hydrogen atom of ethylbenzene is less reactive than a hydrogen atom of cumene toward a peroxy radical [G. A. Russell, THIS JOURNAL, **78**, 1047 (1956)], it is expected that if there is a difference in the deuterium-isotope effect in the propagation reaction, then the largest deuterium-isotope effect will occur in the attack of a peroxy radical on ethylbenzene.

(9) See for example, G. M. Burnett, "Mechanism of Polymer Reactions," Interscience Pub., Inc., New York, N. Y., 1954, p. 290.

(10) Using the bond dissociation energies of T. L. Cottrell ["The Strengths of Chemical Bonds," Academic Press, New York, N. Y., 1954] $D_{(-O-O-)}$, 35 kcal. mole^{-1}; $D_{(\equiv C-H,\ benzyl)}$, 78; $D_{(O_2)}$, 117; $E_{(-C=O,\ ketone)} - E_{(\equiv C-O-)}$, 87; $D_{(RO-H)}$, 100 [P. Gray, *Trans. Faraday Soc.*, **52**, 344 (1956)], it is calculated that 157 kcal. is liberated in the interaction of two moles of peroxy radicals. This estimate is high if the oxygen–oxygen bond dissociation energy of a peroxy [illegible] 35 kcal. mole^{-1}. Since estimates of $D_{(RO-O\cdot)}$

deuterium-isotope effect (k_H/k_D = 1.9) when a deuterium atom is substituted for an α-hydrogen atom.[12]

Vaughan and co-workers have suggested that prim. and sec.-alkylperoxy radicals terminate by the formation and disproportionation of alkoxy radicals.[13]

$$2R_2CHOO\cdot \xrightarrow{k_f} O_2 + 2R_2CHO\cdot \xrightarrow{k_t} R_2CO + R_2CHOH$$

This suggestion lacks experimental verification, particularly in regard to the actual participation of alkoxy radicals in the reaction. However, in the liquid phase oxidation of ethylbenzene a termination reaction involving the formation and disproportionation of alkoxy radicals can be excluded. A deuterium-isotope effect of the magnitude observed would not be expected if alkoxy radicals were formed slowly and disproportionated rapidly ($k_f < k_t$). On the other hand, although a deuterium-isotope effect would be expected if $k_f > k_t$, this process can be eliminated on the basis of stoichiometry of the oxidation reaction, since, if alkoxy radicals were formed rapidly but disproportionated slowly, a majority of the alkoxy radicals would have to enter into chain propagation reactions, *e. g.*

$$C_6H_5CHCH_3O\cdot + RH \longrightarrow C_6H_5CHCH_3OH + R\cdot$$

The observation that only one molecule of oxygen was present in non-peroxidic products per two kinetic chains in the oxidation of ethylbenzene excludes this possibility.

The improbability of $k_f > k_t$ can be demonstrated by a somewhat less direct approach. We can write the following expressions for the oxidation of ethylbenzene performed in the presence of 0.1 *M* AIBN.[14]

$$k_p/k_t = \frac{\text{rate of chain propagation}}{\text{rate of chain termination}} = \frac{k_3[RH][ROO\cdot]}{2k_6[ROO\cdot]^2} = 7.4$$

Therefore, if $k_f > k_t$, $k_p/k_f < 7.4$. It would seem likely that cumylperoxy and α-phenethylperoxy radicals would interact to form alkoxy radicals at about the same rate. In this case, and at the *same* radical concentration, we could write for an oxidation of cumene

$$k_p/k_f < 7.4 \times \frac{6.90}{7.82} \times \frac{1}{1.20} = 5.6$$

where 6.90 and 7.82 are the concentrations of cumene and ethylbenzene, and the ratio 1:1.20 represents the relative reactivities of cumene and ethylbenzene towards a peroxy radical.[8] We have previously shown that α-phenethylperoxy radicals terminate more readily than cumylperoxy radicals.[8,15] Because of this, under conditions of constant rate of initiation, the concentration of peroxy radicals is greater in an oxidation of cumene than in an oxidation of ethylbenzene. It follows, from Table I, that the concentration of peroxy radicals in the oxidation of cumene (0.1 *M* AIBN, 6.90 *M* cumene) is 6.8 times the concentration of α-phenethylperoxy radicals in the oxidation of ethylbenzene (0.1 *M* AIBN, 7.82 *M* ethylbenzene). Therefore, for a 0.1 *M* AIBN-catalyzed oxidation of cumene, $k_p/k_f < 5.6/6.8 = 0.8$. This indicates that if $k_f > k_t$ and if k_f is the same for cumylperoxy and α-phenethylperoxy radicals, that cumylperoxy radicals formed in a 0.1 *M* AIBN-catalyzed oxidation would interact to yield alkoxy radicals more rapidly than they would react with cumene. Such a situation is unlikely in view of the essentially quantitative yield of hydroperoxide obtained in the oxidation of cumene (Table II).

Another possible termination reaction[16] can be

$$2ROO\cdot + R'C_6H_5 \longrightarrow ROOH + R'C_6H_4OOR$$

excluded on the basis of the observed deuterium-isotope effect in the termination reaction and also on the basis of the argument that this reaction should occur as readily for cumylperoxy radicals as for α-phenethylperoxy radicals. In this case the kinetic chain length observed in the oxidation of cumene (0.1 *M* AIBN) should be $^1/_{10}$ (6.90/7.82 × 1/1.20 × 1/6.8) that observed in the oxidation of ethylbenzene (0.1 *M* AIBN) whereas the kinetic chain length is actually much greater in the oxidation of cumene (Table II).

Finally, we would like to point out that the termination mechanism suggested for α-phenethylperoxy radicals is possibly general for prim. and sec.-alkylperoxy radicals. Previously we have demonstrated that most prim.- and sec.-peroxy radical terminate much more readily than sec.-alkylperoxy radicals.[8,15] This suggests that many prim.- and sec.-alkylperoxy radicals terminate in the same manner and that a different termination reaction is involved for ter.-alkylperoxy radicals. Such a circumstance is readily appreciated if prim.- and sec.-alkylperoxy radicals terminate by the cyclic interaction pictured wherein an α-carbon–hydrogen bond is ruptured. Ter.-alkylperoxy radicals, lacking an α-carbon–hydrogen bond, cannot undergo this termination reaction.[6]

Bolland and Cooper have suggested that in the photo-sensitized oxidation of ethanol acetic acid is formed in a termination reaction involving peroxy radicals.[17] In the absence of any data to the contrary, and in view of the present findings, we would prefer to formulate the reactions as shown.

Deuterium-isotope Effects in Aliphatic Substitutions.—The observation that the deuterium-isotope effect observed in the attack of a peroxy radical upon an α-hydrogen atom of an aralkyl hydrocarbon has the magnitude k_H/k_D = 5.5 is in

in the range 45–55 are not unreasonable (see footnote 22), ΔH, may be as low as 59 kcal. per mole of peroxy radical.

(11) C. H. Bamford and M. J. S. Dewar [*Proc. Roy. Soc.* (*London*), **198A**, 252 (1949)] have assigned an energy of activation of about 1, kcal. mole^{-1} to the termination reaction between two α-tetralylperoxy radicals.

(12) K. Wiberg, *Chem. Revs.*, **55**, 713 (1955).

(13) E. R. Bell, J. H. Raley, F. F. Rust, F. H. Seubold, Jr., and W. E. Vaughan, *Disc. Faraday Soc.*, **10**, 242 (1951); F. H. Seubold, Jr., F. F. Rust and W. E. Vaughan, THIS JOURNAL, **73**, 18 (1951).

(14) In the oxidation of ethylbenzene 4.2 molecules of oxygen was consumed per initiating radical. One molecule of oxygen was consumed in the initiating step and one molecule of oxygen was liberated in the termination of two kinetic chains. Therefore, on the average, an α-phenethylperoxy radical abstracted a hydrogen atom 3.7 times before it entered into a termination reaction.

(15) G. A. Russell, THIS JOURNAL, **77**, 4583 (1955).

(16) This reaction is similar to the termination reaction that occurs in peroxidations inhibited by phenols or substituted-anilines [C. E. Boozer and G. S. Hammond, *ibid.*, **76**, 3861 (1954), **77**, 3233, 3238 (1955)].

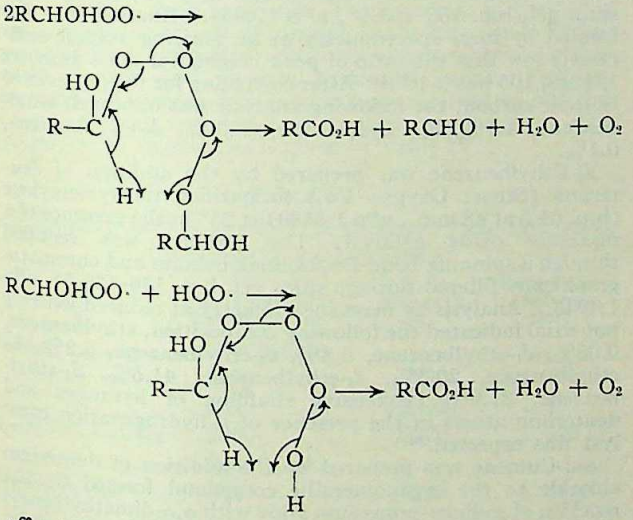
[m] Toward the trichloromethyl radical, E. C. Kooyman, *Disc. Faraday Soc.*, 10, 163 (1951).

excellent agreement with an isotope effect of about 5 reported by Max and Deatherage for the relative rates of autoxidation of *cis*-9-octadecene and its 8,8,11,11-tetradeutero derivative.[18] The isotope



effect reported here has more significance, however, because in the case of the octadecenes isotope effects in both propagation and termination reactions may have been present as well as uncertainties in regard to the rates of initiation.

Wiberg has discussed the correlation between the magnitude of the deuterium-isotope effect in free radical substitution reactions and the reactivity of the attacking radical or atom.[12] In Table III are listed a compilation of data concerning the isotope effect and the reactivity of chlorine atoms, alkoxy radicals, bromine atoms, peroxy radicals and methyl radicals. The exothermicities listed in Table III were calculated assuming a bond dissociation energy for an α-carbon–hydrogen bond of toluene of 77.5 kcal. mole^{-1}.[19] This may be as much as 10 kcal. too low.[20] The exothermicity of the reaction between a peroxy radical and cumene listed in Table III has been calculated assuming $D_{(ROO-H)}$ to be 90–100 kcal. mole^{-1}. This estimate is based on the comments of Vaughan[21] and the recently determined value of $D_{(RO-H)}$ as 100 kcal. mole^{-1}.[10,22]

From Table III it is apparent that the deuterium-isotope effect increases with the energy of activation of the reaction and with the selectivity of the attacking atom or radical. We believe that in reactions involving a low energy of activation and a low deuterium-isotope effect, the carbon–hydrogen (or deuterium) bond is only slightly broken in the transition state. As the atom or radical becomes more selective, the energy of activation increases, the deuterium-isotope effect increases and the transition state for the reaction involves a greater amount of bond breaking. The argument that the transition state in these hydrogen-abstraction reactions varies between one resembling the reactants and one involving a carbon–hydrogen (or deuterium) bond that has been extensively ruptured can be placed on a more quantitative basis. Evans and Polanyi suggested that for processes such as

$$AB + C \longrightarrow A + BC \quad (1)$$
$$DB + C \longrightarrow D + BC \quad (2)$$

involving similar A and D that $\Delta E_1^{\ddagger} - \Delta E_2^{\ddagger} = \alpha(\Delta H_1 - \Delta H_2)$ where α can vary between 0 and 1 and decreases with an increase in the reactivity of the attacking radical or atom.[23] It now appears

(22) Recently published heats of hydroperoxidation of a number of hydrocarbons [W. Pritzkow and K. A. Miller, *Ber.*, 89, 2318 (1956)] are not in disagreement with a bond dissociation energy of 90–100 kcal. if the reaction $R\cdot + O_2 \rightarrow ROO\cdot$ is exothermic by 20–30 kcal. mole^{-1}. For example, the reaction $C_6H_{12} + O_2 \rightarrow C_6H_{11}OOH$ is exothermic by 28 kcal. mole^{-1} while the bond dissociation energy of a cyclohexane carbon–hydrogen bond is about 92 kcal. mole^{-1} [J. L. Franklin, *J. Chem. Phys.*, 21, 2029 (1953)]. If $D_{(ROO-H)}$ is 90–100 kcal., it follows that $D_{(RO-O)}$.) is in the range 45–55 kcal. since $D_{(R-O\cdot)}$ is 92 kcal. [P. Gray, ref. 10].

that the value of α can be used not only as a measure of the reactivity of the atom but also as a measure of the extent of bond breaking in the transition state. We have shown previously that in photochlorination α is 0.1 and suggested that this should be interpreted as meaning that the carbon–hydrogen bond is only about 10% broken in the transition state for the attack of a chlorine atom on a branched-chain hydrocarbon.[24] On the other hand, α is 0.5 for the attack of a methyl radical on an aliphatic hydrocarbon indicating that in this case the original carbon–hydrogen bond is half broken in the transition state.[25] For peroxidation a value of α of 0.39 has been found.[26,27] Values of the deuterium-isotope effect (Table III) are in agreement with these conclusions. The deuterium-isotope effect is small for the reactive chlorine atom and large for the less reactive peroxy or methyl radicals. The deuterium-isotope effect, which occurs because of the freezing out of certain vibrational frequencies in the transition state, should be 1.4 at $\alpha = 0$ and, although temperature dependent, can be calculated at $\alpha = 0.5$ (*e.g.*, $k_H/k_D = 4.7$ at 100°).[12,28] Attempts have been made to calculate α from the values of k_H/k_D by assuming a linear relationship between these quantities over the range $\alpha = 0$ to $\alpha = 0.5$ (reactions of the type under discussion with $\alpha > 0.5$ proceed with great difficulty). From the data of Table III the following values of α were calculated, Cl· (80°), $\alpha = 0.08$; $(CH_3)_3CO\cdot$, (120°), $\alpha = 0.43$; Br· (77°), $\alpha = 0.44$; ROO· (60°), $\alpha = 0.50$; $CH_3\cdot$ (125°), $\alpha = 0.50$. These values of α are in surprisingly good agreement with the experimental values.

Polar Effects in Aliphatic Substitutions.—Table III demonstrates that there is not a direct relationship between the reactivity of an atom or radical and the exothermicity of its reaction with a carbon–hydrogen bond. The value of α is a far better measure of the reactivity of an atom or radical than is the heat of the reaction. Chlorine atoms and methyl radicals react with a hydrocarbon with nearly equal exothermicity, but chlorine atoms ($\alpha = 0.1$) are far more reactive than methyl radicals ($\alpha = 0.5$), as judged from the energy of activation or deuterium-isotope effect, and less selective.[29] This is due undoubtedly to stabilization of transition states by polar resonance forms.[8,24,30] For example, transition state resonance forms such as

$$R\cdot{}^{+}H\bar{:}X \qquad R\cdot{}^{+}H\bar{:}OR \qquad R\cdot{}^{+}H\bar{:}OOR$$

should be important in the attack of atoms or radicals having a high electron affinity on a carbon–hydrogen bond. Of course, the exothermicity of the reaction cannot be completely ignored. For example, when the polar effect is held constant, such as in alkoxy and peroxy radicals, the more exothermic reaction (attack by alkoxy radical) proceeds more readily and with a lower selectivity.

Experimental

Materials.—Cumene and ethylbenzene (Phillips 99 mole % minimum) were rectified in a large Podbielniak column (>50 plates) and middle fractions having constant refractive index and boiling point selected. These fractions were combined, chromatographically filtered through activated silica gel (Davidson, 80–100 mesh) and stored under nitrogen at 0°. Cumene, b.p. 69–69.5 at 42 mm., $n^{20}D$ 1.4912; ethylbenzene, b.p. 138.5–139°, $n^{20}D$ 1.4959.[31]

α-d_1-Ethylbenzene was prepared by the reaction of lithium aluminum deuteride (Metal Hydrides Corp.) with α-phenethyl chloride.[32] The α-d_1-ethylbenzene was purified by rectification through a spinning-band Podbielniak column (*ca.* 50 plates) and chromatographically filtered through silica gel, b.p. 133–133.5°, $n^{20}D$ 1.4954. Analysis was performed by mass spectrometry at an ionizing voltage sufficiently low that the ratio of peak heights for mass numbers 106 and 105 was $>10^4$.[33] After correcting for the presence of isotopic carbon, the following analysis was obtained, ethylbenzene, 1.1%, d_1-ethylbenzene, 98.8%, d_2-ethylbenzene, 0.1%.

d_4-Ethylbenzene was prepared by the addition of deuterium (Stuart Oxygen Co.) to purified phenylacetylene (b.p. 64.5 at 48 mm., $n^{20}D$ 1.5489) at 25° in the presence of a platinum oxide catalyst. The product was rectified through a spinning-band Podbielniak column and chromatographically filtered through silica gel, b.p. 136–136.5°, $n^{20}D$ 1.4943. Analysis by mass spectrometry at reduced ionizing potential indicated the following composition, ethylbenzene, 0.05%, d_1-ethylbenzene, 0.8%, d_2-ethylbenzene, 5.2%, d_3-ethylbenzene, 20.5%, d_4-ethylbenzene, 41.5%, d_5-ethylbenzene, 31.9%. Extensive shuffling of hydrogen and deuterium atoms in the presence of a hydrogenation catalyst was expected.[34]

α-d-Cumene was prepared by the addition of deuterium chloride to the organometallic compound formed by the reaction of sodium–potassium alloy with α,α-dimethylbenzyl methyl ether.[35,36] The α,α-dimethylbenzyl methyl ether was prepared by the addition of hydrogen chloride to purified α-methylstyrene (b.p. 81.5–82° at 40 mm., $n^{20}D$ 1.5382) followed by methanolysis in the presence of potassium hydroxide. The ether was rectified through a small packed column (*ca.* 10 plates), b.p. 84.5–85°, $n^{20}D$ 1.4958, d^{20}_4, 0.946. α,α-Dimethylbenzyl methyl ether (100 g.) was added to 1.77 equivalents of potassium in the form of the sodium–potassium alloy (Na:K = 1:5, 54.5 g.) in 5 l. of ether. The deep red solution of the organometallic compound was stirred for 24 hr. under a dry nitrogen atmosphere before neutralization with 1.9 equivalents of deuterium chloride (prepared from benzoyl chloride and 11.3 g. of 99.5+% deuterium oxide).[37] The deep red color of the

organometallic compound was discharged completely by the first equivalent of deuterium chloride. The solution of α-*d*-cumene in ether was filtered and rectified in the spinning-band Podbielniak column, b.p. 70–70.5° at 47 mm., $n^{20}D$ 1.4908. The product was analyzed after chromatographic filtration by high resolution nuclear magnetic resonance spectroscopy, high resolution infrared spectroscopy and by mass spectrometry.

The high resolution NMR analysis was performed and interpreted by Dr. J. N. Shoolery of Varian Associates. Three different peaks in the spectra of cumene and α-*d*-cumene, each a measure of the concentration of tertiary hydrogen atoms, were compared. The relative heights of all three peaks in the spectra of α-*d*-cumene and cumene (run under comparable conditions) was 1:2.4 ± 0.1. Thus, 41.6% of the cumene molecules contained an α-hydrogen atom and 58.4% of the cumene molecules contained an α-deuterium atom in the sample of α-*d*-cumene. A possible error of ±3% seems possible in this analysis.

Analysis by mass spectrometry at low ionizing voltages (ratio of mass numbers 120 to 119 > 10^4) indicated that 0.85 deuterium atoms were present per molecule of cumene and that the distribution of deuterium was as follows, cumene, 32.8%, d_1-cumene, 52.0%, d_2-cumene, 14.0%, d_3-cumene, 1.2%.

The high resolution infrared absorption spectra were obtained and interpreted by Dr. R. S. McDonald of this Laboratory using a Perkin–Elmer Model 13U spectrometer with a lithium fluoride prism. The spectrum in the 3–4 μ region was resolved into absorption bands for carbon–hydrogen stretching vibrations which are characteristic for aromatic, methyl and tertiary hydrogen atoms. Carbon–deuterium stretching frequencies were resolved in the 4–5 μ region without resort to high resolution techniques. The assignment of frequencies is given in Table IV.

TABLE IV

ASSIGNMENT OF C–H AND C–D STRETCHING FREQUENCIES IN CUMENE AND "α-*d*-CUMENE"

R	R–H stretching frequency, cm.$^{-1}$	R–D frequency, cm.$^{-1}$	Deuterium-isotope shift
C_6H_5–	3100(weak)	..	..
	3080	2280	1.35
	3040	2250	1.35
$C_6H_5CHCH_3CH_2$–	2960	2220	1.345
	2920(weak)	..	..
$C_6H_5C(CH_3)_2$–	2880	2145	1.34

Assuming that $C_6H_5CHCH_3CH_2$–D and $C_6H_5C(CH_3)_2$–D have similar extinction coefficients, it is calculated that not more than 3% of the cumene molecules contained a β-deuterium atom.

From these observations we conclude that 0.24 (0.85 − 0.58 − 0.03) deuterium atoms were present as aromatic deuterium atoms per cumene molecule in the sample of α-*d*-cumene. This is in agreement with the observation that in the NMR spectra the area of the aromatic-hydrogen peak was slightly reduced for the sample of α-*d*-cumene. The neutralization of α,α-dimethylbenzylpotassium is being investigated further in an attempt to prepare pure α-*d*-cumene and to elucidate the mechanism of the formation of ring-deuterated cumenes.

AIBN was recrystallized twice from acetone, m.p. 104–105°. The AIBN was used as a 0.01 *M* solution in benzene which was stored at 0°. The oxygen was 99.3–99.5% pure, the principal impurities being nitrogen and hydrogen.

Procedure.—Oxidations were performed in the general manner described previously.[38] The desired amount of 0.1 *M* AIBN solution was first pipetted into the oxidation flask and the benzene removed under reduced pressure at 0°. The desired amount of hydrocarbon was then weighed into the flask (±0.001 g.) and the oxidation flask attached to a gas buret. The flask, which was a modified 50-ml. erlenmeyer flask, was evacuated at Dry Ice temperature and filled with oxygen five times. After warming to room temperature in the presence of an atmosphere of oxygen, the flask was placed in a shaking rack in a thermostated oil-bath and vigorously shaken while the absorption of oxygen was followed by manual control of the mercury level in a gas buret.

The densities of the deuterated hydrocarbons at 60° were calculated from the densities of cumene, d^{60}_4 0.830,[39] and ethylbenzene, d^{60}_4 0.831,[39] by the equation of McLean and Adams.[40]

Analytical.—The analyses of the deuterated hydrocarbons have been discussed already. The oxidates were analyzed for peroxidic oxygen by the iodimetric procedure of Kokatnur and Jelling[41] and the stannous chloride procedure of Hargrave and Morris.[42] The iodimetric procedure involved the addition of 1 ml. of oxidate to 25 ml. of 99% isopropyl alcohol containing 1 ml. of glacial acetic acid and 1 ml. of saturated potassium iodide solution. This solution was refluxed for 5 minutes under an atmosphere of carbon dioxide, diluted with 25 ml. of water and titrated with 0.1 *N* sodium thiosulfate. There was no blank correction. The stannous chloride procedure used consisted of the reaction of 1 ml. of the oxidate with a mixture of 10 ml. of glacial acetic acid and 10.0 ml. of 0.05 *M* stannous chloride. After 1 hr. at room temperature under a nitrogen atmosphere, the solution was titrated with 0.1 *N* potassium triiodide solution. In this analysis a blank was always run and the concentration of hydroperoxide in the oxidate was proportional to the difference between the blank titer and the titer of the reaction containing the oxidate. The agreement between the two methods (Table II) is somewhat better than expected from the data of Hargrave and Morris.[42]

Analyses for acetophenone in oxidized ethylbenzene were performed by infrared absorption. An appropriate series of standards were prepared and the absorption at 5.9 μ measured by a Perkin-Elmer model 21 spectrometer and plotted as a function of concentration. Attempts to analyze for α-phenethanol by a similar procedure were not successful because of the lack of strong and unique absorption in α-phenethanol.

A New Synthesis and the Stereochemistry of Some 2,3-Disubstituted Dioxanes

BY R. K. SUMMERBELL AND GREGORY J. LESTINA

RECEIVED FEBRUARY 11, 1957

A new synthesis of dioxanes involving the condensation of a diene, a mercuric salt and a glycol has been developed. The product from butadiene, mercuric nitrate and ethylene glycol, after precipitation as the halide and replacement of the halomercuri group with iodine, yielded a mixture of *cis*- and *trans*-2,3-bis-(iodomethyl)-*p*-dioxanes. Nitric acid oxidation of the *trans*-bis-(iodomethyl) compound produced the *trans*-dicarboxylic acid in good yields and without isomerization. The anhydride of the *trans*-acid was converted to the *cis*-anhydride by extended refluxing in acetic anhydride, and hydrolysis of the *cis*-anhydride yielded the *cis*-diacid. The facts that *trans*-diacid could be partially resolved, but that *cis*-diacid could not, were used for definite assignment of configuration. Oxidation of the *cis*-2,3-bis-(iodomethyl)-*p*-dioxane failed to produce a diacid but did produce *cis*-3-hydroxymethyl-2-*p*-dioxanecarboxylic lactone. When *cis*-2,3-bis-(*p*-toluenesulfonatomethyl)-*p*-dioxane, which had been formed from the glycol obtained by the reduction of dimethyl *cis*-2,3-*p*-dioxanedicarboxylate, was treated with sodium iodide, the *cis*-bis-(iodomethyl)-*p*-dioxane was obtained, thus relating the latter to the *cis*-diacid. In the original synthesis, equilibration conditions produced predominantly the *trans* compound, indicating it to be more stable than the *cis* isomer.

Introduction

For several years a great deal of study has been devoted to the structures, configuration, properties and theoretical treatment of cyclohexane derivatives. It would seem desirable to have considerable similar information for comparison purposes concerning six-membered ring compounds containing hetero atoms such as dioxanes.

The structures and configuration of several 2,5- and 2,6-disubstituted dioxanes have been definitely established.[1,2] Although a number of 2,3-disubstituted dioxanes have been reported, and a very few speculative assignments of configuration have been made[3–5] on the basis of the meager available evidence, the configuration of no 2,3-disubstituted dioxane is known with certainty. Most of the 2,3-disubstituted dioxanes that have been prepared were not suitable for such studies, either because both members of a pair of isomers were not available, or because the isomers contained no convenient reactive functional group. We therefore decided to attempt the synthesis of appropriate pairs of isomeric, 2,3-disubstituted dioxanes and the determination of their configuration by conclusive chemical means.

We have recently proposed a mechanism[6] to account for the products and isomer ratios when aqueous mercuric salt solutions are used to cyclize allyl alcohol and allyl ether. The same mechanism may be used to explain the recent similar synthesis of dioxanes from allyl ethers of polyols by Werner and Scholz.[7] On the basis of this mechanism it seemed that a new synthesis of dioxanes involving the mercuric salt condensation of dienes with glycols might prove feasible. Furthermore, these seemed to be a good chance of obtaining the desired pairs of *cis* and *trans* isomers, as both the meso and racemic isomers had been formed in good yields when butadiene was condensed[8] with methanolic solutions of mercuric salts.

Discussion

Mercuric nitrate dissolved in aqueous ethylene glycol was observed to condense readily with 1,3-butadiene to form 2,3-disubstituted dioxanes which, after the appropriate sequence of reactions, yielded a mixture of *cis*- and *trans*-2,3-bis-(iodomethyl)-*p*-dioxanes. When the condensation reaction was conducted in the presence of added strong acid, the proportion of *trans* isomer was increased as was the total yield of dioxane compound.

The *trans* isomer I was isolated easily by simple recrystallization, since it was formed in the larger proportion from the acid synthesis and since it was slightly less soluble than the *cis* compound. The *cis* isomer II was isolated by slowly growing crystals from a methanolic solution of both isomers. Rhombic crystals of I and rod-shaped crystals of II formed and were separated by hand picking. The crystals of II were collected and again subjected to the same procedure. The rod-shaped crystals melted at 83.5–84° in a capillary tube, but on a Fisher–Johns block the compound melted at 77–84°.

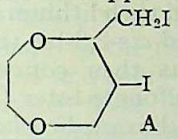
Early experimental results were difficult to interpret until it was realized that we were dealing with two crystalline modifications, IIa and IIb, which were readily interconvertible.

Infrared spectrograms in carbon disulfide solution indicated that I and II were different compounds and that samples of each contained little if any of the other. However, IIa and IIb gave identical infrared spectrograms in carbon disulfide solution, but in potassium bromide pellets a small difference was observed in the region of 10.94 μ where IIa possessed a medium strong absorption which IIb did not have.

It seemed probable that I and II were dioxanes from the method of synthesis, since six-membered rings form more readily than seven-membered ones[9] and 1,4-additions of mercuric salts to butadiene have not been observed, even though carefully sought in a similar situation by McNeely and Wright.[10] If such an addition had occurred here, the product would be a dioxacycloheptane such as A. Chemical evidence supporting the *p*-dioxane



A

structure of I was furnished by the hot concentrated nitric acid oxidation of the iodide I in good yield to a single dicarboxylic acid IV of appropriate empirical formula. Such a compound could hardly be formed by the oxidation of A. Later the smooth conversion of IV back to I afforded additional evidence that Compound I possessed a dioxane rather than a dioxacycloheptane structure.

The presence of a dioxane nucleus in the lower melting iodide II was indicated by the conversion of the *cis*-dicarboxylic acid IX to the *cis*-diiodide II, thus eliminating A as a possible structure for II.

In a somewhat analogous case Johnson[8] and coworkers showed that the two forms of 1,4-diiodo-2,3-dimethoxybutane were diastereoisomers and not structural isomers, since both could be converted to 2,3-dimethoxy-1,3-butadiene by means of a base elimination of hydrogen iodide.

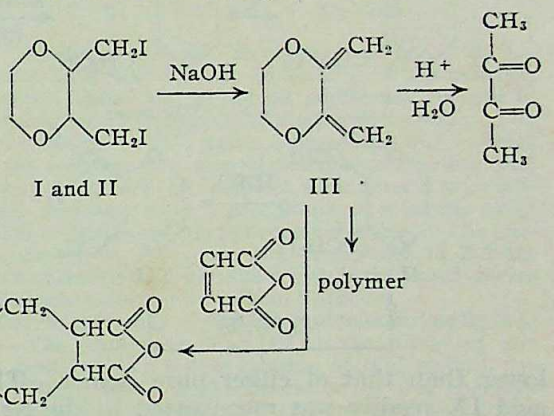
The application of this elimination reaction to 2,3-bis-(iodomethyl)-*p*-dioxane resulted in the formation of an easily polymerized diene which was characterized as 2,3-bis-(exomethylene)-*p*-dioxane (III). This diene readily underwent a Diels–Alder reaction with maleic anhydride to form a compound believed to be 5,8-dioxaoctalin-*cis*-2,3-dicarboxylic anhydride. Substance III was hydrolyzed in dilute hydrochloric acid and, upon treatment of the hydrolysate with phenylhydrazine, a compound was obtained which was identified as the phenylosazone of biacetyl.

The *trans*-iodide I was oxidized to *trans*-2,3-*p*-dioxanedicarboxylic acid (IV) in 73% yield by the action of hot, concentrated nitric acid.[1] The acid which was isolated was believed to be a pure compound and not a mixture of acids by virtue of its unique infrared spectrogram, neutral equivalent, combustion data and sharp melting point.

(9) V. Prelog, *J. Chem. Soc.*, 420 (1950).

(10) K. H. McNeely and G. F. Wright, THIS JOURNAL, **77**, 2553 (1955).

The *trans*-acid IV was converted to *trans*-2,3-*p*-dioxanedicarboxylic anhydride (V) by the action of refluxing acetic anhydride. The empirical formula was indicated by the combustion and neutral equivalent data. The monomeric nature of the anhydride was indicated by the molecular weight of a freshly prepared sample, but when the anhydride was allowed to stand at room temperature for a month, its molecular weight rose from the expected 158 units to 200 units. Upon hydrolysis of the anhydride V the acid IV was regenerated.



I and II III

At one stage in our work, we became suspicious that epimerization might accompany nitric acid oxidation. To test this possibility, we applied our oxidation procedure to a much more sensitive case, the *meso* and racemic diiodo-2,3-dimethoxybutanes and obtained the appropriate corresponding dimethoxysuccinic acids without evidence of isomerization. Such chain compounds would probably be more easily isomerized than our ring compounds. This particular reaction had additional incidental interest in that it supplied chemical evidence to support the supposed configurations of the 1,4-diiodo-2,3-dimethoxybutanes which had been assigned previously on the basis of physical evidence only,[8] when attempted chemical proof by oxidation failed to yield significant products.

As a second test, the acid IV was converted to the iodide I from which it originally was derived by the following reactions which have been shown to proceed without isomerization[1,11] in similar cases. The *trans*-acid IV was esterified with diazomethane to yield dimethyl *trans*-2,3-*p*-dioxanedicarboxylate (VI) which was subsequently reduced with lithium aluminum hydride to an oil assumed to be *trans*-2,3-bis-(hydroxymethyl)-*p*-dioxane. This glycol was converted to *trans*-2,3-bis-(*p*-toluenesulfonatomethyl)-*p*-dioxane (VII) which was then treated with sodium iodide in acetone to yield the *trans*-iodide I.

By extended refluxing in acetic anhydride the *trans*-anhydride V was converted into a new compound which, because of its combustion and neutral equivalent data as well as its melting point, was assumed to be *cis*-2,3-*p*-dioxanedicarboxylic anhydride (VIII). The *cis*-anhydride was hydrolyzed in dilute hydrochloric acid to yield *cis*-2,3-*p*-dioxanedicarboxylic acid (IX). When a mixture of the *cis*-acid IX and the *trans*-acid IV was melted, the melting point of the mixture was considerably

(11) G. A. Harris and L. N. Owen, *J. Chem. Soc.*, 389 (1953).

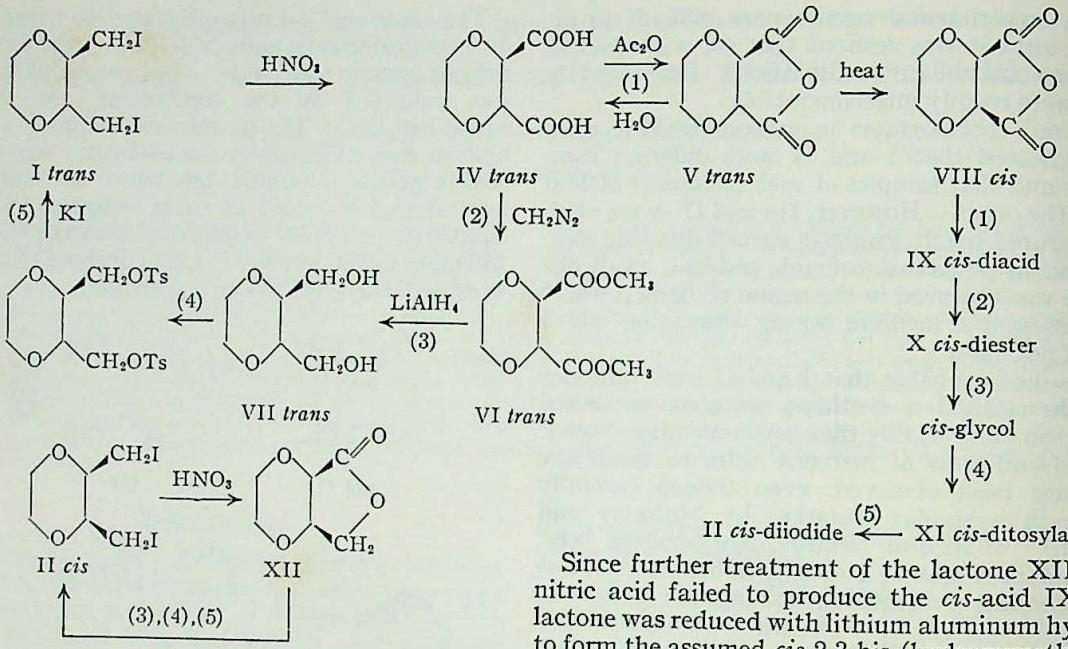
Digitized by Arya Samaj Foundation Chennai and eGangotri



lower than that of either pure isomer. The *cis*-acid IX readily was reconverted to the *cis*-anhydride VIII by the action of refluxing acetic anhydride.

The geometrical nature of the isomerism was indicated by the thermal conversion of the *trans*-anhydride V to the isomeric *cis* compound VIII. The conversion of the *cis*-acid IX to a mixture composed of 58 ± 10% *cis* and 42 ± 10% *trans* by means of aqueous potassium hydroxide, as well as the conversion of the *trans*-acid to a mixture composed of 27 ± 10% *cis* and 73 ± 10% *trans* by the same means, further substantiates the belief that *cis–trans* isomerism rather than skeletal rearrangement is involved.

The relationship between the *cis*-acid IX and the *cis*-iodide II was shown by the following series of reactions, all of which are known to proceed with lack of isomerization.[1,11] The *cis*-acid was esterified with diazomethane to yield dimethyl *cis*-2,3-*p*-dioxanedicarboxylate (X) which was subsequently reduced with lithium aluminum hydride to an oil assumed to be the *cis*-2,3-bis-(hydroxymethyl)-*p*-dioxane. This glycol was converted to *cis*-2,3-bis-(*p*-toluenesulfonatomethyl)-*p*-dioxane (XI) which was treated with sodium iodide in acetone to form the *cis*-iodide II.

When the *cis*-iodide II was treated with concentrated nitric acid in an attempt to form the *cis*-acid IX, a solid was obtained which, when purified, dissolved in water to give a solution neutral to litmus, although its infrared spectrogram indicated the presence of a carbonyl group (strong absorption at 5.6–5.7 μ) and which gave a melting point and combustion analysis different from any of the acids or anhydrides in the dioxane series. The possibility of having formed *cis*-3-hydroxymethyl-2-*p*-dioxanecarboxylic lactone (XII) seemed credible since five-membered rings fused in a *cis* manner to six-membered rings form quite readily.[12]

(12) L. F. Fieser and M. Fieser, "Natural Products Related to Phenanthrene," Reinhold Publishing Corp., New York, N. Y., 1949, pp. 621 622.

Since further treatment of the lactone XII with nitric acid failed to produce the *cis*-acid IX, the lactone was reduced with lithium aluminum hydride to form the assumed *cis*-2,3-bis-(hydroxymethyl)-*p*-dioxane which was then converted to the now known *p*-toluenesulfonate ester (XI).

The *trans*-2,3-*p*-dioxanedicarboxylic acid is the racemic modification and hence should be resolvable into its optical antipodes, whereas the *cis*-acid is the *meso* form and hence would be non-resolvable.

It was found experimentally that the acid IV could be resolved partially, whereas no resolution could be effected with the acid IX. Hence IV was assigned the *trans* configuration and IX was designated the *cis* isomer.

Chemical evidence already mentioned is consistent with this assignment; for example, thermal conversion of the *trans*-anhydride V to the *cis*-anhydride VIII, since one would expect the *trans*-anhydride to be the less stable compound.[13] The behavior of the two methiodides toward nitric acid, where one (I) produces a dibasic acid and the other (II) a lactone, is also pertinent, since the *cis*-lactone would be quite stable in contrast to a *trans*-lactone which, even if formed,[12] would probably be easily hydrolyzed and oxidized further to the *trans*-diacid.

If butadiene is allowed to react with an aqueous mercuric nitrate solution in the absence of an alcohol, 1,4-dinitratomercuri-2,3-dihydroxybutane (XIV) would be the expected product.[14] Our ideas of the mechanism of this reaction[6] suggested that this compound, a glycol, could condense with

more butadiene and mercuric salt to form a tetrasubstituted dioxane (XV), which would probably react with iodine to form 2,3,5,6-tetra-(iodomethyl)-*p*-dioxane (XVI). Furthermore, our mechanism implies that if XIV were treated with strong acid, part of it should be decomposed, regenerating the requisite butadiene and mercuric salt to react with the portion that was not decomposed. When this series of reactions was attempted, a small amount of a compound of the correct analysis and molecular weight for 2,3,5,6-tetra-(iodomethyl)-*p*-dioxane was obtained.

We have previously reported the properties of a number of 2,5- and 2,6-disubstituted dioxanes and explained them in terms of a chair conformation and the equatorial–axial concept of Becket, Pitzer and Spitzer.[15] Assuming a chair conformation, the equatorial–axial isomer, the *cis*-2,5- and the *trans*-2,6-, was found to have a lower melting point and to be less stable than its corresponding more symmetrical isomer. In the present series of 2,3-disubstituted dioxanes, the *cis* compounds would be expected to have the lower melting points and the lesser stabilities. Some of the melting points conform to this prediction and some do not, but this is not particularly serious, since as yet only a few compounds have been made, and since in the related cyclohexane compounds, occasional anomalies in melting points have been observed.[11,16] That the *trans* isomer is the more stable one is indicated quite definitely by our original synthesis, since the yield and proportion of that isomer were increased by equilibration conditions of high acidity and long reaction time. In previous work,[6] the same conditions were found to favor the *trans*-2,5- and the *cis*-2,6-isomers.

The assumption of a chair form for most dioxanes would seem to follow current trends. For instance, Brown, Brewster and Schechter[17] have brought together a large amount of evidence indicating that " . . . an oxygen atom in a ring system can result in the same type of conformational effects as a methylene group." They cite several examples involving two oxygens in the ring.

On the other hand, Kumler and Huitric[18] point out: "When heteroatoms . . . replace CH_2 groups in the cyclohexane ring, the energies of the flexible forms are going to be less, due to fewer intereactions between consecutive CH_2 groups and to more favorable angles in the rings." In our studies thus far, the behavior of dioxane derivatives has paralleled that of cyclohexanes very closely.

Experimental

A. The Formation of 2,3-Bis-(iodomethyl)-*p*-dioxane. 1. The Preparation of 2,3-Bis-(nitratomercurimethyl)-*p*-dioxane.—To 243.0 g. (1.12 moles) of mercuric oxide was added a solution of 300 ml. of concd. (sp. gr. 1.42, 4.7 moles) nitric acid and 150 ml. of water. When solution was complete, there was put in an additional 100 ml. of water and 500 ml. of freshly distilled ethylene glycol. The mixture was cooled to 20°, and 1,3-butadiene was bubbled through the solution at a rate of 2 bubbles/second. The reaction was assumed to be complete when after 3 hr. a 0.5-ml. aliquot no longer gave a precipitate of mercuric oxide when added to a 10% sodium hydroxide solution. The mixture was cooled to −5°, and the precipitate of 2,3-bis-(nitratomercurimethyl)-*p*-dioxane which had formed during the reaction was collected by suction filtration.

Table I

Melting Points of Dioxane Derivatives

	2,3-*cis*	2,3-*trans*	2,5-*cis*	2,5-*trans*	2,6-*cis*	2,6-*trans*
Diacid	183.5	176	178	275	178	162
Dimethylester of diacid	63.5	59	92	143	103	89
Diacid anhydride	116.5	201.5	75	..	106	..
Bis-iodomethyl	77.5 + 84	90	97	158	92	70
Bis-*p*-toluenesulfonatomethyl	97	105	88	205		

2. The Preparation of 2,3-Bis-(iodomercurimethyl)-*p*-dioxane.—The precipitate described in the preceding section was dissolved in a 2-liter solution of 10% sodium hydroxide. There was a slight liberation of free mercury accompanying this solution. To this mixture was added a solution of 133 g. (0.801 mole) of potassium iodide dissolved in 500 ml. of water. A precipitate of 2,3-bis-(iodomercurimethyl)-*p*-dioxane formed. After the solution had been tested for completeness of precipitation, the precipitate was collected by suction filtration. After drying for 24 hr. at 45°, there was obtained 276 g. (0.359 mole), m.p. 196–198°.[19]

3. The Preparation of 2,3-Bis-(iodomethyl)-*p*-dioxane. a. The Isolation of *trans*-2,3-Bis-(iodomethyl)-*p*-dioxane (I).—To a mixture of 800 ml. of chloroform and 200 ml. of water containing 183 g. (0.718 mole) of iodine there was added the substance described in the previous section. The mixture was vigorously stirred and refluxed for 12 hr. When the contents of the flask had cooled, the excess iodine was removed by washing the mixture with a 10% solution of sodium thiosulfate. The mercuric iodide was removed by solution in aqueous potassium iodide. The chloroform layer was separated and evaporated under reduced pressure and the residue dissolved in boiling methanol and filtered. When the solution was cooled slowly, there was obtained 77.0 g. (0.209 mole) of I, m.p. 89–90°, which upon further recrystallization from methanol, deposited rhombic crystals, m.p. 89.5–90°.

Anal. Calcd. for $C_6H_{10}O_2I_2$: C, 19.58; H, 2.71; mol. wt., 368. Found: C, 19.69; H, 2.71; mol. wt., Rast method, 369.

Evaporation of the methanolic mother liquor deposited 42.0 g. (0.114 mole) of crystals, m.p. 57–70°, which, by virtue of the absorbancies in its infrared spectrogram, was adjudged to be a mixture of *cis*- and *trans*-2,3-bis-(iodomethyl)-*p*-dioxane.

Anal. Calcd. for $C_6H_{10}O_2I_2$: C, 19.58; H, 2.71. Found: C, 19.52; H, 2.53.

Thus there was obtained a total of 119 g. (0.323 mole) of 2,3-product for a yield of 56% based on the number of moles of mercuric salt used in the initial reaction. In a similar sequence of reactions, 32 g. (0.1 mole) of mercuric acetate without the addition of any strong acid was treated with excess 1,4-butadiene. There was obtained, after the appropriate sequence of reactions, 7.5 g. (0.02 mole) of 2,3-product, m.p. 64–72°, for a yield of 40%.

b. The Isolation of *cis*-2,3-Bis-(iodomethyl)-*p*-dioxane (II).—The lower melting crops, when dissolved in methanol and allowed to stand in beakers, slowly deposited crystals of the *cis* and *trans* isomers. The *cis* isomer appeared as rod-shaped crystals which could be separated from the rhombic crystalline *trans* isomer by hand picking. The

crystals of the *cis* isomer so obtained were recrystallized from methanol and from hexane. Although its melting point was not sharp, it was assumed to be free of the *trans* isomer because of the lack of the strong *trans* absorption at 10.6 μ in its infrared spectrogram.

When this substance was dissolved in boiling hexane and slowly cooled, needle-shaped crystals (IIa) appeared, m.p. 77–77.5°. The compound was dried at 30° and 0.1 mm. for 12 hr. and the melting point remained unchanged.

Anal. Calcd. for $C_6H_{10}O_2I_2$: C, 19.58; H, 2.71; mol. wt., 368. Found: C, 19.72; H, 2.58; mol. wt., Rast method, 368.

When IIa was melted in a capillary or when melted on a steam-bath and suddenly cooled, the melting point rose to 83.5–84° (IIb). A mixed melting point with the 77.5° isomer melted at 83–84°.

Anal. Calcd. for $C_6H_{10}O_2I_2$: C, 19.58; H, 2.71. Found: C, 19.48; H, 2.64.

Both forms depress the *trans* isomer in a mixed melting point determination.

TABLE II

MIXED MELTING POINTS OF THE 2,3-DIIODIDES

Components	M.p., °C.
I and IIa	60–70
I and IIb	63–73
IIa and IIb	83–84

When IIb was dissolved in hot hexane and the solution allowed to cool slowly, there were obtained fine needles, m.p. 77–77.5°. When IIa was melted at 80° on the Fisher–Johns block and the liquid seeded with a crystal of IIb, the liquid slowly solidified and melted at 83.5–84°.

In carbon disulfide solution, forms IIa and IIb gave identical infrared spectrograms. In a 2% mixture of the iodides in potassium bromide, form IIb had a medium strong absorption at 10.94 which form IIa did not possess. The pellets weighed *ca.* 60 mg. and were formed under 6000 p.s.i.

B. **The Synthesis of 2,3-Bis-(exomethylene)-*p*-dioxane (III). 1. The Preparation of III.**—In a 1-liter claisen flask fitted with an addition funnel and a condenser there was placed 100 ml. of carbitol and 44 g. (1.1 moles) of sodium hydroxide dissolved in 50 ml. of water. The temperature of the heating bath was kept between 200–210° so that a slow distillation occurred. By means of the addition funnel 110 g. (0.3 mole) of 2,3-bis-(iodomethyl)-*p*-dioxane suspended in 200 ml. of an equivolume water–carbitol mixture was added in small portions. Each addition was followed by the sudden ebullition of vapor which condensed to give a milky liquid composed of water and III which was collected in a receiver immersed in an ice–salt-bath and under an atmosphere of nitrogen. When the addition of the iodide was completed, 50 ml. of a water–carbitol mixture was added and the heating continued until the distillate became clear. The distillate separated into two layers, the upper layer of water and the lower layer of III. Substance III was removed and dried by means of anhydrous sodium carbonate and stored at −78° under a nitrogen atmosphere. Compound III was considerably soluble in water, hence there was obtained only 14 g. (0.12 mole) of diolefin for a 40% yield, $n^{20}D$ 1.4922.

2. The Polymerization of III.—Substance III, when allowed to stand at 25°, polymerizes noticeably within 5 minutes. At the end of 24 hr. a white, glass-like polymer was obtained which did not melt at 240°.

3. The Hydrolysis of III.—To 40 ml. of water containing two drops of 12 *N* hydrochloric acid 1.0 g. (0.009 mole) of III was added. The mixture was warmed gently for 15 minutes and then allowed to stand overnight. Upon standing, the solution assumed a canary-yellow color. The phenylosazone of biacetyl was prepared according to the method listed by Shriner and Fuson.[20,21] There was obtained 0.75 g. (0.0028 mole) of substance which was assumed to be the phenylosazone of biacetyl, m.p. 243–244° (lit. m.p. 242–243°).[21] There was no depression in the melting point when this osazone was mixed with an authentic sample of the phenylosazone of biacetyl.

Anal. Calcd. for $C_{16}H_{18}N_4$: N, 21.04. Found: N, 21.22.

4. The Reaction of III with Maleic Anhydride.—To 30 ml. of benzene containing 2.0 g. (0.020 mole) of maleic anhydride and 0.5 g. of hydroquinone under a nitrogen atmosphere there was added 2.0 g. (0.018 mole) of III. The ensuing reaction was exothermic so that cooling became necessary. After the mixture was allowed to stand overnight, the benzene was removed under reduced pressure. The residue was extracted twice with 10 ml. of ethyl ether to remove the hydroquinone. The resulting solid was recrystallized from a hexane–benzene mixture to yield 2.22 g. (0.0105 mole) of 5,8-dioxaoctalin-*cis*-2,3-dicarboxylic anhydride, m.p. 81.5–82°, for a 58.3% yield.

Anal. Calcd. for $C_{10}H_{10}O_5$: C, 57.14; H, 4.79; neut. equiv., 105. Found: C, 57.36; H, 4.67; neut. equiv., 108.

5. The Reaction of III with Mercuric Acetate in Ethylene Glycol.—To a solution of 200 ml. of ethylene glycol and 10 ml. of acetic acid containing 64 g. (0.036 mole) of mercuric acetate there was added 4.0 g. (0.036 mole) of III. After 4 hr., a yellow gelatinous precipitate formed which was removed by filtration. This precipitate did not dissolve in aqueous sodium hydroxide but did take up iodine in the replacement reaction. There was obtained 0.15 g. of substance, m.p. 118–118.5°, which smelled similar to iodoform and which did not depress authentic iodoform in a mixed m.p. determination.

Aqueous potassium iodide was added to the filtrate of the reaction mixture and a precipitate formed. This precipitate was treated with excess iodine in chloroform for 2 hr. Upon evaporation of the chloroform under reduced pressure there was obtained 0.56 g. (0.0013 mole) of compound which, after crystallization from methanol, melted at 136° and was assumed to be 4a,8a-bis-(iodomethyl)-1,4,5,8-tetroxadecalin.

Anal. Calcd. for $C_8H_{12}O_4I_2$: C, 22.55; H, 2.83. Found: C, 22.66; H, 2.87.

C. **The Oxidation of *trans*-2,3-Bis-(iodomethyl)-*p*-dioxane (I). 1. The Formation of *trans*-2,3-*p*-Dioxanedicarboxylic Acid (IV).**—To 2 liters of concd. (sp. gr. 1.42) nitric acid there was added 161 g. (0.44 mole) of I. The mixture was heated on a steam-bath until only a solid remained. There was obtained 56.5 g. (0.32 mole) of impure IV for a 73% yield. The acid was recrystallized by dissolving it in boiling acetone, adding hexane until a slight cloudiness developed and then allowing the mixture to cool slowly to room temperature. Crystals of IV were thus obtained melting at 175–176°.

Anal. Calcd. for $C_6H_8O_6$: C, 40.91; H, 4.57; neut. equiv., 88.1. Found: C, 40.95; H, 4.50; neut. equiv., 88.9.

2. *trans*-2,3-*p*-Dioxanedicarboxylic Anhydride (V).—A sample, 17.6 g. (0.10 mole), of IV was refluxed in 100 ml. of acetic anhydride for 1 hr. After one-half of the solvent was distilled under reduced pressure, the mixture was allowed to cool to room temperature. Crystals formed which, after collection by filtration, weighed 10.8 g. (0.068 mole) for a 68% yield of impure V. Further crystallization from acetic anhydride produced the solid, m.p. 201–201.5°.

Anal. Calcd. for $C_6H_6O_4$: C, 45.57; H, 3.83; neut. equiv., 79; mol. wt., 158. Found: C, 45.72; H, 3.75; neut. equiv., 79.6; mol. wt., Rast method, 165; mol. wt., Rast method after one month, 200.

3. The Hydrolysis of V.—To 10 ml. of water containing 2 drops of 12 *N* hydrochloric acid there was added 1.0 g. (0.0063 mole) of V, and the mixture was heated for 1 hr. on a steam-bath. When the excess solvent was removed under reduced pressure, there was obtained 0.82 g. (0.0047 mole), yield 74%, of IV which, after recrystallization from acetone–hexane, melted at 175–176° and did not depress the melting point of authentic IV in a mixed m.p. determination.

D. **The Conversion of *trans*-2,3-*p*-Dioxanedicarboxylic Acid (IV) to *trans*-2,3-Bis-(iodomethyl)-*p*-dioxane (I). 1. The Formation of Dimethyl *trans*-2,3-*p*-Dioxanedicarboxylate (VI).**—To 100 ml. of ethyl ether containing a suspension of 3.0 g. (0.017 mole) of IV there was added an ethereal solution of diazomethane[22] until the yellow color of the diazomethane persisted. The ether solution was allowed to

stand for 24 hr. and was then filtered. The filtrate was evaporated to dryness by heating and a colorless oil remained which solidified on standing. After recrystallization from ethyl ether there was obtained 2.5 g. (0.012 mole) of VI, m.p. 59°, for a 71% yield.

Anal. Calcd. for $C_8H_{12}O_6$: C, 47.05; H, 5.92. Found: C, 47.34; H, 5.60.

2. **The Reduction of VI with Lithium Aluminum Hydride.**—To 150 ml. of anhydrous ethyl ether containing a suspension of 2.0 g. (0.052 mole) of lithium aluminum hydride there was added slowly 2.34 g. (0.0115 mole) of VI dissolved in 50 ml. of ethyl ether. The reaction was mildly exothermic. The mixture was refluxed for 4 hr., and then 2 ml. of methyl alcohol was added to destroy the excess anhydride reagent. To this mixture was added 9 ml. of water and the reaction was allowed to stand overnight. The hydroxides were precipitated in the form of pellets which could be removed easily by filtration. This hydroxide precipitate was extracted in a Soxhlet apparatus for three days. Upon evaporation of the combined ether solvents there was obtained *ca.* 1.4 g. of a colorless oil which was assumed to be the *trans*-2,3-bis-(hydroxymethyl)-*p*-dioxane.

3. **The Preparation of *trans*-2,3-Bis-(*p*-toluenesulfonatomethyl)-*p*-dioxane (VII).**—The *p*-toluenesulfonate derivative was made from the oil from the previous experiment according to the method of Tipson.[23] There was obtained 1.26 g. (0.0025 mole) of VII which, after repeated recrystallization from acetone–hexane, melted at 105° for an overall yield of 24% from the dimethyl ester.

Anal. Calcd. for $C_{20}H_{24}O_8S_2$: C, 52.61; H, 5.29. Found: C, 52.53; H, 5.05.

4. **The Conversion of VII to I.**—To 30 ml. of anhydrous acetone[24] containing 2.0 g. (0.013 mole) of anhydrous sodium iodide there was added 0.46 g. (0.001 mole) of VII. The solution was refluxed for 6 hr. during which time a precipitate formed. The acetone was evaporated by means of an air jet, and water was added to the residual solid. The insoluble material (I) was collected by filtration. There was obtained 0.36 g. (0.0098 mole) of compound for a 98% yield. The substance was recrystallized from methanol to yield crystals, m.p. 89.5–90°, which gave no depression with authentic I in a mixed m.p. determination. The infrared spectrogram of this compound was identical to that of authentic I.

E. **The Formation of *cis*-2,3-*p*-Dioxanedicarboxylic Anhydride (VIII).** 1. **The Isomerization of V.**—A mixture of 70 ml. of acetic anhydride and 10.0 g. (0.068 mole) of the *trans*-anhydride V was refluxed for 9 hr. During this time the reaction mixture turned dark brown. The solvent was distilled at reduced pressure until 60 ml. had been collected. The reaction mixture was cooled in an ice–salt-bath and crystals slowly formed. There was collected 1.18 g. (0.0075 mole) of VIII which upon further recrystallization from acetic anhydride melted at 116–116.5° for an 11.8% yield.

Anal. Calcd. for $C_6H_6O_4$: C, 45.57; H, 3.83; neut. equiv., 79.4; mol. wt., 158. Found: C, 45.88; H, 3.86; neut. equiv., 79.4; mol. wt., Rast method, 164.

2. **From IX.**—A mixture of 15 ml. of acetic anhydride and 1.15 g. (0.0065 mole) of *cis*-diacid IX was refluxed for 1 hr. The solvent was then distilled under reduced pressure, and there was obtained on cooling 0.72 g. (0.0046 mole) of substance which upon recrystallization from acetic anhydride melted at 116–116.5° and which did not depress the melting point of VIII in a mixed m.p. determination.

F. **The Formation of *cis*-2,3-*p*-Dioxanedicarboxylic Acid (IX).**—To 25 ml. of water containing 2 drops of concd. hydrochloric acid there was added 1.0 g. (0.0063 mole) of VII. The mixture was heated for 2 hr. on a steam-bath and then the solvent was evaporated at 25° and reduced pressure. There was obtained 0.94 g. (0.0053 mole) of IX, m.p. 177–180°, for an 84% yield. The substance was recrystallized from an acetone–hexane mixture as described in section C to yield crystals, m.p. 182.5–183.5°, which in a mixed m.p. determination with IV melted at 150–163°.

Anal. Calcd. for $C_6H_8O_6$: C, 40.91; H, 4.57; neut. equiv., 88.1. Found: C, 41.15; H, 4.54; neut. equiv., 88.6.

G. **The Conversion of *cis*-2,3-*p*-Dioxanedicarboxylic Acid (IX) to *cis*-2,3-Bis-(iodomethyl)-*p*-dioxane (II).** 1. **The Preparation of Dimethyl *cis*-2,3-*p*-Dioxanedicarboxylate (X).**—The conversion of IX to II was performed in exactly the same manner as that of V to I. The diester was prepared in 83% yield and after recrystallization from ethyl ether melted at 63–63.5°. A mixed melting point with the *trans*-diester melted at 45–55°.

Anal. Calcd. for $C_8H_{12}O_6$: C, 47.05; H, 5.92. Found: C, 47.31; H, 5.69.

2. **The Reduction of X with Lithium Aluminum Hydride.**—After the reduction procedure there was obtained *ca.* 0.7 g. of a clear viscous liquid assumed to be the *cis*-2,3-bis-(hydroxymethyl)-*p*-dioxane.

3. **The Formation of *cis*-2,3-Bis-(*p*-toluenesulfonatomethyl)-*p*-dioxane (XI).**—The *p*-toluenesulfonate derivative was made from the oil obtained in the previous experiment according to the method of Tipson.[23] Substance XI was obtained in 38% yield from the diester and after recrystallization from acetone–hexane melted at 97°.

Anal. Calcd. for $C_{20}H_{24}O_8S_2$: C, 52.61; H, 5.29. Found: C, 52.35; H, 5.03.

4. **The Formation of II from XI.**—After the appropriate reaction there was obtained a compound in 83% yield which after recrystallization from methanol melted at 82–83.5° and which did not depress authentic II in a mixed melting point determination. The infrared spectrogram in carbon disulfide solution was identical to that of authentic II.

H. **The Interconversions of the 2,3-*p*-Dioxanedicarboxylic Acids.** 1. **IV to IX.**—To 50 ml. of water containing 12 g. of potassium hydroxide there was added 1.0 g. of IV. The mixture was heated for 12 hr. on a steam-bath, cooled to 0°, acidified with 6 *N* hydrochloric acid to *p*H 2 and evaporated to dryness by heating on a steam-bath. The residue was pulverized and extracted three times with 30-ml. portions of acetone. The acetone was evaporated to dryness by heating and there was obtained 0.92 g., m.p. 130–138°, for a 92% recovery. The recovered substance had a neutral equivalent of 90 compared to the theoretical value of 88 for the diacids. The mixture contained 73 ± 10% *trans*-acid and 27 ± 10% *cis*-acid as determined by infrared analysis.

2. **IX to IV.**—A solution of 50 ml. of water containing 6.0 g. of potassium hydroxide and 0.5 g. of IX was heated for 12 hr. on a steam-bath. The product was isolated as described in the previous section. There was obtained upon evaporation of the acetone extract 0.33 g., m.p. 140–145°, for a 66% recovery. The recovered substance had a neutral equivalent of 91 as compared to a theoretical value of 88 for the diacids. The mixture contained 58 ± 10% *cis*-acid and 42 ± 10% *trans*-acid as determined by infrared analysis.

3. **Infrared Analysis.**—The analyses were performed by preparing a 2% mixture of the acids in potassium bromide. Pellets of the order of 65 mg. were analyzed on the Baird infrared recording spectrophotometer. The *cis*-acid absorbed at 11.1 and at 11.4 μ, whereas the *trans* isomer absorbed at 11.4 μ. The concentrations were determined by comparing the relative absorptions at 11.1 and 11.4 μ with known mixtures.

The known mixtures were prepared by weighing the appropriate amounts of pure acids, dissolving them in acetone and boiling the acetone to dryness. The resulting solid was pulverized with an agate mortar and pestle and its spectrogram determined in the same manner as the unknown acid mixtures.

I. **The Partial Resolution of *trans*-2,3-*p*-Dioxanedicarboxylic Acid (IV).**—To 2 liters of acetone containing 2.37 g. (0.0060 mole) of brucine there was added 1.0 g. (0.0057 mole) of IV dissolved in 50 ml. of acetone. The solution was

TABLE III

FRACTIONAL CRYSTALLIZATION OF *trans*-ACID BRUCINATE

Fraction	Yield, g.	M.p., °C.	$\alpha^{25}D$[a]
1	1.8	242–243	+0.37°[b]
2	0.34	230–232	−1.0
3	.24	225–230	−0.65
4	.20	232–234	− .60
5	.20	218–223	− .63

[a] Defined as the optical rotation after the removal of brucine. [b] Defined as the rotation observed from the acid obtained from 0.30 g. of brucinate.

boiled for 15 minutes and allowed to cool. Overnight some crystals were formed which were removed by filtration. The remainder of the solution was allowed to stand in a 3-liter beaker at room temperature. From time to time crystals of the brucinate salt were deposited and collected.

To each set of crystals was added 1 ml. of concd. ammonium hydroxide. To the mixture containing precipitated brucine there was added 2 ml. of chloroform with vigorous shaking. The resulting two-liquid layers were separated and the ammoniacal layer was extracted twice with chloroform, filtered and put in a one-decimeter polarimeter tube. The magnitude of its optical rotation was measured with an Aminco photomultiplier microphotometer whose accuracy was estimated at ±0.03.

J. The Attempted Resolution of *cis*-2,3-*p*-Dioxanedicarboxylic Acid (IX).—To 1.5 liters of acetone containing 0.48 g. (0.0012 mole) of brucine there was added 0.200 g. (0.0011 mole) of IX in 50 ml. of acetone. The solution was boiled for 15 minutes and allowed to stand. Over the period of a month crystals were deposited and collected.

TABLE IV

FRACTIONAL CRYSTALLIZATION OF *cis* ACID BRUCINATE

Fraction	Yield, g.	M.p., °C.	$\alpha^{25}D$[a]
1	0.19	214–215	+0.03°
2	.13	214–215	0°
3	.23	213–215	0°
4	.10	210–214	+0.03°

[a] Defined as optical rotation after the removal of brucine.

The acids were liberated from the brucine and the optical rotations measured in the same manner as described in the previous section.

K. The Oxidation of *cis*-2,3-Bis-(iodomethyl)-*p*-dioxane (II). 1. The Formation of *cis*-3-Hydroxymethyl-2-*p*-dioxanecarboxylic Lactone (XII).—To 15 ml. of concd. (sp. gr. 1.42) nitric acid there was added 2.0 g. (0.0054 mole) of II. The mixture was heated on a steam-bath for 10 hr. A clear oil was obtained which solidified on standing. The resulting solid, after drying on a clay plate, weighed 0.55 g. (0.0038 mole) for a 70% yield of XII. When it was recrystallized from carbon tetrachloride the substance melted at 86–86.5°.

Anal. Calcd. for $C_6H_8O_4$: C, 50.00; H, 5.59. Found: C, 49.99; H, 5.39.

An infrared spectrogram of this compound was obtained from a 2% mixture in potassium bromide. The compound possessed a strong absorption at 5.62 μ which was attributed to the carbonyl group.

A neutral equivalent was attempted by titrating the sodium salt of the acid with 0.1 *N* hydrochloric acid. When the reaction was followed potentiometrically, no break was observed in the titration curve.

2. The Conversion of XII to XI. a. The Reduction of XII with Lithium Aluminum Hydride.—To 100 ml. of anhydrous ethyl ether containing 0.60 g. (0.015 mole) of lithium aluminum hydride there was added 0.80 g. (0.0056 mole) of XII. The mixture was refluxed for 6 hr. and then hydrolyzed by the addition of 1 ml. of methanol followed by the addition of 3 ml. of water. The mixture was allowed to stand overnight. The hydroxide precipitate was collected by filtration and extracted in a Soxhlet apparatus for 4 days. Upon evaporation of the ether there was obtained *ca.* 0.70 g. of an oil which was assumed to be *cis*-2,3-bis-(hydroxymethyl)-*p*-dioxane.

b. The Formation of XI.—The *p*-toluenesulfonate derivative was made from the oil isolated in the previous experiment according to the method of Tipson.[21] There was obtained 0.70 g. (0.0015 mole) of XI which, after recrystallization from methanol, melted at 96–97° for a 27% yield from the lactone. A mixed m.p. with authentic XI gave no depression (m.p. 96–97°).

L. The Oxidation of 2,3-Dimethoxy-1,4-diiodobutane. 1. The Formation of *meso*-α,α'-Dimethoxysuccinic Acid (XIII).—To 60 ml. of concd. (sp. gr. 1.42) nitric acid there was added 5.35 g. (0.0144 mole) of *meso*-2,3-dimethoxy-1,4-diiodobutane.[8]

The mixture was heated on a steam-bath until a heavy oil remained. There was obtained 1.80 g. (0.0101 mole) of XIII which, after recrystallization from an acetone–hexane mixture, melted at 160–161.5° (lit.[25] m.p. 161°) for a 65.8% yield.

2. The Formation of *rac.*-α,α'-Dimethoxysuccinic Acid (XIV).—To a 20 ml. of concd. (sp. gr. 1.42) nitric acid there was added 1.5 g. (0.0041 mole) of *rac.*-2,3-dimethoxy-1,4-diiodobutane.[8] The mixture was allowed to react and was worked up as described in the previous section. There was obtained 0.22 g. (0.0012 mole) of XIV which, after recrystallization from acetone–hexane, melted at 168–169° (lit.[26] m.p. 168–171°) for a 29% yield. In a mixed m.p. determination with XIII the mixture melted at 140–150°.

M. The Formation of 2,3,5,6-Tetra-(iodomethyl)-*p*-dioxane (XVI).—A solution of 114 g. (0.35 mole) of mercuric nitrate dissolved in 200 ml. of water containing 30 ml. of concd. nitric acid was prepared and 1,4-butadiene was bubbled through at a rate of 2 bubbles/second. The reaction was assumed complete when a 0.5-ml. portion no longer gave a mercuric oxide precipitate when added to a 10% sodium hydroxide solution. During the course of the reaction a precipitate was formed which was removed by filtration and suspended in 50 ml. of 6 *N* nitric acid for 24 hr. The mixture was then added to a liter of 1 *N* sodium hydroxide. A slight liberation of free mercury accompanied this solution. A solution of 40 g. (0.24 mole) of potassium iodide dissolved in 200 ml. of water was added with vigorous stirring. A precipitate formed which was collected and then treated with 25 g. (0.1 mole) of iodine in a water–chloroform mixture. Upon evaporation of the chloroform by an air jet, a solid remained which was recrystallized from methanol to yield 2.0 g. (0.0031 mole) of compound assumed to be XVI, m.p. 206–206.5°.

Anal. Calcd. for $C_8H_{12}O_2I_4$: C, 14.83; H, 1.87; mol. wt., 648. Found: C, 14.87; H, 1.78; mol. wt., Rast method, 654.

Proximity Effects. IV. Reaction of Cycloöctene Dibromide with Silver Acetate[1]

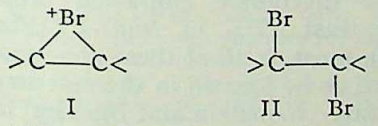
BY ARTHUR C. COPE AND GEOFFREY W. WOOD

RECEIVED MARCH 8, 1957

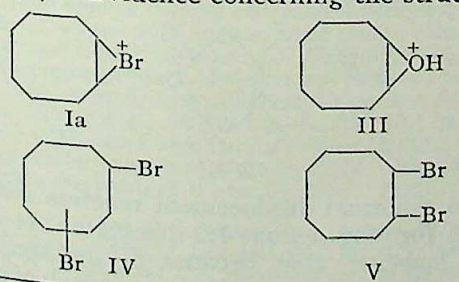
The reaction of cycloöctene dibromide with silver acetate in dry acetic acid has been shown to yield 3-cycloöcten-1-yl acetate, 4-cycloöcten-1-yl acetate, *cis*-1,4-cycloöctanediol diacetate, *trans*-1,4-cycloöctanediol diacetate and only a small amount of the expected *trans*-1,2-cycloöctanediol diacetate. The structures of the cycloöctenyl acetates have been elucidated by ozonolysis of the corresponding phenylurethans and reduction of the ozonides with sodium borohydride, followed by treatment with phenyl isocyanate to form the corresponding octanetriol tris-phenylurethans. Authentic specimens of 1,3,8- and 1,4,8-octanetriol tris-phenylurethans have been prepared for comparison. The course of the reactions leading to the abnormal products listed above is interpreted as resulting from the spatial proximity of opposite sides of the eight-membered ring.

The existence of a "transannular effect" (which we also term a "proximity effect") that influences the course of the reaction between cyclic olefins with medium-sized rings and performic acid has been reported recently.[2-4] In the case of *cis*-cycloöctene this influence results in the formation of a 1,4-cycloöctanediol as well as the expected *trans*-1,2-cycloöctanediol,[2] whereas with both *cis*- and *trans*-cyclononenes and cyclodecenes only the formation of abnormal products has been reported.[3,4] This paper describes the reaction between cycloöctene dibromide and silver acetate in dry acetic acid, which also has been found to be influenced by a "proximity effect."

Addition of bromine to *cis*-cycloöctene has been reported to give *trans*-1,2-dibromocycloöctane (V).[5-7] The addition of bromine to simple olefins is known to proceed *via* an intermediate bromonium ion (I), which then reacts with bromide ion to yield a *trans*-1,2-dibromide (II) (or the *threo* isomer from acyclic olefins).



In the addition of bromine to *cis*-cycloöctene the similarity between the structure of the intermediate bromonium ion Ia and that of protonated *cis*-cycloöctene oxide (III) suggested that the reaction of Ia with bromide ion might give a 1,x-dibromocycloöctane (IV) as well as *trans*-1,2-dibromocycloöctane (V). Evidence concerning the structure of the dibromide was obtained by considering the products formed by treating the dibromide with dimethylamine. This reaction has been found[5,8] to yield 1-bromocycloöctene in 70–77% yield. These observations indicate that the crude dibromide obtained by the addition of bromine to *cis*-cycloöctene probably contains at least 77% of V, although the possibility exists that other dibromides (IV) could be dehydrobrominated abnormally forming 1-bromocycloöctene.



The cycloöctene dibromide described above was treated with silver acetate in dry acetic acid[9] to yield a mixture of acetates, which could be separated by distillation into two fractions. The lower boiling fraction (56–58%) on redistillation afforded material which proved to be a mixture of isomers with the molecular formula $C_{10}H_{16}O_2$. The infrared absorption spectrum of this material contained bands indicative of an isolated ethylenic linkage (3000 and 1620 cm.$^{-1}$) and of an acetoxyl group (1725 and 1200 cm.$^{-1}$) and showed that it was different from the isomeric 2-cycloöcten-1-yl acetate[10] and 1-cycloöcten-1-yl acetate. A specimen of the latter compound was prepared from cycloöctanone and isopropenyl acetate.[11] Saponification of the mixture of acetates gave the corresponding unsaturated alcohols ($C_8H_{14}O$), which on hydrogenation over a platinum catalyst absorbed one mole of hydrogen and formed cycloöctanol, characterized as the phenylurethan. These results established the fact that the unsaturated alcohol fraction was 3-cycloöcten-1-ol (VI) or 4-cycloöcten-1-ol (VII) or a mixture of VI and VII.

The unsaturated alcohol fraction gave a mixture of phenylurethans, which was partially separated by chromatography over alumina into 3-cycloöcten-1-yl phenylurethan (IX), m.p. 101.5–102.5°, and a phenylurethan with m.p. 73–74° that is shown in the following paper to be a mixture of the isomers IX and X. The structures of the phenylurethans IX and XI and the presence of X in the mixture with m.p. 73–74° were proved by ozonolysis, followed by reduction of the ozonides to give (after treatment with phenyl isocyanate) the corresponding *n*-octanetriol tris-phenylurethans XII, XIII and XIV. Some trial ozonizations with XI

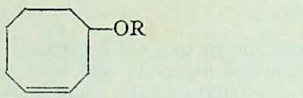
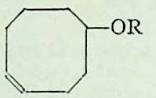
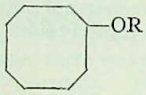
indicated that the ozonide was very unstable, decomposing before it could be reduced to the corresponding triol monophenylurethan by a catalytic hydrogenation procedure. It was found that when a solution of ozone in ethyl acetate at −70°[12]



VI, R = H
IX, R = $OCNHC_6H_5$



VII, R = H
X, R = $OCNHC_6H_5$



VIII, R = H
XI, R = $OCNHC_6H_5$

$RO(CH_2)_5CH(OR)(CH_2)_2OR$
XII, R = $OCNHC_6H_5$

$RO(CH_2)_4CH(OR)(CH_2)_3OR$
XIII, R = $OCNHC_6H_5$

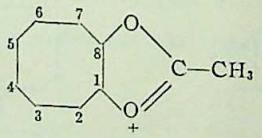
$RO(CH_2)_6CH(OR)CH_2OR$
XIV, R = $OCNHC_6H_5$

was added to a solution of XI in ethyl acetate at −70° until a faint blue color persisted, followed by the immediate addition of an excess of sodium borohydride dissolved in methanol, that XIV could be isolated after treatment with phenyl isocyanate in 90% yield.

In a similar manner IX and the mixture melting at 73–74° that contained X were ozonized, reduced and treated with phenyl isocyanate to give XII and XIII, respectively. It was found that the higher melting phenylurethan corresponded to IX and that it was identical with the phenylurethan prepared from the mixture of cycloöctenols formed in the solvolysis of *cis*-cycloöctene oxide.[13] The identities of XII and XIII were established by a comparison of their melting points and infrared absorption spectra with those of authentic specimens described below.

The physical properties and infrared absorption spectrum of the high boiling fraction (23%) from the reaction of cycloöctene dibromide with silver acetate indicated that it was a mixture of cyclooctanediol diacetates. Hydrolysis of this fraction gave a mixture of the corresponding diols. It was possible to separate all of the 1,2-cycloöctanediol from the diol mixture as the isopropylidene ketal, formed by treating the mixture with acetone and anhydrous cupric sulfate.[14] Chromatography of the resultant mixture separated the less polar isopropylidene ketal from the more polar, and hence more strongly absorbed, cycloöctanediols. This chromatographic procedure for the separation of isopropylidene ketals from glycols has been found to be more convenient than the previous method which involved distillation[2] and has been used throughout this work. The isopropylidene ketal obtained in this way was shown to be derived from *trans*-1,2-cycloöctanediol by comparison of boiling point, index of refraction and infrared absorption spectrum with data for an authentic specimen. Solvolysis of the isopropylidene ketal with formic acid, followed by hydrolysis of the monoformate which was formed, gave *trans*-1,2-cycloöctanediol in 10% yield from the crude diol mixture (2.3% from cycloöctene dibromide). This compound was further characterized by conversion to the bis-*p*-nitrobenzoate. After removal of all of the *trans*-1,2-cycloöctanediol from the crude diol mixture, the residue was chromatographed over alumina and thereby separated into four main fractions. The first fraction (36%, or 8.3% from cycloöctene dibromide) on crystallization from ethyl acetate yielded a material with m.p. 90–91°, which depressed the melting point of the known *cis*-1,4-cycloöctanediol. Elemental analysis and conversion to a bis-phenylurethan indicated that this material was a cycloöctanediol. The diol was identified as *trans*-1,4-cycloöctanediol by preparation of the bis-*p*-nitrobenzoate.[15] Continued development of the chromatogram yielded an intermediate fraction (20%, 4.6% based on cycloöctene dibromide) followed by pure *cis*-1,4-cycloöctanediol (10%, 2.3% based on cycloöctene dibromide), which was further characterized as the bis-*p*-nitrobenzoate. Further development of the chromatogram gave a more polar fraction (17%, 3.9% based on cycloöctene dibromide), which could not be induced to crystallize and has not been identified.

It is of interest that only a 2.3% yield of the "normal" product of reaction of cycloöctene dibromide and silver acetate (*trans*-1,2-cycloöctanediol diacetate) could be isolated while larger amounts of the "abnormal" products, acetates of VI and VII and diacetates of *cis*- and *trans*-1,4-cycloöctanediols, were isolated. Since as previously noted the cycloöctene dibromide employed probably contained at least 77% of *trans*-1,2-dibromocyclooctane (V), most or all of these abnormal products are believed to be formed in the reaction of V with silver acetate. Winstein and Buckles[9] have shown that *trans*- or *threo*-1,2-dibromo compounds react with silver acetate *via* a cyclic acetoxonium ion. In this case the intermediate may be represented by XVII. This intermediate has a structure somewhat similar to the protonated epoxide III, which is an intermediate in the "abnormal" hydroxylation of *cis*-cycloöctene. XVII would be expected to



XVII

undergo a normal displacement reaction with acetate ion forming a *trans*-1,2-diacetate. It is suggested, however, that because of the steric hindrance at C_1, which retards the approach of acetate ion, a transannular hydride shift from C_3 or C_5 to C_1 occurs with concomitant attack by an acetate ion at the relatively unhindered C_3- or C_5-position, forming both stereoisomeric 1,4-cycloöctanediol diacetates. As in the case of *cis*-cycloöctene oxide,[2] it is thought that a 1,3(or 1,5)-hydride shift will be particularly facile because of the close spatial

proximity of the transannular hydrogen atoms. The loss of a proton from C_2, C_4 or C_6 instead of attack by acetate ion at C_3 or C_5 would give rise to the 3- and 4-cycloöcten-1-yl acetates.

Authentic specimens of the *n*-octanetriol *tris*-phenylurethans obtained from the ozonolysis of IX and X were prepared by the following methods.

Lithium aluminum hydride reduction of dimethyl 4-ketosuberate[16] gave 1,4,8-octanetriol, which on treatment with phenyl isocyanate gave XIII identical with the product obtained from X.

Condensation of the magnesium derivative of diethyl malonate with δ-carbethoxyvaleryl chloride gave after hydrolysis the substituted malonic ester XV. This compound when heated with a catalytic amount of 2-naphthalenesulfonic acid[17] at 200–220° for 7 hr. decomposed to give diethyl 3-ketosuberate (XVI).

$$EtOOC(CH_2)_4COCH(COOEt)_2 \qquad XV$$

$$EtOOC(CH_2)_4COCH_2COOEt \qquad XVI$$

Since the reduction of β-ketoesters with lithium aluminum hydride sometimes gives anomalous results,[18] the carbonyl group in XVI was first reduced with sodium borohydride. The resulting hydroxyester on reduction with lithium aluminum hydride gave 1,3,8-octanetriol, which on treatment with phenyl isocyanate gave XII identical with the product obtained from IX.

Experimental[19,20]

Cycloöctene Dibromide.—A solution of bromine (32 g., 10.9 ml.) in carbon tetrachloride (100 ml.) was added dropwise, with stirring, to a solution of *cis*-cycloöctene (22 g.) in carbon tetrachloride (50 ml.). The internal temperature was maintained between 0–5° during the course of the addition with an external ice–salt cooling bath. The reaction mixture was kept at room temperature for either 1 hr. or overnight, after which the solvent was removed under reduced pressure below 30°. The residue on distillation afforded cycloöctene dibromide (43.5 g., 80%), b.p. 70° (0.15 mm.), $n^{25}D$ 1.5526.

Reaction of Cycloöctene Dibromide with Silver Acetate.—A suspension of silver acetate (44 g.) in glacial acetic acid (100 ml.) and acetic anhydride (5 ml.) was heated at 110° in an oil-bath, with stirring and exclusion of atmospheric moisture for 90 minutes. Cycloöctene dibromide (27 g.) was added dropwise to the foregoing suspension, and the stirring and heating were continued for 14 hr. The reaction mixture was then cooled, diluted with ether and filtered. The organic extract was washed with seven 150-ml. portions of water, with sodium bicarbonate solution until acid free and finally with water. After drying over anhydrous magnesium sulfate, the ether was removed on a steam-bath. The residue on distillation afforded a low boiling fraction (A) (9.8 g., 58%), b.p. 62–65° (0.1 mm.), $n^{25}D$ 1.4694–1.4720, and a high boiling residue (B) (5.2 g., 23%). In three similar experiments the yields of A were 56, 56 and 58%, while the yields of B were 24, 23 and 24%.

Fraction A.—Fractional distillation of A through a semi-micro column[21] yielded a mixture of isomeric cycloöctenyl acetates, b.p. 50° (0.14 mm.), $n^{25}D$ 1.4691.

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59. Found: C, 71.20; H, 9.71.

Hydrolysis of Fraction A.—Fraction A (15.8 g.) in methanol (220 ml.) was heated under gentle reflux for 1 hour with a solution of sodium hydroxide (20 g.) in water (25 ml.). After removal of the bulk of the methanol under reduced pressure, the residue was diluted with water (150 ml.) and extracted with six 75-ml. portions of ether. After drying the extract with magnesium sulfate, the ether was removed on a steam-bath. The residue (10.96 g., 87%) was distilled through a column with a spinning band (30 × 0.8-cm.) to give five fractions, b.p. 69–69.2° (3.00 mm.), $n^{27.5}D$ 1.4958–1.4965. Fraction 3 ($n^{25}D$ 1.4960) was submitted for analysis.

Anal. Calcd. for $C_8H_{14}O$: C, 76.14; H, 11.18. Found: C, 76.36; H, 11.26.

Hydrogenation of a sample of the unsaturated alcohol (252 mg.) in acetic acid (17 ml.) in the presence of 200 mg. of prereduced platinum oxide was complete after the absorption of 102% of one molar equivalent of hydrogen in 1 hr. The reduction product was identified as cycloöctanol by conversion to the phenylurethan, m.p. 56–58°, which was undepressed on admixture with an authentic specimen.

Phenylurethans of the Alcohols Obtained from Fraction A.—The mixture of alcohols (500 mg.) was warmed on a steam-bath with phenyl isocyanate (650 mg.) in a sealed flask for 5–10 minutes. After keeping at room temperature overnight the excess phenyl isocyanate was removed under reduced pressure (50° at 0.01 mm.) to give the phenylurethans as a white solid (1.0 g.). The foregoing solid was dissolved in benzene and passed onto a column of alumina (120 g. of Grade "H"). Elution with benzene:ether (9:1) and benzene:ether (3:1) mixtures afforded a series of crystalline fractions. The early fractions were combined and crystallized from aqueous methanol to give 140 mg. of a mixture (see following paper), m.p. 73–74°, containing the phenylurethans IX and X.

Anal. Calcd. for $C_{15}H_{19}O_2N$: C, 73.43; H, 7.81. Found: C, 73.21; H, 7.76.

The last fractions from the chromatograms were combined and recrystallized from aqueous methanol to give 3-cycloocten-1-yl phenylurethan (IX) (140 mg.), m.p. 101.5–102.5°.

Anal. Calcd. for $C_{15}H_{19}O_2N$: C, 73.43; H, 7.81. Found: C, 73.17; H, 7.68.

Ozonolysis of 2-Cycloöcten-1-yl Phenylurethan.—A saturated solution of ozone in ethyl acetate at −70° was added dropwise with swirling to a solution of the phenylurethan (200 mg.) in ethyl acetate (15 ml.) at −70° until a faint blue color persisted. A solution of sodium borohydride (0.5 g.) in methanol (15 ml.) was then added in one portion and the solution was allowed to warm to room temperature. After 2 hr. it was poured into dilute hydrochloric acid and extracted with ether. Removal of the ether gave a gum (220 mg.), which on treatment with phenyl isocyanate gave 1,2,8-octanetriol tris-phenylurethan (390 mg., 92%), m.p. 122–124°. An analytical sample that was crystallized from aqueous methanol had m.p. 134.5–135.5°.

Anal. Calcd. for $C_{29}H_{33}O_6N_3$: C, 67.02; H, 6.40. Found: C, 67.10; H, 6.14.

Treatment of 3-cycloöcten-1-yl phenylurethan in a similar manner gave 1,3,8-octanetriol tris-phenylurethan, m.p. 143.5–145° (from aqueous methanol).

Anal. Calcd. for $C_{29}H_{33}O_6N_3$: C, 67.02; H, 6.40. Found: C, 67.06; H, 6.55.

Treatment of the mixture of phenylurethans, m.p. 73–74° (see the following paper), in a similar manner gave 1,4,8-octanetriol tris-phenylurethan, m.p. 127–128° (from aqueous methanol), proving that it contained X. Neither of the above tris-phenylurethans depressed the melting points of the corresponding authentic specimens (see below). The mixed melting points of mixtures of *n*-octanetriol tris-phenylurethans are: 1,2,8 and 1,3,8, mixed m.p. 118–122°; 1,2,8 and 1,4,8, mixed m.p. 115–118°; 1,3,8 and 1,4,8, mixed m.p. 113–117°.

1,4,8-Octanetriol Tris-phenylurethan.—An excess of diazomethane in ether was added with gentle swirling to a suspension of 4-ketosuberic acid[16] (850 mg.) in ether. After the vigorous reaction had subsided, the solvent was removed under reduced pressure to give the corresponding dimethyl ester as an oil (980 mg.). The foregoing ester was dissolved in anhydrous ether (50 ml.) and added to a solution of lithium aluminum hydride (600 mg.) in dry ether (100 ml.). The solution was heated under gentle reflux for 2 hr., after which the excess lithium aluminum hydride was decomposed with ethyl acetate. Dilute sulfuric acid was added to dissolve the inorganic salts, and the reaction mixture was then extracted continuously with chloroform for 5 days to give 1,4,8-octanetriol as a viscous gum. The foregoing triol (330 mg.) was treated with phenyl isocyanate as described before to give a gum (950 mg.), which crystallized with difficulty from aqueous methanol to give 1,4,8-octanetriol tris-phenylurethan, m.p. 127.5–128.5°.

Anal. Calcd. for $C_{29}H_{33}O_6N_3$: C, 67.02; H, 6.40. Found: C, 66.71; H, 6.44.

Diethyl 3-Ketosuberate.—Diethyl malonate (16.2 g.), absolute ethanol (10.5 ml.), dry ether (30 ml.), carbon tetrachloride (0.1 ml.) and clean magnesium turnings (2.5 g.) were heated under gentle reflux with stirring for 3 hr. The reaction mixture was protected from atmospheric moisture with calcium chloride tubes. To the above mixture was added a solution of δ-carbethoxyvaleryl chloride (21 g.) in dry ether (50 ml.) at such a rate that the ether boiled gently. The mixture was then stirred and heated under gentle reflux for 1 hr. Sulfuric acid (40 ml. of 10% by volume) was added slowly with stirring after which the mixture was extracted with ether. Removal of the ether, after drying over magnesium sulfate, gave a residue (34 g.), which was heated with 2-naphthalenesulfonic acid (1.5 g.) in an oil-bath at 190–200° for 4 hr. and at 220° for 3.5 hr., by which time the evolution of carbon dioxide had ceased. The reaction mixture was cooled, diluted with ether and washed with saturated sodium bicarbonate solution. Removal of the ether gave a dark residue, which was flash distilled to give 20.2 g. of a colorless distillate, b.p. 45–140° (0.5 mm.). Fractionation gave substantially pure diethyl 3-ketosuberate (11.1 g., 45%). A sample redistilled for analysis had b.p. 118° (0.55 mm.), $n^{25}D$ 1.4480.

Anal. Calcd. for $C_{12}H_{20}O_5$: C, 58.99; H, 8.25. Found: C, 59.31; H, 8.26.

1,3,8-Octanetriol Tris-phenylurethan.—Diethyl 3-ketosuberate (1.25 g.) was dissolved in methanol (10 ml.) and added dropwise to a stirred solution of sodium borohydride (0.5 g.) in methanol (35 ml.) containing one drop of 3 *N* sodium hydroxide solution. The mixture was stirred at room temperature for 45 minutes and then acidified with dilute hydrochloric acid and extracted with ether. The dried ether extract was concentrated under reduced pressure at room temperature and then dissolved in anhydrous ether and added to a solution of lithium aluminum hydride (1.0 g.) in dry ether (50 ml.). The mixture was stirred and heated under gentle reflux for 1 hr. After the excess reagent had been decomposed with ethyl acetate, the reaction mixture was acidified with hydrochloric acid, the ether removed under reduced pressure and the residue extracted continuously with chloroform for 36 hr. to give 1,3,8-octanetriol as a viscous gum (1.1 g.). Treatment of the foregoing triol (300 mg.) with phenyl isocyanate afforded (after crystallizing from aqueous methanol) 1,3,8-octanetriol tris-phenylurethan, m.p. 142.5–144.5°.

Hydrolysis of Fraction B.—Fraction B (7.75 g.) in methanol (200 ml.) was heated under gentle reflux for 1 hr. with a solution of sodium hydroxide (20 g.) in water (25 ml.). After removal of the bulk of the methanol under reduced pressure, the residue was diluted with water (75 ml.) and then extracted continuously with chloroform overnight to give a mixture of diols (4.8 g.). The foregoing diols were dissolved in acetone (150 ml.) and stirred overnight in a stoppered flask with anhydrous cupric sulfate (12 g.). After removal of the cupric sulfate and the acetone the residue was dissolved in benzene and passed onto a column of alumina (100 g., Grade III). Elution with benzene afforded *trans*-1,2-cycloöctanediol isopropylidene ketal (700 mg.), b.p. 109° (22 mm.), $n^{25}D$ 1.4585. Elution with ether:methanol (3:1) afforded a mixture of cycloöctanediols (4.12 g.). The foregoing *trans*-1,2-cycloöctanediol isopropylidene ketal (700 mg.) was dissolved in 88% formic acid (20 ml.) and heated on a steam-bath for 2 hr. After removal of the bulk of the formic acid under reduced pressure, the residue was dissolved in methanol (50 ml.) and heated under gentle reflux with a solution of sodium hydroxide (8 g.) in water (15 ml.) for 30 minutes. After removal of the methanol under reduced pressure, the residue was diluted with water (30 ml.) and then extracted continuously with chloroform for 18 hr. Removal of the chloroform gave *trans*-1,2-cycloöctanediol (480 mg.) as a sirup. The bis-*p*-nitrobenzoate formed short needles from ethyl acetate:methanol with m.p. 105–106°, which was undepressed on admixture with an authentic specimen.

The mixture of cycloöctanediols (4.14 g.) after removal of all of the *trans*-1,2-cycloöctanediol as the isopropylidene ketal was dissolved in the minimum amount of chloroform and passed onto a column of alumina (350 g., Grade III). Elution with ether:methanol (1600 ml., 99:1) gave *trans*-1,4-cycloöctanediol (1.6 g.), which after crystallizing from ethyl acetate had m.p. 90–91°.

Anal. Calcd. for $C_8H_{16}O_2$: C, 66.62; H, 11.18. Found: C, 66.45; H, 10.94.

The foregoing diol gave a bis-*p*-nitrobenzoate, which after crystallizing from ethyl acetate:methanol formed needles, m.p. 156–156.6°, undepressed on admixture with an authentic specimen.[15] Treatment of the diol with phenyl isocyanate in the manner described for the alcohols obtained from fraction A afforded (after crystallizing from ethyl acetate) *trans*-1,4-cycloöctanediol bis-phenylurethan, m.p. 180.2–181.7°.

Anal. Calcd. for $C_{22}H_{26}O_4N_2$: C, 69.09; H, 6.85. Found: C, 69.16; H, 6.95.

Continued elution with the same solvent mixture gave an intermediate fraction (960 mg.), m.p. 70–78°. Elution with ether:methanol (98:2) gave *cis*-1,4-cycloöctanediol (450 mg.), m.p. 82–83°, which was undepressed on admixture with an authentic specimen. Elution with ether:methanol (3:1) afforded a more polar material (820 mg.) which has not been identified.

1-Cycloöcten-1-yl Acetate.—Cycloöctanone (2.52 g.), isopropenyl acetate (4.0 g.) and *p*-toluenesulfonic acid (50 mg.) were heated together at a bath temperature of 95° for 3 hr. Acetone (0.7 ml.) was removed through a semimicro column. The reaction mixture was poured into water and extracted with ether. After removal of the ether, the residue was fractionated under reduced pressure to yield the enol acetate, b.p. 50° (0.15 mm.), $n^{25}D$ 1.4697.

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59. Found: C, 71.52; H, 9.60.

Proximity Effects. V. Reaction of Cycloöctene Dibromide with Tetraethylammonium Acetate

BY ARTHUR C. COPE AND HERBERT E. JOHNSON[1]

RECEIVED MARCH 8, 1957

The reaction of cycloöctene dibromide with tetraethylammonium acetate in acetone, unlike the reaction with silver acetate in acetic acid, has been found to yield only normal elimination and displacement products, rather than compounds formed by "transannular reactions." The compounds isolated were 1-bromocycloöctene (9%), 2-cycloöcten-1-yl acetate (45%), *cis*-2-bromocycloöctyl acetate (9%) and *trans*-1,2-cycloöctanediol diacetate (5%). *trans*-2-Bromocycloöctyl acetate has been prepared from *cis*-cycloöctene oxide and hydrogen bromide and shown to react with tetraethylammonium acetate to form 2-cycloöcten-1-yl acetate (45%) and *cis*-1,2-cycloöctanediol diacetate (17%). The reaction of cycloöctene dibromide with silver acetate in dry acetic acid at 60° has been found to give the same products in approximately the same yields that were obtained at 110–120°.

The results described in the preceding paper[2] show that the reaction of cycloöctene dibromide with silver acetate in dry acetic acid yields only a small amount (2.3%) of *trans*-1,2-cycloöctanediol diacetate, the remaining products being formed by "transannular reactions." Indirect evidence showed that the liquid cycloöctene dibromide probably contained a minimum of 77% of *trans*-1,2-dibromocycloöctane, indicating that most or all of the "transannular products" are formed during the reaction of cycloöctene dibromide with silver acetate, rather than in the addition of bromine to cycloöctene. Since the reaction of silver acetate with halides proceeds by an ionization (SN1) mechanism,[3] it was of interest to investigate the reaction of cycloöctene dibromide with a reagent known to react by a bimolecular (SN2) mechanism. This paper describes the reaction with such a reagent, tetraethylammonium acetate.[4]

Reaction of cycloöctene dibromide with tetraethylammonium acetate in refluxing acetone for 17 hr. resulted in incomplete reaction, and 20% of the dibromide was recovered. Extension of the reaction time to 72 hr. produced essentially complete reaction, and only 1% of the dibromide was recovered. Distillation of the products gave two low boiling fractions: (1) 9% of 1-bromocycloöctene and (2) 45% of 2-cycloöcten-1-yl acetate (yields based on cycloöctene dibromide). The identity of fraction 1 was established by comparison of the physical properties and infrared spectrum with data for an authentic sample of 1-bromocycloöctene. Hydrolysis of fraction 2 followed by the reaction of the resulting alcohol with phenyl isocyanate formed 2-cycloöcten-1-yl phenylurethan, identical by comparison of melting point, mixed melting point and infrared spectra with an authentic sample.[5] The absence of isomeric phenylurethans was established by chromatography of the derivative.

Chromatography of the higher boiling material (fraction 3) on alumina yielded: (a) 1% of cycloöctene dibromide, (b) 9% of *cis*-2-bromocycloöctyl acetate and (c) 5% of *trans*-1,2-cycloöctanediol diacetate.

Hydrolysis of (b) with dilute sulfuric acid formed a 2-bromocycloöctanol which was converted into a 3,5-dinitrobenzoate, m.p. 116.5–117.5°. This derivative was found to be identical with an authentic sample of *cis*-2-bromocycloöctyl 3,5-dinitrobenzoate, which was prepared by the following method. Bromination of cycloöctanone with N-bromosuccinimide formed 2-bromocycloöctanone, which was reduced with sodium borohydride to a mixture of *cis*- and *trans*-2-bromocycloöctanol. The mixture yielded two 3,5-dinitrobenzoates, m.p. 117.0–117.5° and 94–95°, which were separated by crystallization from hexane. The lower melting derivative was identified as the *trans* isomer by comparison with an authentic sample, obtained as follows. The reaction of *cis*-cycloöctene oxide with anhydrous hydrogen bromide in carbon tetrachloride formed *trans*-2-bromocycloöctanol. This alcohol formed a 3,5-dinitrobenzoate, m.p. 95.0–95.6°, that was identical (mixed m.p. and comparison of infrared spectra) with the derivative melting at 94–95° obtained from the mixture of 2-bromocycloöctanols formed by reduction of 2-bromocycloöctanone. The higher melting 3,5-dinitrobenzoate isolated from the mixture, m.p. 117.0–117.5°, accordingly is the *cis* isomer.

Fraction c was saponified and the neutral product was treated with acetone and anhydrous copper sulfate. Subsequent purification by chromatography yielded the isopropylidene ketal of *trans*-1,2-cycloöctanediol, identified by comparison of the infrared spectrum with the spectrum of an authentic sample and showed that no other glycols were present.

The formation of unsaturated compounds from cycloöctene dibromide and tetraethylammonium acetate probably occurs by an elimination process (E2) in which acetate ion serves as the base. Two products could be formed initially by such a process, 1-bromocycloöctene and 3-bromocycloöctene. The first of these compounds was one of the products isolated, while the second would react with tetraethylammonium acetate under the conditions employed to form 2-cycloöcten-1-yl acetate, which also was isolated. Another possible route to 2-cycloöcten-1-yl acetate would involve initial formation of a 2-bromocycloöctyl acetate (probably the *cis* isomer, which has been shown to be one of

the products), followed by elimination of hydrogen bromide, with acetate ion serving as the base.

trans-1,2-Cycloöctanediol diacetate, the only glycol derivative isolated from the reaction mixture, could be formed either through a succession of neighboring group participations,[3] or more probably by two Walden inversions, with *cis*-2-bromocycloöctyl acetate as an intermediate. Insufficient *cis*-2-bromocycloöctyl acetate was available to determine whether it would react with tetraethylammonium acetate with inversion. However, the reaction of the more accessible *trans*-2-bromocycloöctyl acetate with tetraethylammonium acetate in refluxing acetone for 72 hr. gave 45% of 2-cycloöcten-1-yl acetate and 17% of *cis*-1,2-cycloöctanediol diacetate (formed by inversion) as the only isolable products. With the shorter reaction time of 24 hr., 43% of the original *trans*-2-bromocycloöctyl acetate was recovered. The observation that *trans*-2-bromocycloöctyl acetate and tetraethylammonium acetate form *cis*-1,2-cycloöctanediol diacetate leads to the conclusion that the intermediate in the reaction in which *trans*-1,2-cycloöctanediol diacetate is formed from cycloöctene dibromide is *cis*-2-bromocycloöctyl acetate.

It is of interest that all of the products isolated from the reaction of cycloöctene dibromide and tetraethylammonium acetate can be formed by normal displacement or elimination reactions from *trans*-1,2-dibromocycloöctane. This result provides good evidence that cycloöctene dibromide is essentially homogeneous and is the *trans*-1,2-dibromide. If appreciable amounts of a dibromide other than the 1,2-isomer had been present, the diacetate formed from it by a normal displacement reaction should have been isolated as a glycol after saponification. As noted above, only the *trans*-1,2-glycol was isolated (as the isopropylidene ketal, by chromatography), under conditions capable of revealing the presence of a fraction of 1% of an isomer.

The results of the bimolecular displacement reaction of cycloöctene dibromide with tetraethylammonium acetate leading solely to normal products are in contrast to the reaction of the dibromide with silver acetate in dry acetic acid, in which abnormal "transannular" products are formed predominantly.[2] A conclusion that receives strong support from these data is that the transannular hydride shift characterizing the "transannular reactions" is favored by the transitory formation of a carbonium ion, as in the removal of bromide ion from cycloöctene dibromide by silver ion (S_N1 or ionization mechanism), and does not occur in the bimolecular nucleophilic displacement (S_N2, reaction with tetraethylammonium acetate. Other "transannular reactions" observed to date have involved the reaction of cyclic olefins with medium-sized rings with performic acid,[6,7] acid hydrolysis or solvolysis of the epoxides of such cyclic olefins[6,8] and the reaction of cyclodecylamine with nitrous acid.[9] All of these reactions were conducted in polar media and proceed through intermediates with at least partially charged (ionic) character. In contrast, reactions involving cyclic compounds with ring sizes favoring "transannular reactions" that have been observed to give only normal products in non-polar media include, in addition to the reaction of cycloöctene dibromide with tetraethylammonium acetate in acetone, the addition of bromine to *cis*-cycloöctene in carbon tetrachloride forming *trans*-1,2-dibromocycloöctane and the reaction of hydrogen bromide with *cis*-cycloöctene oxide in carbon tetrachloride forming *trans*-2-bromocycloöctanol.

In order to make certain that the strikingly different course of the reaction of cycloöctene dibromide with silver acetate[2] and tetraethylammonium acetate was not due in part to a temperature effect, the reaction with silver acetate (previously conducted at 110–120°) was repeated at 60°. The high-boiling diacetate fraction was saponified and gave the same yields of *cis*- and *trans*-1,4-cycloöctanediol and *trans*-1,2-cycloöctanediol that were formed at 110–120°.[2] No 1-bromocycloöctene appeared to be present in the low-boiling fraction. The cycloöctenyl acetate fraction was saponified and the mixture of cycloöctenols was converted to a mixture of phenylurethans, which was chromatographed as before.[2] The first fractions eluted yielded a small amount of 4-cycloöcten-1-yl phenylurethan, m.p. 92–94°, identical with a slightly purer sample, m.p. 93–94°, obtained by the cleavage of 1,4-epoxycycloöctane with acetic anhydride and boron trifluoride.[10] The identity of this derivative was established by ozonization, reduction of the ozonide with sodium borohydride and treatment with phenyl isocyanate, which formed the known 1,4,8-octanetriol tris-phenylurethan.[2] Proof that the previously isolated[2] phenylurethan of m.p. 73–74° was a mixture was obtained by cocrystallization of equal quantities of 3-cycloöcten-1-yl phenylurethan and 4-cycloöcten-1-yl phenylurethan. The material that crystallized had an infrared spectrum identical to the spectrum of the phenylurethan of m.p. 73–74°. As before, the majority of the fractions from the chromatogram were mixtures of 3- and 4-cycloöcten-1-yl phenylurethan, while the final fractions yielded 3-cycloöcten-1-yl phenylurethan, m.p. 102–103°.

Experimental[11]

Reaction of *trans*-1,2-Dibromocycloöctane with Tetraethylammonium Acetate.—A solution of 22.3 g. (0.0825 mole) of cycloöctene dibromide and 62.2 g. (0.30 mole) of tetraethylammonium acetate monohydrate[4c] in 300 ml. of dry acetone was refluxed for 72 hr. At this time the acetone was removed by warming under reduced pressure and the pasty residue was taken up in water and ether. The ether layer was separated and the aqueous phase further extracted with ether. Combination of the ether extracts, drying over anhydrous magnesium sulfate and distillation of the ether left a light yellow residue. Fractional distillation of this

Digitized by Arya Samaj Foundation Chennai and eGangotri

material gave three fractions: (1) 1.44 g. (9%), b.p. 35–40° (0.2 mm.), $n^{25}D$ 1.5003; (2) 6.26 g. (45%), b.p. 49–51° (0.2 mm.), $n^{25}D$ 1.4688; (3) 3.98 g., b.p. 75–79° (0.2 mm.), $n^{25}D$ 1.4830.

Fraction 1 was dissolved in petroleum ether and passed onto a column of 10-mm. diameter containing 65 g. of grade I alumina. Elution with 160 ml. of petroleum ether gave 0.94 g. of a volatile liquid. Distillation of this material afforded 1-bromocycloöctene, b.p. 108° (30 mm.), $n^{25}D$ 1.5150, with an infrared spectrum identical with the spectrum of an authentic sample.[12]

A portion of **fraction 2** was saponified and converted to its phenylurethan by a procedure previously described.[2] Chromatography of 2.54 g. of this material over 200 g. of grade I alumina in a 24-mm. diameter column and elution with benzene–ether (9:1) gave 2-cycloöcten-1-yl phenylurethan as a colorless solid, m.p. 92.5–93.5°, in 80% yield. The mixed melting point of this derivative with an authentic sample[5] showed no depression, and comparison of the infrared spectra showed them to be identical. Although the last fractions (5% of the phenylurethan isolated) eluted from the column were somewhat impure as indicated by the range in melting point, no derivative could be isolated from them other than 2-cycloöcten-1-yl phenylurethan.

Fraction 3 was dissolved in petroleum ether and passed onto a column of 24-mm. diameter containing 200 g. of grade I alumina. Elution with 600 ml. of petroleum ether gave (a) 0.25 g. (1%) of cycloöctene dibromide, $n^{25}D$ 1.5510, identified by comparison of its infrared spectrum with that of an authentic sample. Elution with 800 ml. of 10% ether in petroleum ether gave (b) 1.87 g. (9%) of *cis*-2-bromocycloöctyl acetate. Distillation resulted in isolation of this compound as a colorless, pleasant-smelling liquid, b.p. 72° (0.25 mm.), $n^{25}D$ 1.4960.

Anal. Calcd. for $C_{10}H_{17}BrO_2$: C, 48.20; H, 6.88. Found: C, 48.47; H, 6.86.

A solution of 62 mg. of *cis*-2-bromocycloöctyl acetate in 8 ml. of methanol containing 1 ml. of concentrated sulfuric acid and 3 ml. of water was allowed to stand at room temperature for 16 hr. Most of the volatile material was removed below room temperature by evaporation under reduced pressure. The remaining residue was poured into water and the mixture was extracted with ether. After drying the extracts over anhydrous sodium sulfate, the ether was evaporated, leaving 52 mg. of a nearly colorless liquid. This material was treated with 99 mg. of *p*-toluenesulfonyl chloride and 55 mg. of 3,5-dinitrobenzoic acid in 10 ml. of dry pyridine[13] to give 68 mg. of a nearly white solid, m.p. 107–113°. One crystallization from hexane gave shiny, colorless plates, m.p. 116.5–117.5°. A mixed melting point with an authentic sample of *cis*-2-bromocycloöctyl 3,5-dinitrobenzoate (see below) showed no depression and the infrared spectra of the two compounds were identical in every respect.

Further elution of the column with 1700 ml. of 50% ether in petroleum ether gave (c) 0.97 g. (5%) of *trans*-1,2-cycloöctanediol diacetate. This material was saponified and converted to its isopropylidene ketal with acetone in the presence of anhydrous copper sulfate. Chromatography of the product according to the procedure previously described[2] revealed no isomeric cycloöctanediols, the ketal being the only material that was eluted from the column. The infrared spectrum of the eluted ketal was identical with that of an authentic sample of the isopropylidene ketal of *trans*-1,2-cycloöctanediol.

2-Bromocycloöctanone.—N-Bromosuccinimide (8.40 g., 0.047 mole) was added to a solution of 5.92 g. (0.047 mole) of cycloöctanone in 30 ml. of carbon tetrachloride, and the mixture was refluxed for 2 hr. During this time the reaction proceeded to completion as evidenced by the disappearance of the N-bromosuccinimide. After filtration of the succinimide the solvent was removed by heating under reduced pressure, leaving a dark residue. Distillation afforded 7.50 g. (78%) of 2-bromocycloöctanone as a colorless liquid, b.p. 65–73° (0.2–0.5 mm.), $n^{25}D$ 1.5126; a redistilled analytical sample had b.p. 79–81° (1 mm.), $n^{25}D$ 1.5161, d^{25}_4 1.382.[14]

Anal.[14] Calcd. for $C_8H_{13}BrO$: C, 46.85; H, 6.39; Br, 38.97. Found: C, 47.13; H, 6.41; Br, 38.94.

***cis*- and *trans*-2-Bromocycloöctanol.**—A solution of 2.0 g. (0.054 mole) of sodium borohydride in 50 ml. of absolute methanol was added over a period of 30 minutes to a solution of 2.74 g. (0.0134 mole) of 2-bromocycloöctanone in 20 ml. of absolute methanol. The temperature of the mixture was kept below 25° throughout the addition. After the mixture stood for an additional period of 2 hr. at room temperature, most of the methanol was removed by evaporation under reduced pressure. Fifty milliliters of water was added and the mixture was acidified with dilute hydrochloric acid. The mixture was extracted with ether, and the extracts were dried over anhydrous sodium sulfate and evaporated, leaving a nearly colorless liquid. Distillation gave 1.91 g. (69%) of a colorless liquid mixture of *cis*- and *trans*-2-bromocycloöctanol, b.p. 85–90° (0.7 mm.), $n^{25}D$ 1.5140. Redistillation afforded material of b.p. 72–75° (0.3 mm.), $n^{25}D$ 1.5172. The mixture was not analytically pure, presumably because of some hydrolysis or loss of hydrogen bromide.

***cis*- and *trans*-2-Bromocycloöctyl 3,5-Dinitrobenzoates.**—A 442-mg. sample of the bromohydrin mixture from the reduction of 2-bromocycloöctanone was converted in the usual manner with 460 mg. of 3,5-dinitrobenzoic acid, 820 mg. of *p*-toluenesulfonyl chloride and 15 ml. of pyridine to 766 mg. (94%) of a mixture of dinitrobenzoates, m.p. 82–94°. Three crystallizations from hexane gave pure *cis*-2-bromocycloöctyl 3,5-dinitrobenzoate as colorless, glistening plates, m.p. 117.0–117.5°.

Anal. Calcd. for $C_{15}H_{17}BrN_2O_6$: C, 44.90; H, 4.27; Br, 19.87. Found: C, 44.98; H, 4.39; Br, 19.72.

Evaporation of the mother liquors gave an oil that slowly solidified, m.p. 58–70°. Four crystallizations from hexane gave *trans*-2-bromocycloöctyl 3,5-dinitrobenzoate as colorless needles, m.p. 94–95°. A mixed melting point with an authentic sample (see below) was undepressed and the infrared spectra of the two compounds were identical.

Anal. Calcd. for $C_{15}H_{17}BrN_2O_6$: C, 44.90; H, 4.27; Br, 19.87. Found: C, 45.29; H, 4.52; Br, 20.20.

***trans*-2-Bromocycloöctanol.**—A slow stream of anhydrous hydrogen bromide was passed into a solution of 5.38 g. (0.043 mole) of *cis*-cycloöctene oxide in 50 ml. of carbon tetrachloride for a period of 2 hr. The temperature of the mixture was kept at approximately 20° by a cold water-bath. Evaporation of the solvent left a dark residue which was distilled, yielding 6.46 g. (74%) of *trans*-2-bromocycloöctanol as a colorless liquid, b.p. 80–88° (0.2 mm.), $n^{25}D$ 1.5246. Redistillation afforded material of b.p. 74–75° (0.1 mm.), $n^{25}D$ 1.5246.

Anal. Calcd. for $C_8H_{15}BrO$: C, 46.39; H, 7.30; Br, 38.59. Found: C, 46.13; H, 7.26; Br, 38.37.

A 393-mg. sample of the bromohydrin was treated with 410 mg. of 3,5-dinitrobenzoic acid and 744 mg. of *p*-toluenesulfonyl chloride in 15 ml. of pyridine to give 726 mg. (96%) of derivative, m.p. 90–92°. Three crystallizations from hexane gave pure *trans*-2-bromocycloöctyl 3,5-dinitrobenzoate as clusters of colorless needles, m.p. 95.0–95.6°.

***trans*-2-Bromocycloöctyl Acetate.**—A mixture of 5.95 g. (0.029 mole) of the *trans*-bromohydrin and 3.54 g. (0.035 mole) of acetic anhydride was cooled in an ice-bath. Several drops of concentrated sulfuric acid were added with swirling. After the initial reaction subsided, the mixture was kept at room temperature for 2 hr. and then diluted with 50 ml. of ether. Calcium carbonate was added, and after 30 minutes the mixture was filtered. The ether was evaporated and the residue distilled to give 6.87 g. (96%) of *trans*-2-bromocycloöctyl acetate as a colorless liquid, b.p. 84–85° (0.5 mm.), $n^{25}D$ 1.4962.

Anal. Calcd. for $C_{10}H_{17}BrO_2$: C, 48.20; H, 6.88; Br, 32.08. Found: C, 48.31; H, 6.94; Br, 32.34.

Reaction of *trans*-2-Bromocycloöctyl Acetate with Tetraethylammonium Acetate.—A solution of 3.28 g. (0.013 mole) of *trans*-2-bromocycloöctyl acetate and 6.0 g. (0.029 mole) of tetraethylammonium acetate monohydrate in 70 ml. of dry acetone was refluxed for 72 hr. At the end of this time the acetone was removed by warming under reduced

pressure and the product isolated as described above for the products of the reaction of cycloöctene dibromide with tetraethylammonium acetate to give 2.17 g. of a colorless liquid, b.p. 50–87° (0.4 mm.), $n^{25}D$ 1.4675. Redistillation of this material through a semimicro column gave: (a) 0.95 g. (45%), b.p. 41° (0.2 mm.), $n^{25}D$ 1.4675, identified as 2-cyclooctenyl-1-yl acetate by hydrolysis and conversion to the phenylurethan; (b) 0.40 g. of intermediate fractions, b.p. 41–82° (0.2 mm.), $n^{25}D$ 1.4675–1.4680; and (c) 0.51 g. (17%) of *cis*-1,2-cycloöctanediol diacetate, b.p. 82° (0.2 mm.), $n^{25}D$ 1.4645. A solution of 464 mg. of (c) in 10 ml. of methanol containing 5 ml. of water and 2 g. of sodium hydroxide was refluxed for 2 hr. After cooling, most of the methanol was removed by warming the mixture under reduced pressure. The residue was diluted with water and extracted continuously for 20 hr. with chloroform to give 235 mg. (80%) of a white solid, m.p. 69–75°. One crystallization from hexane gave 190 mg. of colorless glistening plates of *cis*-1,2-cycloöctanediol, m.p. and mixed m.p. with an authentic sample 78.0–78.5°.

Reaction of *trans*-1,2-Dibromocycloöctane with Silver Acetate at 60°.—To a stirred suspension of 42.5 g. (0.25 mole) of silver acetate in 200 ml. of glacial acetic acid and 20 ml. of acetic anhydride at room temperature was added 25.3 g. (0.095 mole) of cycloöctene dibromide. After 2 hr. at room temperature essentially no reaction had taken place. The mixture was then heated to 60° and held at that temperature for 24 hr. After that period the solids were collected on a filter, washed well with glacial acetic acid, slurried with 20% aqueous nitric acid, again separated by filtration, washed with water and dried, giving 33.7 g. (96%) of silver bromide. The acetic acid filtrates were returned to the reaction flask along with 10 g. of silver acetate and stirred for an additional period of 17 hr. at 60°. No more silver bromide precipitated. About 80% of the acetic acid was removed by warming under reduced pressure, and the remaining residue was poured into water. After thorough extraction of the mixture with ether, the extracts were washed with saturated sodium bicarbonate solution until free from acid. The extracts were dried over anhydrous potassium carbonate and evaporated, leaving a nearly colorless residue. Distillation of the residue gave 8.84 g. (57%) of an unsaturated acetate fraction, b.p. 110–112° (20 mm.), $n^{25}D$ 1.4680–1.4693, and 5.34 g. (26%) of a diacetate fraction, b.p. 95–102° (0.25 mm.), $n^{25}D$ 1.4650.

A sample of the unsaturated acetate fraction was saponified and converted to a mixture of phenylurethans. This mixture (4.53 g.) was chromatographed on 400 g. of grade I alumina in a 30-mm. diameter column, eluting with 4:1 petroleum ether:ether followed by 2:1 petroleum ether:ether. Thirty-two crystalline fractions were obtained. From the first three fractions material of m.p. 92–94° was obtained by repeated crystallization from hexane. A mixed melting point with 4-cycloöcten-1-yl phenylurethan of m.p. 93–94° obtained from another source[10] was undepressed, and the infrared spectra of the two compounds were identical with the exception of a small band at 10.2 μ and minor intensity differences indicating the presence of a small amount of an impurity in the derivative with m.p. 92–94°. Crystallization of the intermediate fractions from either hexane or methanol–water failed to narrow the melting range. From the last fractions, material of m.p. 102–103° was obtained as colorless needles from hexane. No depression in melting point was observed upon admixture of this derivative with an authentic sample of 3-cycloöcten-1-yl phenylurethan, and the infrared spectra of the two samples were found to be identical in detail.

A mixture of 21 mg. of the phenylurethan of m.p. 92–94° and 20 mg. of 3-cycloöcten-1-yl phenylurethan was crystallized from methanol–water to give 31 mg. of colorless needles, m.p. 76–78°. The infrared spectrum of this material was found to be identical in every respect to that of the mixture of phenylurethans, m.p. 73–74°, described in the preceding paper.[2]

Saponification of the diacetate fraction gave the same yields of *trans*-1,2-, 1,4- and *cis*-1,4-cycloöctanediol as reported in the preceding paper.[2]

Ozonolysis of 4-Cycloöcten-1-yl Phenylurethan.[15]—An ethyl acetate solution of 35 mg. of 4-cycloöcten-1-yl phenylurethan,[10] m.p. 93–94°, was ozonized, reduced and treated with phenyl isocyanate as previously described[2] to give 78 mg. (98%) of an octanetriol tris-phenylurethan. Several crystallizations from hexane gave 55 mg. of colorless crystals, m.p. 126.5–128.0°. One further crystallization from methanol–water afforded 38 mg. of 1,4,8-octanetriol tris-phenylurethan, m.p. and mixed m.p. with an authentic sample,[2] 127–128°. The infrared spectra of the two compounds were identical in every respect.

Proximity Effects. VI. Stereospecific Syntheses of *cis*- and *trans*-1,4-Cycloöctanediols

BY ARTHUR C. COPE AND BURTON C. ANDERSON

RECEIVED MARCH 8, 1957

1,4-Epoxycycloöctane (I) has been prepared by a sequence of reactions beginning with 3,6-epoxycycloheptanecarbonitrile (II and III, *cis* and *trans* isomers). Each of the nitriles was hydrogenated to a single primary amine, but in the synthesis a mixture of amines formed by hydrogenation of a mixture of II and III was employed. The mixture of amines (IV and V) was treated with nitrous acid, and the mixture of alcohols formed was oxidized with N-bromosuccinimide to the ketone IX. Wolff–Kishner reduction of IX yielded I. The 1,4-oxide I was cleaved with acetic anhydride and boron trifluoride to a diacetate, which upon saponification formed *trans*-1,4-cycloöctanediol. The 1,4-oxide I also was cleaved with acetyl bromide, forming *trans*-4-bromocycloöctyl acetate, which was converted into a diacetate by treatment with tetraethylammonium acetate. Saponification of the diacetate yielded *cis*-1,4-cycloöctanediol. The *cis*- and *trans*-1,4-cycloöctanediols obtained by these syntheses proved to be identical with compounds previously prepared by "transannular reactions" from *cis*- and *trans*-cycloöctene, respectively, thereby confirming the structures and stereochemical assignments previously suggested for these compounds.

It has been shown that the solvolysis of *cis*-cycloöctene oxide with formic acid followed by saponification, or hydrolysis of the oxide with dilute hydrochloric acid, forms a 1,4-cycloöctanediol as well as *trans*-1,2-cycloöctanediol.[1] The 1,4-cyclooctanediol formed in this manner tentatively was assigned the *cis* configuration on the basis of a reaction mechanism that was proposed to explain its formation. Later, similar reasoning was used to assign tentatively the *trans* configuration to a 1,4-cycloöctanediol obtained by solvolysis of *trans*-cycloöctene oxide with formic acid followed by saponification.[2] The assignments of configuration to these diols have been confirmed in the

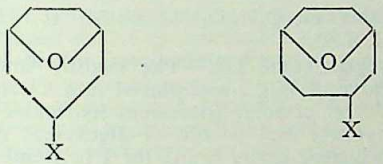
present work by stereospecific syntheses of *cis*- and *trans*-1,4-cycloöctanediols from *cis*-1,4-epoxycyclooctane (I).

A sample of each of the isomeric 3,6-epoxycycloheptanecarbonitriles[3] (II and III) was hydrogenated to the 3,6-epoxycycloheptanemethylamine (IV and V) of similar configuration (*cis* or *trans*) and the amines were identified as crystalline picrates. Since it appeared that the oxide I could be obtained from either of the isomeric amines, the synthesis described below was carried out using a mixture of amines prepared by hydrogenation of a mixture of the nitriles II and III. The nitriles were obtained by decarboxylating a mixture of the isomeric 1-cyano-3,6-epoxycycloheptanecarboxylic acids in quinoline.[3] In this way a mixture of the amines IV and V was obtained from *cis*-2,5-bis-(hydroxymethyl)-tetrahydrofuran ditosylate in 44% yield.



II and III, X = C≡N
IV and V, X = CH_2NH_2
VII, X = CH_2OH
VIII, X = CO_2H

I, X = H
VI, X = OH
IX, X = =O

Treatment of the mixture of amines with nitrous acid afforded a mixture of olefins (see below) and 3,6-epoxycycloöctanol (VI), probably contaminated with 3,6-epoxycycloheptanemethanol (VII) and 1-methyl-3,6-epoxycycloheptan-1-ol, if this Demjanov rearrangement is analogous to other well-studied cases.[4] The mixture of alcohols was oxidized with N-bromosuccinimide in aqueous acetone. These conditions should cause no change in the tertiary alcohol, 1-methyl-3,6-epoxycycloheptan-1-ol, while the primary alcohol VII would form 3,6-epoxycycloheptanecarboxylic acid (VIII) by further oxidation of the intermediate aldehyde, if it is attacked at all, and the secondary alcohol VI would be oxidized to 3,6-epoxycycloöctanone (IX). The ketone obtained by this oxidation procedure was contaminated with small amounts of hydroxylic compounds as shown by the infrared spectrum of the product.

The impure ketone IX was reduced to the 1,4-oxide I by the Wolff–Kishner method in 57% yield. The oxide I separated from the reaction mixture by steam distillation as it was formed and was purified by heating with molten sodium and redistillation. The distillate crystallized on cooling and melted at 30.8–32.2°. The infrared spectrum of the 1,4-oxide I showed strong absorption at 9.45 μ (absent from the spectrum of *trans*-cyclooctene oxide) and 12.25 μ (absent from the spectrum of *cis*-cycloöctene oxide).[2] These data ensure that the 1,4-oxide I is not present in preparations of these cycloöctene oxides which have been shown to form 1,4-cycloöctanediols on solvolysis.[1,2]

The olefins from the diazotization, a mixture of some or all of the olefins 3,6-epoxycycloöct-1-ene, 4,7-epoxycycloöct-1-ene, 1-methylene-3,6-epoxycycloheptane and 1-methyl-3,6-epoxycyclohept-1-ene, which showed two olefin bands in its infrared spectrum, was hydrogenated to a mixture of I and 1-methyl-3,6-epoxycycloheptane. The infrared spectrum of this mixture showed all the absorption peaks of I as well as several other strong bands. Chromatography of the mixture on silica gel, with elution by benzene–ether mixtures, afforded a partial separation as shown by the infrared spectra of succeeding fractions.

The oxide I was treated with acetic anhydride and boron trifluoride, which should cleave the ether with Walden inversion[5] forming *trans*-1,4-cycloöctanediol diacetate. The cycloöctenyl acetate which also was formed was distilled from the product and the viscous residue was saponified without purification. The glycol formed was chromatographed on alumina and yielded *trans*-1,4-cycloöctanediol (6% from 1,4-epoxycycloöctane), m.p. 89.5–91°, identical with the diol obtained from *trans*-cycloöctene oxide, and tentatively assigned the *trans* structure,[2] as shown by mixed-melting point and a comparison of the infrared spectra, which were identical.

The low-boiling product of this reaction was saponified and converted in good yield to a crystalline phenylurethan, m.p. 93–94°. It was not identical with 2-cycloöcten-1-yl phenylurethan, m.p. 92.5–93.5°, but absorbed 98% of one mole of hydrogen to form cycloöctyl phenylurethan, identical with an authentic sample. The phenylurethan melting at 93–94° has been shown to be 4-cycloöcten-1-yl phenylurethan by ozonization.[6] It is of interest that there was no indication of the presence of the isomeric 3-cycloöcten-1-yl phenylurethan,[7] which also could be formed from the 1,4-oxide I, in this derivative.

The oxide I was cleaved with acetyl bromide and formed 4-bromocycloöctyl acetate, presumably the *trans* isomer,[5] in 40% yield. This product was converted to *cis*-1,4-cycloöctanediol diacetate by treatment with tetraethylammonium acetate in acetone.[8] Saponification of the crude ester followed by chromatography of the product afforded 30% of *cis*-1,4-cycloöctanediol, which was converted in 81% yield to a bis-*p*-nitrobenzoate. Both the glycol and the bis-*p*-nitrobenzoate were identical with the same compounds prepared from *cis*-cycloöctene oxide as shown by melting points, mixed melting points and infrared spectra.

These syntheses of *cis*- and *trans*-1,4-cycloöctanediols confirm the configurations previously suggested for these compounds.

Experimental[9]

Hydrogenation of 3,6-Epoxycycloheptanecarbonitrile (II or III), M.p. 87–88°.—In a 335-ml. stainless steel autoclave

Digitized by Arya Samaj Foundation Chennai and eGangotri

were placed 0.533 g. of 3,6-epoxycycloheptanecarbonitrile,[2] m.p. 87–88°, 30 ml. of methanol and about 1 g. of commercial Raney nickel (washed with methanol). The mixture was cooled in a Dry Ice–acetone-bath and 30 ml. of liquid ammonia was added. The vessel was sealed, pressured to 1650 p.s.i. with hydrogen and rocked and heated at 140° for 1 hr. After cooling, the autoclave was opened, the catalyst was removed by filtration and the solvents were distilled. The residue was diluted with 20 ml. of 10% aqueous potassium hydroxide and extracted with four 25-ml. portions of ether. The ether solution was dried with potassium hydroxide and the ether was distilled. The residue, 0.254 g., was dissolved in 10 ml. of dry ether and a saturated solution of picric acid in ether was added until no further precipitate formed. There was obtained 0.490 g. (34%) of 3,6-epoxycycloheptanemethylamine (IV or V) picrate, which after four crystallizations from ethyl acetate had m.p. 212.3–214.0° dec.

Anal. Calcd. for $C_{14}H_{18}N_4O_8$: C, 45.40; H, 4.90; N, 15.13. Found: C, 45.70; H, 5.20; N, 14.97.

Hydrogenation of 3,6-Epoxycycloheptanecarbonitrile (II or III), M.p. 102.8–103.6°.—Reduction of 0.625 g. of 3,6-epoxycycloheptanecarbonitrile,[3] m.p. 102.8–103.6°, under conditions similar to those described above afforded 0.290 g. of 3,6-epoxycycloheptanemethylamine (IV or V), which was converted to 0.712 g. (42%) of the amine picrate. A sample of this picrate that was recrystallized from ethyl acetate had m.p. 189.2–190.8° dec.

Anal. Calcd. for $C_{14}H_{18}N_4O_8$: C, 45.40; H, 4.90; N, 15.13. Found: C, 45.54; H, 4.79; N, 14.95.

Ethyl 1-cyano-3,6-epoxycycloheptanecarboxylate was prepared as previously described[3]; 200 g. of *cis*-2,5-bis-(hydroxymethyl)-tetrahydrofuran ditosylate yielded 65.4 g. (69%) of a mixture of the isomeric ethyl 1-cyano-3,6-epoxycycloheptanecarboxylates, b.p. 95–111° (0.25 mm.), which partially crystallized.

1-Cyano-3,6-epoxycycloheptanecarboxylic acid was prepared by saponification[3] of the esters described above and afforded 55.5 g. (98%) of a crystalline mixture of the acids which was not further purified.

3,6-Epoxycycloheptanecarbonitriles (II and III).—The mixture of acids (55.5 g.) described above was decarboxylated in quinoline[3] and yielded 34.1 g. (81%) of a waxy semi-solid mixture of the nitriles II and III which was not further purified.

3,6-Epoxycycloheptanemethylamine.—The crude nitrile (34.1 g.) obtained from the decarboxylation was hydrogenated by a procedure similar to the one described above for the reduction of 3,6-epoxycycloheptanecarbonitrile, m.p. 87–88°, and afforded 28.3 g. [44% from *cis*-2,5-bis-(hydroxymethyl)-tetrahydrofuran ditosylate] of 3,6-epoxycycloheptanemethylamine, b.p. 104–111.5° (10 mm.), $n^{25}D$ 1.4951–1.5010. A middle fraction showed no absorption characteristic of hydroxylic or carbonyl compounds or nitriles in its infrared spectrum.

A sample of a similar mixture, purified by redistillation, had b.p. 53–54° (0.30 mm.) and $n^{25}D$ 1.4953.

Anal. Calcd. for $C_8H_{15}NO$: C, 68.04; H, 10.71; N, 9.92. Found: C, 68.27; H, 10.58; N, 10.14.

Diazotization of 3,6-Epoxycycloheptanemethylamine (IV and V).—3,6-Epoxycycloheptanemethylamine, 27.0 g., was dissolved in a solution of 17.3 g. of 85% phosphoric acid in 125 ml. of ice-water. The slightly cloudy solution was extracted with ether to remove any neutral impurities, a solution of 13.2 g. of sodium nitrite in 30 ml. of water was added and the solution was allowed to stand for 16 hr. The greenish organic layer which had formed was extracted with ether. The solution was heated at 100° for 1 hr., cooled and extracted with two 100-ml. portions of ether, and the processes of heating and extraction were repeated twice in the same way. Phosphoric acid (1.7 g.) was added, then 1.6 g. of sodium nitrite, and the solution was heated at 100° for 1 hr., cooled and extracted with two 100-ml. portions of ether. The heating and extraction were repeated, the extract was dried with potassium carbonate and distilled. When it was found that the high-boiling residue from this operation was less than 1 g., all of the ether extracts were combined and dried with potassium carbonate and the ether was distilled. The residue was fractionated through a semi-micro column, affording an olefin fraction, b.p. 54–59.5° (11 mm.), and an alcohol fraction, b.p. 60–83° (0.30 mm.). The olefins amounted to 4.95 g. or 22% of the theoretical amount; the alcohols amounted to 11.6 g. or 43%.

N-Bromosuccinimide Oxidation of the Alcohol Mixture.—The alcohol fraction from the nitrous acid reaction, 11.6 g., was dissolved in 400 ml. of reagent acetone and 40 ml. of water. N-Bromosuccinimide (36 g.) was added, and the solution was allowed to stand for 19.5 hr. During the course of the reaction the mixture turned gradually from colorless to orange and back to colorless again. The reaction mixture was neutralized with saturated sodium bicarbonate solution, and the excess N-bromosuccinimide was destroyed with sodium thiosulfate solution. The acetone was distilled, and the solution was cooled and extracted with nine 50-ml. portions of chloroform. The combined extracts were dried with potassium carbonate and the chloroform was distilled. Fractionation through a semi-micro column afforded 9.23 g. or 81% of the theoretical amount of a product, b.p. 58° (1.40 mm.) to 64° (0.18 mm.), $n^{25}D$ 1.4872–1.4933. All fractions gave precipitates with 2,4-dinitrophenylhydrazine reagent. Refractionation of this product through a 30 × 0.8-cm. semi-micro column with a spinning band afforded 6.64 g. (58%) of a product, b.p. 56–61° (0.7 mm.), $n^{25}D$ 1.4893–1.4906. The infrared spectrum of this product showed a small hydroxyl band.

Anal. Calcd. for $C_8H_{12}O_2$: C, 68.54; H, 8.63. Found: C, 68.11; H, 8.80.

1,4-Epoxycycloöctane (I).—The slightly impure ketone described above, 5.65 g., was placed in a Claisen distilling flask with 7.0 g. of solid potassium hydroxide, 5.0 ml. of hydrazine hydrate and 50 ml. of diethylene glycol. The mixture was heated under reflux for 1 hr., and then a mixture of water and the 1,4-oxide I was distilled slowly for 1.5 hr., after which 5.0 ml. of water was added and distilled over the course of 1 hr. Another addition of water followed by distillation gave a clear distillate, indicating that the reaction was complete. The distillates were combined, the water solution was made strongly acidic with hydrochloric acid and the product was extracted with three 20-ml. portions of petroleum ether. The combined extracts were dried with sodium hydride, filtered and the solvent was distilled. Sodium (about 0.5 g.) was added, and the mixture was heated in a flask attached to a semi-micro column until the sodium had melted and this temperature was maintained for 15 minutes. Distillation yielded 2.82 g. (57%) of 1,4-epoxycycloöctane, b.p. 89–95° (53 mm.). The later fractions crystallized when cooled. A middle fraction had b.p. 94° (53 mm.), $n^{25}D$ 1.4720, m.p. 30.8–32.2°.

Anal. Calcd. for $C_8H_{14}O$: C, 76.14; H, 11.18. Found: C, 76.44; H, 11.29.

The infrared spectrum of this compound was free of hydroxyl and carbonyl bands (Fig. 1).

***trans*-1,4-Cycloöctanediol.**—1,4-Epoxycycloöctane, 0.95 g., 1.5 g. of acetic anhydride and 0.1 ml. of boron trifluoride etherate were heated on a steam-bath for 90 minutes, cooled and diluted to a volume of 50 ml. with ether. The ether solution was washed with two 20-ml. portions of water, dried overnight with anhydrous magnesium sulfate and the ether was distilled. The residue was placed in a flask attached to a semi-micro column, and 0.47 g. (37%) of material boiling in the range of the cycloöctenyl acetates was distilled. (Characterization of this material is described below.) The residue in the distilling flask was saponified by heating in methanol (15 ml.) with sodium hydroxide (1.0 g.) for 90 minutes. The methanol was distilled, the residue was taken up in water and the water solution was extracted continuously with chloroform overnight. Distillation of the extract afforded 0.16 g. of high-boiling residue which was chromatographed on Brockmann Grade III alumina.

Fractions 1–3 were eluted with benzene and amounted to 0.025 g.; fractions 4–15 were eluted with benzene–ether mixtures (0.002 g.); fractions 16–28 were eluted with 0.5% methanol–99.5% ether (0.009 g.); fractions 29–45 were eluted with 1% methanol–99% ether (0.066 g.); fractions 46–56 were eluted with 2% methanol–98% ether (0.002 g.); and fractions 57 and 58 were eluted with 50% methanol–50% ether (0.002 g.).

Fractions 29–45 contained 0.066 g. or 6% of the theoretical amount of crystalline *trans*-1,4-cycloöctanediol. A sample recrystallized twice from ethyl acetate had m.p. 89.5–91° (hot-stage) and did not depress the melting point (90.5–91.5°) of *trans*-1,4-cycloöctanediol that was identical with a sample prepared from *trans*-cycloöctene.[2] The in-

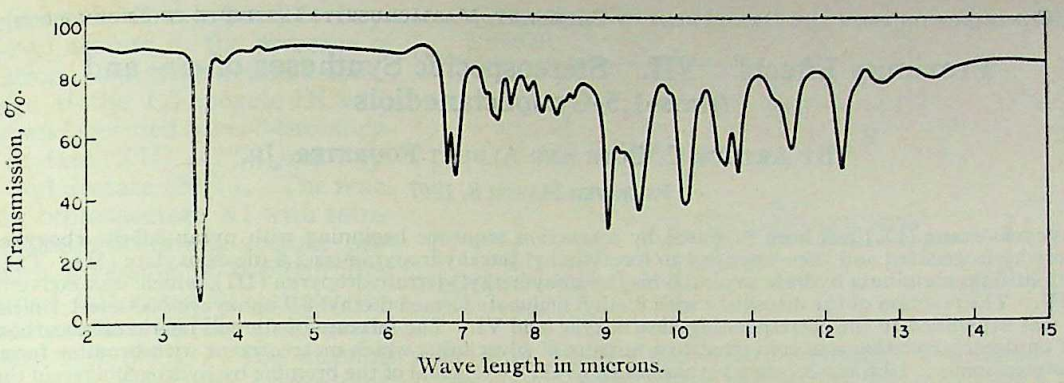

Fig. 1.—Infrared absorption spectrum of 1,4-epoxycycloöctane as a solution (100 mg./ml.) in carbon tetrachloride in the region 2–8μ and in carbon disulfide in the region 8–16μ.

frared spectra of these compounds determined at 1% concentration in a potassium bromide pellet were superimposable.

The other fractions, which did not crystallize, were discarded. There was no indication that they contained the easily crystallized *cis*-1,4-cycloöctanediol.

Treatment of the Low-boiling Fraction.—A mixture of 0.47 g. of the cycloöctenyl acetate fraction, 5.0 ml. of methanol and 2.0 g. of potassium hydroxide was heated under reflux for 40 minutes, and the mixture was then diluted with water. Extraction of the product with ether and fractionation of the dried extracts afforded 0.28 g. (79%) of an unsaturated alcohol. This material was treated with 0.4 g. of phenyl isocyanate, and when the mixture had solidified, the excess phenyl isocyanate was distilled under reduced pressure. Chromatography of the product on alumina afforded 0.472 g. (87%) of a product which was homogeneous. A sample purified by recrystallization from methanol–water had m.p. 93–94°.

Anal. Calcd. for $C_{15}H_{19}NO_2$: C, 73.43; H, 7.81; N, 5.71. Found: C, 73.55; H, 7.89; N, 5.57.

Hydrogenation of the Phenylurethan, M.p. 93–94°.—In a micro hydrogenation apparatus were placed 15 ml. of 95% ethanol and 0.40 g. of 10% palladium-on-carbon hydrogenation catalyst. After the catalyst and solvent had equilibrated with the hydrogen atmosphere, a sample (0.0307 g.) of the phenylurethan described above was added. When the reduction was complete, after absorption of 98% of one molar equivalent of hydrogen, the solution was filtered and the ethanol was distilled. There was obtained 0.031 g. of a product, m.p. 53–56.5°. Recrystallization from aqueous methanol afforded cycloöctyl phenylurethan, m.p. 55.6–56.6°, alone or admixed with an authentic sample. The infrared spectra of the hydrogenation product and the authentic sample were identical. As noted earlier, the phenylurethan with m.p. 93–94° now has been identified as 4-cycloöcten-1-yl phenylurethan by ozonization.[6]

***cis*-1,4-Cycloöctanediol.**—1,4-Epoxycycloöctane (1.01 g.) and 1.5 g. of acetyl bromide were heated on a steam-bath for 1 hr. The brown mixture was cooled and poured into water. The product was extracted with ether, and the ethereal extract was washed with water, saturated sodium bicarbonate solution and again with water. The extract was dried and fractionated. There was obtained 0.79 g. or 40% of *trans*-4-bromocycloöctyl acetate, b.p. 90–95° (0.17 mm.), $n^{25}D$ 1.4980–1.4994. This product was dissolved in a solution of 0.90 g. of tetraethylammonium acetate monohydrate in 25 ml. of reagent acetone and the solution was heated under reflux for 4 hr. The acetone was distilled, water was added and the product was extracted with three 25-ml. portions of ether. The extracts were combined and dried with magnesium sulfate. The solvent was distilled, and the residue obtained was saponified by heating in methanol (25 ml.) with potassium hydroxide (2.0 g.) for 30 minutes. The methanol was distilled, 20 ml. of water was added and the mixture was extracted continuously with chloroform for 24 hr. Distillation of the solvent afforded 0.30 g. of viscous residue which was chromatographed on activity III alumina.

Fractions 1–14 were eluted with benzene–ether mixtures and amounted to 0.010 g.; fractions 15–18 were eluted with ether (0.005 g.); fractions 18–27 were eluted with 1% methanol–99% ether (no material); fractions 28–47 were eluted with 2% methanol–98% ether (0.137 g.); fractions 48–52 were eluted with 10% methanol–90% ether (0.007 g.); fractions 53–56 were eluted with 30% methanol–70% ether (no material).

Fractions 28–52 crystallized on evaporation of the solvent, and contained only one compound as shown by melting points and mixed melting points. A middle fraction after two recrystallizations from ethyl acetate melted at 83.0–84.5° alone or admixed with *cis*-1,4-cycloöctanediol prepared from *cis*-cycloöctene.[1] The yield of 0.144 g. was 31% from *trans*-4-bromocycloöctyl acetate.

Fractions 1–18 did not crystallize and were discarded.

***cis*-1,4-Cycloöctanediol Bis-*p*-nitrobenzoate.**—A portion (0.0549 g.) of the above glycol was treated with *p*-nitrobenzoyl chloride in pyridine under conditions previously described,[10] and the product was purified by chromatography on alumina. The yield of *cis*-1,4-cycloöctanediol bis-*p*-nitrobenzoate was 0.136 g. (81%), and after two recrystallizations from ethyl acetate the compound melted at 161.5–162.7° alone or admixed with the corresponding ester prepared from *cis*-1,4-cycloöctanediol obtained from *cis*-cycloöctene.[1]

The infrared spectra of the *cis*-1,4-glycol and its bis-*p*-nitrobenzoate were identical with the spectra of the same compounds prepared from *cis*-cycloöctene.

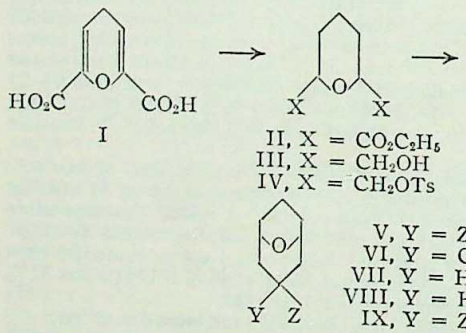
Proximity Effects. VII. Stereospecific Syntheses of *cis*- and *trans*-1,5-Cyclooctanediols

BY ARTHUR C. COPE AND ALBERT FOURNIER, JR.

RECEIVED MARCH 8, 1957

1,5-Epoxycyclooctane (IX) has been prepared by a reaction sequence beginning with pyran-2,6-dicarboxylic acid (I). This acid was hydrogenated and then esterified to form diethyl tetrahydropyran-*cis*-2,6-dicarboxylate (II). The ester was reduced with lithium aluminum hydride to *cis*-2,6-bis-(hydroxymethyl)-tetrahydropyran (III), which was converted to the ditosylate IV. The reaction of the ditosylate with diethyl malonate formed diethyl 3,7-epoxycyclooctane-1,1-dicarboxylate (V), which was saponified to the corresponding dicarboxylic acid VI. The mixture of stereoisomeric monocarboxylic acids VII formed on decarboxylation was converted to a mixture of silver salts, which on treatment with bromine formed a mixture of the stereoisomeric 1-bromo-3,7-epoxycyclooctanes (VIII). Removal of the bromine by hydrogenolysis in the presence of Raney nickel in triethylamine yielded the 1,5-epoxide IX. Cleavage of 1,5-epoxycyclooctane with a mixture of trifluoroacetic acid and acetic anhydride formed *trans*-1,5-cyclooctanediol (X), 4-cycloocten-1-ol (XI) and a very small amount of *trans*-1,4-cyclooctanediol. The reaction of the 1,5-epoxide with acetyl bromide formed *trans*-5-bromocyclooctyl acetate (XII) and 4-cycloocten-1-ol. Treatment of the bromoacetate XII with tetraethylammonium acetate followed by saponification yielded *cis*-1,5-cyclooctanediol (XIII) and 4-cycloocten-1-ol.

This paper reports stereospecific syntheses of *cis*- and *trans*-1,5-cyclooctanediol. The synthesis employed was similar to the one used for preparation of the *cis*- and *trans*-1,4-cyclooctanediols described in the preceding paper.[1] The key intermediate in these syntheses was 1,5-epoxycyclooctane, which was prepared by the reaction sequence outlined below.



Pyran-2,6-dicarboxylic acid (I)[2] was reduced catalytically in the presence of palladium-on-Norit forming *cis*-tetrahydropyran-2,6-dicarboxylic acid, which was esterified without isolation, forming diethyl *cis*-tetrahydropyran-2,6-dicarboxylate (II). Reduction of the ester with lithium aluminum hydride formed the crystalline *cis*-glycol III, which was converted to the crystalline ditosylate IV. The alkylation of diethyl malonate with this ditosylate formed the cyclic ester V in 72% yield. It is of interest that only this product of dialkylation was isolated, even though its formation requires the intramolecular alkylation of an intermediate in which two bulky substituents in a six-membered ring occupy the sterically unfavorable axial positions. Saponification of the dicarboxylic ester V formed the corresponding acid VI (83%), and decarboxylation yielded a mixture of the stereoisomeric monocarboxylic acids VII in 98% yield. Both of these isomers were isolated in pure form. The less soluble and higher melting form with m.p. 137.2–137.8° was purified by crystallization from carbon tetrachloride, while the lower melting isomer, which was present in much smaller amount, was isolated from the mother liquors by partition chromatography by the method of Ramsey and Paterson.[3] The evidence available at present is insufficient to determine which acid contains the carboxyl group *cis* and which *trans* to the oxide bridge.

The method chosen for removal of the carboxyl group in VII was treatment of the corresponding silver salt with bromine. For this purpose, the mixture of the stereoisomers VII was converted to a mixture of the corresponding silver salts. Subsequent treatment with bromine in carbon tetrachloride formed a mixture of the stereoisomeric bromides VIII in 54% yield (allowing for 22% recovery of the higher melting acid VII). Attempts to remove the bromine atom in VIII by hydrogenolysis in the presence of palladium-on-Norit or platinum-in-glacial acetic acid containing sodium acetate were unsuccessful, because the catalysts became poisoned rapidly. However, the hydrogenolysis was successful in the presence of Raney nickel in triethylamine as a solvent and afforded 1,5-epoxycyclooctane (IX) (82%), a very volatile solid, m.p. 52.5–53.9°, with a camphoraceous odor.

Cleavage of the 1,5-oxide IX by treatment with a mixture of zinc chloride and acetic anhydride gave almost exclusively 4-cycloocten-1-ol and very little glycol. The amount of elimination was decreased by using a mixture of acetic anhydride and trifluoroacetic acid for the cleavage. With this mixture, the products isolated after saponification were 4-cycloocten-1-ol (40%), identified as the phenylurethan, and a mixture of glycols (28%) that was separated by chromatography on alumina. This mixture contained *trans*-1,5-cyclooctanediol (X) and *trans*-1,4-cyclooctanediol in a ratio of approximately 4:1. The *trans*-1,5-glycol was obtained as a very viscous oil that has failed to crystallize during a period of months. It formed a crystalline bis-*p*-nitrobenzoate, m.p. 182.3–183.3°, which is different from any of the other seven isomeric cyclooctanediol bis-*p*-nitrobenzoates (mixed melting points are depressed, and the infrared spectra of the isomers differ). The formation of a small amount of *trans*-1,4-cyclooctanediol in this reaction may be explained by addition of

acetic acid to the double bond in 4-cycloöcten-1-yl acetate in the presence of the very strong acid, trifluoroacetic acid.

Cleavage of the 1,5-epoxide IX with acetyl bromide formed *trans*-5-bromocycloöctyl acetate (XII) (47%) and 4-cycloöcten-1-yl acetate (20%). The reaction of the bromoacetate XI with tetraethylammonium acetate in acetone proceeded with inversion of configuration and afforded (after saponification) *cis*-1,5-cycloöctanediol (XIII) (14%) and 4-cycloöcten-1-ol (26%). The alcohols were separated by chromatography on alumina. The *cis*-1,5-glycol was obtained as a crystalline solid, m.p. 73.8–74.5°, which formed a bis-*p*-nitrobenzoate, m.p. 181.4–182.8°, that was different from the corresponding derivative of the *trans* isomer (mixed melting point and comparison of infrared spectra).

Evidence pointing to the steric proximity of groups attached to the 1- and 5-positions of the cycloöctane ring was obtained by observation of the behavior of *trans*-5-bromocycloöctyl acetate on saponification. This reaction resulted in the formation of the 1,5-epoxide IX.

Experimental[4]

Diethyl Tetrahydropyran-*cis*-2,6-dicarboxylate (II).—Diethyl oxaloacetate was regenerated from the commercial sodium enolate by treatment with dilute sulfuric acid and ether and isolated by extraction with ether and distillation; b.p. 92.5° (2.4 mm.), $n^{25}D$ 1.4482–1.4491. To the freshly distilled ester (179 g.) at 0° was added 40 g. of formalin (37% formaldehyde), sufficient 95% ethanol to give a homogeneous solution and 0.85 ml. of glacial acetic acid. Piperidine (3 ml.) was added with stirring while the temperature was maintained at 5–10°, and the solution was then placed in a refrigerator at 5°. After 7 hr. a solution of 1.5 ml. of piperidine and 0.41 ml. of glacial acetic acid in a small volume of ethanol was added to the yellow mixture with stirring, and it was allowed to stand at 5° for an additional period of 36 hr. The nearly solid mass was filtered, and the solid was washed with ice-cold methanol until the yellow color was removed. After drying at 1 mm. and room temperature overnight, there was obtained 136.4 g. (74%) of methylene bis-(diethyl oxaloacetate) as fine white crystals, m.p. 74.7–76.2° (lit.[5] m.p. 81°).

The above ester (228 g.) was stirred and heated under reflux with 230 ml. of concentrated hydrochloric acid and 230 ml. of water until the oily drops of the ester disappeared (about 2 hr.). The solution was concentrated under reduced pressure, and the residue was dried at 1 mm. for 4 hr. and recrystallized from a mixture of acetone and benzene to give 64.4 g. (71%) of α,α'-diketopimelic acid, m.p. 127.8–129.6° (lit.[6] m.p. 127°). Pyran-2,6-dicarboxylic acid[2] was prepared by dissolving 64.4 g. of finely powdered α,α'-diketopimelic acid in 325 ml. of concentrated sulfuric acid with stirring at 10–20° and allowing the solution to stand at 0° for 2.5 hr. The solution was poured into 3 l. of ice and water and the solid was collected on a filter and washed with 3 l. of water and 300 ml. of methanol. After drying at 0.5 mm. and room temperature, the yield of pyran-2,6-dicarboxylic acid was 54 g. (93%) (no definite m.p. below 300°).

A suspension of 54 g. of crude pyran-2,6-dicarboxylic acid in 600 ml. of absolute ethanol was hydrogenated at room temperature and 26–21 p.s.i. in the presence of 5 g. of 10% palladium-on-Norit. After 3.5 hr. the reduction was complete and the very slightly soluble acid had dissolved. The catalyst was removed by filtration and washed with two 150-ml. portions of hot absolute ethanol. Benzene (1.2 l.) and 2 ml. of concentrated sulfuric acid were added and the solution was refluxed overnight. The solution was slowly concentrated at atmospheric pressure during a period of 4 hr. and finally under reduced pressure. The residue was dissolved in ether and the solution was washed with saturated sodium bicarbonate solution, water, saturated sodium chloride solution and dried over Drierite. Distillation of the product gave 64.8 g. (91%) of diethyl *cis*-tetrahydropyran-2,6-dicarboxylate, b.p. 95° (0.07 mm.), $n^{25}D$ 1.4527, d^{25}_4 1.118.

Anal. Calcd. for $C_{11}H_{18}O_5$: C, 57.38; H, 7.88. Found: C, 57.35; H, 7.94.

A sample of the ester was refluxed overnight with potassium hydroxide in ethanol. The solution was concentrated, diluted with water, acidified and extracted with chloroform in a continuous extractor. The extract was dried over magnesium sulfate and concentrated to dryness. The residue of tetrahydropyran-*cis*-2,6-dicarboxylic acid had m.p. 191–192.2° (lit.[7] m.p. 193°).

***cis*-2,6-Bis-(hydroxymethyl)-tetrahydropyran (III).**—A solution of diethyl tetrahydropyran-*cis*-2,6-dicarboxylate (64.2 g.) in 550 ml. of dry ether was added with stirring to a slurry of lithium aluminum hydride (13.6 g.) in 400 ml. of dry ether with stirring in a 3-l., three-necked flask which was protected against moisture. The rate of addition was such that a gentle reflux was maintained. After refluxing for an additional 1.5 hr., the excess lithium aluminum hydride was destroyed by the cautious addition of water. The complex was decomposed with approximately 275 ml. of 20% sulfuric acid. The ether layer was separated and dried over magnesium sulfate. The aqueous layer was extracted with chloroform in a continuous extractor for 26 hr. and the chloroform extract dried over magnesium sulfate. The extracts were combined and the product distilled to give 37.6 g. (92%) of *cis*-2,6-bis-(hydroxymethyl)-tetrahydropyran. The product solidified on standing overnight in a refrigerator and had m.p. 41–44.4°. After several recrystallizations from ether–petroleum ether (30–60°) it had m.p. 45.7–46.4°.

Anal. Calcd. for $C_7H_{14}O_3$: C, 57.44; H, 9.65. Found: C, 57.33; H, 9.69.

***cis*-2,6-Bis-(hydroxymethyl)-tetrahydropyran Ditosylate (IV).**—To a solution of *cis*-2,6-bis-(hydroxymethyl)-tetrahydropyran (37.6 g.) in 130 ml. of dry pyridine was added at 0° in one portion *p*-toluenesulfonyl chloride (108 g.) in 400 ml. of dry pyridine. The solution was stirred at 0° for approximately 20 hr. and poured with stirring into about 2 l. of ice and water. The product separated as an oil but soon solidified. It was collected on a filter, washed with large amounts of water and recrystallized from methanol to give 103 g. (95%) of *cis*-2,6-bis-(hydroxymethyl)-tetrahydropyran ditosylate, m.p. 93–94°. An analytical sample that was recrystallized from methanol had m.p. 93.8–94.8°.

Anal. Calcd. for $C_{19}H_{22}O_7S_2$: C, 55.49; H, 5.76. Found: C, 55.42; H, 5.61.

Diethyl 3,7-Epoxycycloöctane-1,1-dicarboxylate (V).—A 3-l. stainless steel autoclave was charged with a solution of diethyl malonate (13.6 g.) in 100 ml. of dry tetrahydrofuran. Sodium hydride (4.1 g.) was added over the course of 2 hr., followed by *cis*-2,6-bis-(hydroxymethyl)-tetrahydropyran ditosylate (35 g.) and 1400 ml. of dry tetrahydrofuran. The autoclave was sealed and rocked and heated at 110–120° for 27 hr. The mixture was rinsed from the bomb with dry ether and concentrated under reduced pressure. To the

Digitized by Arya Samaj Foundation Chennai and eGangotri

concentrate was added about 350 ml. of 10% hydrochloric acid, and the product was extracted with three 170-ml. portions of ether. The extracts were combined, washed with saturated sodium chloride solution and dried over magnesium sulfate. Two additional preparations were made under similar conditions from 35 and 33 g. of the ditosylate, respectively. The ether extracts of the three preparations were combined, concentrated and the product was distilled, yielding 43.6 g. (72%) of diethyl 3,7-epoxycycloöctane-1,1-dicarboxylate, b.p. 104° (0.15 mm.), $n^{25}D$ 1.4639. An analytical sample had b.p. 104° (0.15 mm.), $n^{25}D$ 1.4650, d^{25}_4 1.133.

Anal. Calcd. for $C_{14}H_{22}O_5$: C, 62.20; H, 8.21. Found: C, 62.40; H, 8.17.

The residue from the distillation was dissolved in methanol and treated with Norit; it yielded 4.25 g. of the recovered crystalline ditosylate.

3,7-Epoxycycloöctane-1,1-dicarboxylic Acid (VI).—Diethyl 3,7-epoxycycloöctane-1,1-dicarboxylate (43.6 g.) was heated under reflux with potassium hydroxide (27 g.) in 130 ml. of 95% ethanol and 20 ml. of water for 21 hr. The solution was concentrated under reduced pressure, 130 ml. of water was added to the residue and the aqueous solution was acidified. The precipitated dicarboxylic acid was removed by filtration and the mother liquor was extracted continuously overnight with chloroform. A total of 28.8 g. (83%) of crude 3,7-epoxycycloöctane-1,1-dicarboxylic acid was obtained, m.p. 167° dec. (the fraction separated by filtration) and 182° dec. (from the chloroform extracts). An analytical sample was obtained by recrystallization from ethyl acetate and had m.p. 186.5–187° dec.

Anal. Calcd. for $C_{10}H_{14}O_5$: C, 56.07; H, 6.59; neut. equiv., 107. Found: C, 56.18; H, 6.71; neut. equiv., 108.

Decarboxylation of 3,7-Epoxycycloöctane-1,1-dicarboxylic Acid.—3,7-Epoxycycloöctane-1,1-dicarboxylic acid (28.8 g.) was heated at 200° until the evolution of gas ceased. The product, a mixture of the stereoisomeric 3,7-epoxycycloöctane-1-carboxylic acids, weighed 22.8 g. (98%), m.p. 122.5–134°.

Separation of the Isomeric 3,7-Epoxycycloöctane-1-carboxylic Acids (VII).—A 1.509-g. sample of the mixture of isomers was recrystallized once from carbon tetrachloride and gave 1.05 g. of material with m.p. 133–137°, a recovery of 70%. This proved to be one of the isomeric 3,7-epoxycycloöctane-1-carboxylic acids. After two additional recrystallizations, it had m.p. 137.2–137.8°.

Anal. Calcd. for $C_9H_{14}O_3$: C, 63.54; H, 8.29; neut. equiv., 170. Found: C, 63.58; H, 8.21; neut. equiv., 168.

The other isomeric 3,7-epoxycycloöctane-1-carboxylic acid was isolated by partition chromatography[3] of the mother liquors from recrystallization of the mixture. The mixture (100 mg.) was chromatographed on 40 g. of 100-mesh silicic acid and during the elution with isoöctane two bands appeared on the column. They were fractionally eluted with 4 fractions being collected. Fraction 1 (41 mg., main portion of the first band) had m.p. 137–137.6°; fraction 2 (9 mg., remainder of the first band) had m.p. 134–135.6°; fraction 3 (19 mg., front portion of the second band) had m.p. 87.2–89.7°; and fraction 4 (18 mg., main portion of the second band) had m.p. 89.6–90.4°.

Fractions 3 and 4 were combined and recrystallized from hexane and furnished the second isomeric 3,7-epoxycycloöctane-1-carboxylic acid, m.p. 90–90.6°. The infrared absorption spectrum of this acid was different from the spectrum of the higher melting isomer.

Anal. Calcd. for $C_9H_{14}O_3$: C, 63.54; H, 8.29; neut. equiv., 170. Found: C, 63.85; H, 8.51; neut. equiv., 163.

1-Bromo-3,7-epoxycycloöctane (VIII).—A mixture of the isomeric 3,7-epoxycycloöctane-1-carboxylic acids (11.6 g.) and 50 ml. of water was heated to boiling and neutralized to the phenolphthalein end-point with 30% potassium hydroxide. The solution of the potassium salts was again heated to boiling and treated with a solution of silver nitrate (11.6 g.) in 10 ml. of water with constant agitation. The mixture was allowed to cool and filtered. The solid was washed with 100 ml. of methanol and dried at 1 mm. to give 15.3 g. (81%) of silver 3,7-epoxycycloöctane-1-carboxylate.

The silver salt (14.89 g.) was dried at 0.05 mm. and 90–100° for 34 hr. in a 500-ml. round-bottomed three-necked flask. The flask was then equipped with a Hershberg stirrer and an addition funnel. Carbon tetrachloride which had been dried over phosphorus pentoxide was added and about 50 ml. of the solvent distilled from the flask. A solution of bromine (8.8 g.) in 40 ml. of carbon tetrachloride (the solution was dried over phosphorus pentoxide) was then added dropwise over a period of 17 min. while the temperature was maintained at 0–5°. The mixture was stirred for an additional period of 15 min. at 0–5° and then allowed to warm with stirring to room temperature; during this time some carbon dioxide was evolved. Upon heating under reflux carbon dioxide was evolved vigorously and ceased after 1.3 hr. After cooling, the silver bromide was removed by filtration and washed with a total of 100 ml. of hot carbon tetrachloride. The combined extracts were washed with 20 ml. of 10% sodium carbonate solution and dried over magnesium sulfate. The solution was concentrated under reduced pressure, and the residue was fractionally distilled through a semi-micro column to give 3.76 g. of the crude bromide. Decomposition was noted during the distillation of the last fraction and the distillation was stopped. The residue on short-path distillation yielded an additional 0.964 g. of a waxy solid, making a total of 4.73 g. (43%) of 1-bromo-3,7-epoxycycloöctane. All of the fractions eventually solidified. A center cut had these properties: b.p. 78.5° (1.5 mm.), m.p. 34.7–40°, $n^{25}D$ 1.5298.

Anal. Calcd. for $C_8H_{13}BrO$: C, 46.84; H, 6.39; Br, 38.97. Found: C, 46.75; H, 6.38; Br, 38.72.

The sodium carbonate extract was acidified and 1.97 g. of the higher melting isomer of 3,7-epoxycycloöctane-1-carboxylic acid was separated, m.p. 136.2–137.8° and m.p. 137–137.8° after recrystallization from carbon tetrachloride.

1,5-Epoxycycloöctane (IX).—1-Bromo-3,7-epoxycycloöctane (8.99 g.) in 50 ml. of dry triethylamine was shaken with hydrogen overnight in the presence of approximately 2 g. of Raney nickel at 1500 p.s.i. and 90–100° in a 200-ml. glass-lined autoclave. After cooling, ether was added to the mixture and the solid was removed by filtration and washed several times with ether. The ether solution was washed with iced dilute hydrochloric acid, and the aqueous solution was extracted with two 15-ml. portions of ether. The combined extracts were washed with saturated sodium bicarbonate solution, saturated sodium chloride solution and dried over Drierite. The ether was distilled through a fractionating column and the residue was fractionated through a semi-micro column. The fractions solidified, and a center fraction had the following properties: b.p. 81° (30 mm.), m.p. 52.5–53.9° (after sublimation).

Anal. Calcd. for $C_8H_{14}O$: C, 76.14; H, 11.18. Found: C, 75.90; H, 10.88.

Cleavage of 1,5-Epoxycycloöctane with Acetic Anhydride and Trifluoroacetic Acid.—To 1,5-epoxycycloöctane (1.033 g.) was added a cold mixture of acetic anhydride (2.52 g.) and trifluoroacetic acid (7 g.). The solution was allowed to warm to room temperature, and after 40 min. it was heated at 80–85° for 1 hr. The solution was concentrated at 30 mm. by distillation through a semi-micro column with a final bath temperature of 105°. The dark residue was heated under reflux overnight with potassium hydroxide (4.6 g.) in 14 ml. of ethanol and 7 ml. of water. The solution was concentrated under reduced pressure, water was added to the residue and concentrated hydrochloric acid was added with cooling until a *p*H of 8–9 was reached. The aqueous mixture was extracted continuously with chloroform for 48 hr. and the chloroform removed under reduced pressure, leaving 860 mg. of a dark viscous oil. This product was taken up in 14 ml. of 1:1 ether–benzene and chromatographed on 30 g. of Activity III alumina, in a column 20 mm. in diameter, collecting 30-ml. fractions. Fractions 1, 4–9, 13–14, 30–31, 55–63 and 64–75 were discarded.

4-Cycloöcten-1-ol (XI).—The combined fractions 2 and 3 were distilled in a short-path still under reduced pressure to give a colorless liquid, $n^{25}D$ 1.4952. A 114-mg. sample was treated with 274 mg. of phenyl isocyanate, and the mixture was heated on a steam-bath for a few minutes and allowed to stand at room temperature overnight. Removal of the excess reagent at 1 mm. left 209 mg. of a phenylurethan with m.p. 86.8–93°. After several recrystallizations from hexane it had m.p. 94.5–95.4° and was identified as 4-cycloöcten-1-ol phenylurethan by comparison of the infrared spectrum with the spectrum of an authentic sample.[1]

***trans*-1,5-Cycloöctanediol Bis-*p*-nitrobenzoate.**—Fractions 15–20 (62 mg.) were treated with *p*-nitrobenzoyl

Fraction	Eluent	Weight, mg.
1	Benzene–ether (1:1)	5
2–3	Benzene–ether (1:1)	364
4–9	Benzene–ether (1:1)	32
13–14	Ether	9
15–20	Ether	63
21–29	Ether	30
30–31	0.5% methanol–ether	3
32–37	0.5% methanol–ether	115
38–46	0.5% methanol–ether	75
47–54	0.5% methanol–ether	27
55–63	1.5% methanol–ether	11
64–75	10% methanol–ether	12

chloride (192 mg.) in a few milliliters of dry pyridine, and the solution was allowed to stand overnight. The solution was poured into water and the solid collected on a filter and washed with water. The product was dissolved in benzene and chromatographed on 5 g. of Activity II alumina to give 133 mg. (72%) of *trans*-1,5-cycloöctanediol bis-*p*-nitrobenzoate, which after recrystallization from ethanol had m.p. 182.3–183.3°.

Anal. Calcd. for $C_{22}H_{22}O_8N_2$: C, 59.72; H, 5.01; N, 6.33. Found: C, 59.91; H, 5.19; N, 6.32.

The infrared absorption spectrum of the *trans*-1,5-cyclooctanediol bis-*p*-nitrobenzoate was quite different from the spectra of the bis-*p*-nitrobenzoates of the other seven cyclooctanediols.

Treatment of fractions 21–29 (30 mg.) with *p*-nitrobenzoyl chloride (140 mg.) in the manner described above gave 76 mg. (86%) of *trans*-1,5-cycloöctanediol bis-*p*-nitrobenzoate, m.p. 182–182.8° after recrystallization from ethanol.

trans-1,5-Cycloöctanediol bis-*p*-nitrobenzoate (25 mg.) was heated under reflux with 0.2 g. of potassium hydroxide in 5 ml. of ethanol for 2 hr. The ethanol was removed under reduced pressure, water added and the aqueous solution extracted continuously with chloroform for 2 hr. After drying over magnesium sulfate and removal of solvent, there was left 5 mg. (63%) of *trans*-1,5-cycloöctanediol as an oil which has not crystallized in a period of several months.

Identification of *trans*-1,4-Cycloöctanediol.—Fractions 47–54 (27 mg.) were treated with *p*-nitrobenzoyl chloride (105 mg.) in dry pyridine, and the product was isolated by the procedure described above. The crude bis-*p*-nitrobenzoate amounted to 89 mg. and after six recrystallizations was identified as *trans*-1,4-cycloöctanediol bis-*p*-nitrobenzoate, m.p. 154.9–156.3°, not depressed on mixture with an authentic sample.[8]

Cleavage of 1,5-Epoxycycloöctane with Acetyl Bromide.—To 1,5-epoxycycloöctane (1.01 g.) was added acetyl bromide (2.25 g.), and the mixture was heated under reflux for 75 min. The mixture was cooled, poured into water and the product was extracted with three 15-ml. portions of ether. The combined extracts were washed with saturated sodium bicarbonate solution, water, saturated sodium chloride solution and dried over magnesium sulfate. After removal of the ether the product was distilled through a semi-micro column. A low boiling fraction (1) 228 mg., b.p. 40° (0.2 mm.), $n^{25}D$ 1.4702, was separated from three fractions totaling 948 mg., b.p. 82–83° (0.2 mm.), $n^{25}D$ 1.4955–1.4984. Fraction 1 was identified as 4-cycloöcten-1-yl acetate (20% yield) by saponification to the alcohol (75 mg., $n^{25}D$ 1.4969), which was converted to the phenylurethan, m.p. and mixed m.p. with an authentic sample[1] (after recrystallization from hexane) 93–94.5°. The higher boiling fractions correspond to a 47% yield of *trans*-5-bromocycloöctyl acetate (XII).

1,5-Epoxycycloöctane from *trans*-5-Bromocycloöctyl Acetate.—*trans*-5-Bromocycloöctyl acetate (599 mg.) was heated under reflux with potassium hydroxide (522 mg.) in 5 ml. of absolute ethanol. The mixture was poured into 30 ml. of water and the product was extracted with four 10-ml. portions of ether. The combined extracts were washed with water and saturated sodium chloride solution and dried over magnesium sulfate. The solvent was removed at atmospheric pressure and the product sublimed at 90 mm. and 50°. There was obtained in two fractions 107 mg. (42%) of 1,5-epoxycycloöctane, m.p. 48.2–52.4°.

***cis*-1,5-Cycloöctanediol (XIII).**—Crude *trans*-5-bromocycloöctyl acetate (0.99 g.) and tetraethylammonium acetate monohydrate (1.7 g.) were heated under reflux in 20 ml. of reagent grade acetone for 16 hr. Most of the acetone was removed by distillation and water was added. The product was extracted with ether and the extract washed with water and saturated sodium chloride solution and dried over magnesium sulfate. The ether was removed under diminished pressure and the product heated under reflux with 2 g. of potassium hydroxide in 15 ml. of 95% ethanol. The ethanol was removed under reduced pressure, water was added and the aqueous solution was extracted with ether. The aqueous solution also was extracted continuously with chloroform for several hours, and the total amount of glycol from the two extracts (300 mg.) was chromatographed on 10 g. of grade II alumina in a column 10 mm. in diameter, collecting 15-ml. fractions.

Fraction	Eluent	Weight, mg.
1	Benzene–ether	5
2–10	Benzene–ether	123
11–16	Ether	0
17–23	1% methanol–ether	78

Fractions 2–10 were distilled in a short-path still under reduced pressure and yielded 4-cycloöcten-1-ol, $n^{25}D$ 1.4951, identified as the phenylurethan (m.p. and mixed m.p. of 92.4–93.4°, and by its infrared spectrum, which was identical to the spectrum of an authentic sample[1]).

Fraction 18 solidified on removal of the eluent and had m.p. 72.5–73.5°. After 2 recrystallizations from ether–petroleum ether (30–60°) there was obtained crystalline *cis*-1,5-cycloöctanediol, m.p. 73.8–74.8°.

Anal. Calcd. for $C_8H_{16}O_2$: C, 66.62; H, 11.19. Found: C, 66.72; H, 11.13.

The infrared absorption spectrum of the *cis*-1,5-glycol was different from the spectra of the other seven cycloöctanediols.

The combined fractions 19–23 had m.p. 68.7–71.9° and yielded the pure *cis*-1,5-glycol upon recrystallization.

***cis*-1,5-Cycloöctanediol Bis-*p*-nitrobenzoate.**—A sample of the above diol (20 mg.) was treated with *p*-nitrobenzoyl chloride (75 mg.) in a few milliliters of dry pyridine. The yield of *cis*-1,5-cycloöctanediol bis-*p*-nitrobenzoate was 51 mg. (83%). After two recrystallizations from ethanol, the derivative had m.p. 181.4–182.6°. A mixture with *trans*-1,5-cycloöctanediol bis-*p*-nitrobenzoate had m.p. 159–168°. An analytical sample had m.p. 181.4–182.8°.

Anal. Calcd. for $C_{22}H_{22}O_8N_2$: C, 59.72; H, 5.01; N, 6.33. Found: C, 59.99; H, 5.13; N, 6.33.

Proximity Effects. VIII. Solvolysis of *cis*-Cycloöctene Oxide; Synthesis of Alcohols in the Cycloöctane Series[1]

BY ARTHUR C. COPE, ALLEN H. KEOUGH, PAUL E. PETERSON,[2] HOWARD E. SIMMONS, JR.,[3] AND GEOFFREY W. WOOD

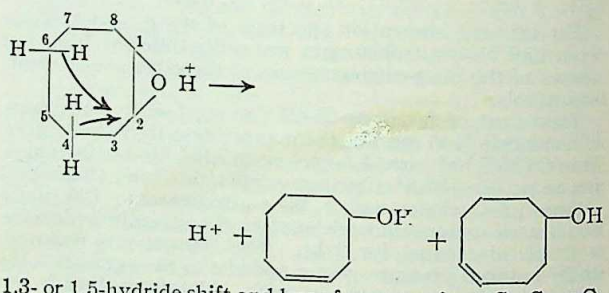
RECEIVED MARCH 8, 1957

The solvolysis of *cis*-cycloöctene oxide in formic acid has been shown to yield, in addition to the *cis*-1,4- and *trans*-1,2-cycloöctanediols already reported, a lower boiling fraction containing 3-cycloöcten-1-ol and 4-cyloöcten-1-ol (15% total), a saturated alcohol that appears to be a bicycloöctanol (at least 0.1%), cycloöctanone (trace), 1,4- and 1,5-epoxycycloöctane (about 0.1% total) and an unidentified alcohol (about 1%). Three non-stereospecific syntheses of 1,4-cycloöctanediols are reported. *cis*- and *trans*-1,4-cycloöctanediol have been shown to be epimers by oxidation to the same diketone, which on reduction formed a mixture of the two glycols. The *cis* isomer has been converted to the *trans* through the monotosylate (not isolated). *trans*-1,3-Cycloöctanediol has been prepared, and its stereochemistry has been determined by establishing the configuration of the intermediate compound, *trans*-2,3-epoxycycloöctan-1-ol. *trans*-1,3-Cycloöctanediol has been converted to the *cis* isomer through the monotosylate (not isolated). Derivatives of various alcohols in the cycloöctane series have been prepared.

Solvolysis of *cis*-Cycloöctene Oxide.—Previous papers in this series have described reactions of cycloöctane derivatives that are influenced by what has been called a "proximity effect." The original example of such a reaction, *i.e.*, the solvolysis of *cis*-cycloöctene oxide in formic acid,[4] has now been reinvestigated. Additional products have been found, some of which appear to arise through the influence of proximity effects.

Repetitions of the solvolysis of *cis*-cycloöctene oxide resulted in isolation of the previously reported diols, *trans*-1,2-cycloöctanediol (5.6–19%) and *cis*-1,4-cycloöctanediol (23–30%). The structure and *cis* configuration of the latter diol have since been confirmed by synthesis.[5]

In addition, distillation of the alcohol mixture obtained in the solvolysis of the oxide gave a low-boiling fraction amounting to 16–17% of the weight of the oxide. This fraction yielded a phenylurethan which, after several recrystallizations, melted at 102.4–103.6°. This phenylurethan has been shown to be 3-cycloöcten-1-yl phenylurethan.[6] Infrared analysis, based upon the available spectra of 2-cycloöcten-1-ol, 3-cycloöcten-1-ol and 4-cycloöcten-1-ol and upon the spectra of the corresponding phenylurethans, indicated that the low boiling material contained considerable 4-cycloöcten-1-ol in addition to 3-cycloöcten-1-ol. The presence of 4-cycloöcten-1-ol in the alcohol mixture was confirmed by preparation of a *p*-nitrobenzoate. The product, which was isolated in 13% yield, proved to be the *p*-nitrobenzoate of 4-cycloöcten-1-ol, m.p. 83–85°. The failure of 3-cycloöcten-1-yl *p*-nitrobenzoate to crystallize from the mixture was explained when an authentic sample was prepared and found to have a melting point of 32–33°. It is of interest that no appreciable amount of 2-cycloöcten-1-ol, which might be considered a "normal" product of the *cis*-cycloöctene oxide solvolysis, appeared to be present in the alcohol mixture. The unsaturated alcohols therefore represent additional products formed by a transannular reaction. They could originate directly from the oxide by a concerted elimination reaction or could result from dehydration of the initially formed *cis*-1,4-cycloöctanediol.



1,3- or 1,5-hydride shift and loss of a proton from C_3, C_5 or C_7

Hydrogenation of the alcohol mixture resulted in uptake of 92–100% of one mole of hydrogen giving cycloöctanol, which was isolated as its phenylurethan in 85% yield. These results would be expected for an alcohol mixture consisting mostly of 3-cycloöcten-1-ol and 4-cycloöcten-1-ol.

In order to isolate any bicyclic alcohol that might be present in the low-boiling material, a sample was subjected to a separation procedure involving silver nitrate extraction, conversion of alcohols to the phenylurethans, ozonolysis (to remove the phenylurethans of unsaturated alcohols) and chromatography. From the chromatogram the phenylurethan of a saturated alcohol was obtained with an analysis in agreement with a bicycloöctyl phenylurethan structure. The yield was 0.1% based on *cis*-cycloöctene oxide. The presence of a bicyclic alcohol among the solvolysis products could be due to a transannular reaction in which the double bond of one of the cycloöctenols forms a bond bridging the cycloöctane ring subsequent to or concomitant with removal of the protonated hydroxyl group. The absence of either isomer of bicyclo[3.3.0]octan-2-ol[7] in the original alcohol mixture was shown by vapor phase chromatography. Comparison of melting points showed that the saturated phenylurethan of unknown structure is not derived from either of these bicycloöctanols. The structure of the unknown phenylurethan is being investigated.

When the low boiling distillate from *cis*-cycloöctene oxide solvolysis was collected in several

Digitized by Arya Samaj Foundation Chennai and eGangotri

fractions, the first fractions contained a carbonyl compound that was shown to be cycloöctanone by comparison of the 2,4-dinitrophenylhydrazone with authentic cycloöctanone 2,4-dinitrophenylhydrazone.

Vapor phase chromatography of the first distillation fractions from the *cis*-cycloöctene oxide solvolysis revealed the presence of two major peaks which could not be attributed to any of the compounds previously identified. Comparison with known samples on the vapor phase column showed that the compounds were not cycloöctadienes or *cis*-cycloöctene oxide. Samples of the unknown materials were collected by condensation from the effluent gas from the vapor-phase apparatus. The infrared spectrum of one of the fractions indicated that it was a mixture of 1,4- and 1,5-epoxycyclooctane.[5,8] These ethers could be formed from the 3- and 4-cycloöcten-1-ol produced in the *cis*-cycloöctene oxide solvolysis.

The infrared spectrum of the second fraction indicated that it was an unsaturated alcohol. Further characterization of this compound will be reported in connection with another problem.

Synthesis of Cycloöctanediols.—Although stereospecific syntheses of 1,4- and 1,5-cycloöctanediols now have been accomplished[5,8] other methods of preparation are of interest as more practical sources of the glycols. Since *cis*-1,4-cycloöctanediol was available from solvolysis of *cis*-cycloöctene oxide, it was made the starting material for synthesis of *trans*-1,4-cycloöctanediol. Oxidation of *cis*-1,4-cycloöctanediol with N-bromosuccinimide in aqueous acetone gave 1,4-cycloöctanedione, characterized by preparation of the dioxime and bis-2,4-dinitrophenylhydrazone, in 63% yield. Hydrogenation of the diketone over Raney nickel gave a mixture of glycols which was separated by chromatography on alumina into approximately equal amounts of *cis*-1,4-cycloöctanediol and *trans*-1,4-cycloöctanediol. The latter glycol formed a bis-*p*-nitrobenzoate identical with a sample derived from the *trans*-1,4-glycol obtained by solvolysis of *trans*-cycloöctene oxide.[9]

Alternatively, the *cis*-1,4-cycloöctanediol was epimerized to the *trans* isomer *via* the crude mono-*p*-toluenesulfonate obtained by reaction of one molar equivalent of *p*-toluenesulfonyl chloride with *cis*-1,4-cycloöctanediol. Treatment of the product with tetraethylammonium acetate followed by hydrolysis and chromatography gave *trans*-1,4-cycloöctanediol (21%) and some recovered *cis*-1,4-cycloöctanediol (5%).

The bromination of 2-cycloöcten-1-yl acetate with N-bromosuccinimide also was studied as a possible route leading eventually to 1,4-cycloöctanediols. A bromoacetate was obtained in 43% yield which is formulated as 4-bromo-2-cycloöcten-1-yl acetate, but presumably exists as a mixture with its allylic isomer, 2-bromo-3-cycloöcten-1-yl acetate. Treatment with tetraethylammonium acetate in acetone followed by hydrogenation and saponification gave a glycol mixture in 47% yield, from which *trans*-1,4-cycloöctanediol was isolated in 19% yield (based on the glycol mixture) by crystallization from ethyl acetate. Chromatography of the mother liquors gave an additional 4% of *trans*-1,4-cycloöctanediol. When silver acetate in acetic acid was allowed to react with the allylic bromoacetate, a 53% yield of unsaturated diacetate was obtained which was converted to a saturated glycol mixture from which *trans*-1,4-cycloöctanediol was isolated in 37% yield (based on unsaturated diacetate).

Another sequence for the synthesis of 1,4-cycloöctanediols was based on the reported ease with which cyclopentadiene and 1,3-cyclohexadiene can be autoxidized.[10] *cis-cis*-1,3-Cycloöctadiene absorbed 40–43% of one mole of oxygen on stirring at room temperature with ultraviolet illumination for 28 hr. The crude reaction mixture was reduced directly with lithium aluminum hydride by modification of a procedure used for reduction of the polymeric peroxide of styrene to phenylethylene glycol,[11] and the resulting mixture of unsaturated glycols was hydrogenated. A mixture of cycloöctanediols was isolated in 8% yield. Treatment of the glycol mixture with acetone and copper sulfate afforded *trans*-1,2-cycloöctanediol isopropylidene ketal in 15% yield. Chromatographic analysis of the glycol residue (66% based on the glycol mixture) showed that it was composed of essentially pure *trans*-1,4-cycloöctanediol.

Previous papers in this series have described the preparation of all the possible cycloöctanediols by methods leading to products of known stereochemistry with the exception of the two epimeric 1,3-cycloöctanediols. Accordingly, the preparation of these diols, needed for comparison with diols obtained in the solvolysis of *trans*-cycloöctene oxide, was undertaken, beginning with 2-cycloöcten-1-ol. Epoxidation of the 2-cycloöcten-1-ol gave 2,3-epoxycycloöctan-1-ol as an oil which was hydrogenated over Raney nickel to give a mixture of 1,2- and 1,3-cycloöctanediols. Reaction of the glycol mixture with acetone in the presence of cupric sulfate gave *trans*-1,2-cycloöctanediol isopropylidene ketal in 75% yield. Crystallization of the glycol residue from the acetone–cupric sulfate reaction gave *trans*-1,3-cycloöctanediol in 12% yield. Assignment of configuration to the latter compound is based in part upon the above results, which show that the oxide group in 2,3-epoxycycloöctan-1-ol is *trans* to the hydroxyl group to the extent of at least 75% and also upon the result of lithum aluminum hydride reduction. When the latter reaction was carried out by addition of lithium aluminum hydride to 2,3-epoxycycloöctan-1-ol, a 1,3-cycloöctanediol identical with the 1,3-glycol obtained by hydrogenation with Raney nickel was isolated in 50% yield. It can thus have been formed only from *trans*-2,3-epoxycycloöctan-1-ol and must therefore be the *trans*-1,3-glycol. The lithium aluminum hydride reduction also gave *trans*-1,2-cycloöctanediol, isolated in 35% yield as the

It was purified by recrystallization from ether–pentane.

isopropylidene ketal. These results indicate that the epoxidation of 2-cycloöcten-1-ol results almost exclusively in addition of oxygen *trans* to the hydroxyl group, in contrast to the epoxidation of 2-cyclohexen-1-ol, which forms *cis*-2,3-epoxycyclohexan-1-ol.[12]

2-Cycloöcten-1-one also was investigated as an intermediate which could lead to 1,3-cycloöctanediols. Preparation of this known[13] ketone was accomplished in improved yield by oxidation of 2-cycloöcten-1-ol with active manganese dioxide in pentane. Epoxidation with sodium hydroperoxide in methanol gave 2,3-epoxycycloöctan-1-one. This epoxide was not investigated further, since the corresponding alcohol was obtained more readily.

trans-1,3-Cycloöctanediol was epimerized to the *cis* isomer *via* the crude mono-*p*-toluenesulfonate in a manner similar to that employed in the epimerization of *cis*-1,4-cycloöctanediol. *cis*-1,3-Cycloöctanediol was isolated in 20% over-all yield. *trans*-1,3-Cycloöctanediol was further characterized by oxidation with chromic anhydride–pyridine complex to give 1,3-cycloöctanedione, isolated as the bis-2,4-dinitrophenylhydrazone. The same method was employed to convert both *cis*- and *trans*-1,4-cycloöctanediol to 1,4-cycloöctanedione bis-2,4-dinitrophenylhydrazone. The bis-2,4-dinitrophenylhydrazone of 1,2-cycloöctanedione also was prepared for comparison.

The melting points of all the cycloöctanediols and of the derivatives which have been prepared from them are collected in Table I. Melting points of derivatives of the cycloöctenols are listed in Table II.

Experimental[14]

Solvolysis of *cis*-Cycloöctene Oxide.—Several repetitions of the solvolysis of *cis*-cycloöctene oxide on a large scale have given results of which the following are typical. *cis*-Cycloöctene oxide (80.5 g.) was added in portions over a period of 1 hr. to 1 l. of 90% formic acid heated on a steam-bath. After 2 additional hr. of heating, the formic acid was removed by distillation at 100 mm. The resulting mixture of formates was saponified by stirring with 300 ml. of 40% sodium hydroxide at the reflux temperature for 1 hr. The resulting two-phase mixture was extracted with 300 ml. of chloroform. Short-path distillation of the chloroform extract gave 60.0 g. of material which was distilled through a spinning-band column. A low-boiling material (13.2 g.) was collected in five fractions, b.p. 55–70° (1 mm.), and was shown by the methods described below to consist principally of 3- and 4-cycloöcten-1-ol. This fraction was followed by the glycol fraction, b.p. 115–130° (1 mm.), containing *trans*-1,2-cycloöctanediol and *cis*-1,4-cycloöctanediol.

TABLE II

CYCLOÖCTENOLS AND DERIVATIVES

Identification of 3-Cycloöcten-1-ol and 4-Cycloöcten-1-ol.—Earlier experiments indicated that the low-boiling material consisted mostly of 3-cycloöcten-1-ol or a mixture of cycloöctenols. This was shown by hydrogenation of a sample to cycloöctanol, identified as its phenylurethan, which was isolated in 85% yield, and by preparation of a phenylurethan from the low boiling material. Recrystallization of the unsaturated phenylurethan yielded 3-cycloöcten-1-yl phenylurethan, m.p. 102.4–103.6°, whose structure was known from ozonization.[6]

The presence of 4-cycloöcten-1-ol in the low boiling material was indicated by the infrared spectrum of the crude unsaturated phenylurethan, which contained bands characteristic of 4-cycloöcten-1-yl phenylurethan at 697 and 724 $cm.^{-1}$ as well as those of 3-cycloöcten-1-yl phenylurethan at 685, 705, 768 and 780 $cm.^{-1}$. The absence of any appreciable amount of 2-cycloöcten-1-yl phenylurethan was demonstrated by the fact that there was no band at 950 $cm.^{-1}$ where 2-cycloöcten-1-yl phenylurethan has an absorption band of medium intensity. Further evidence for the composition of the unsaturated alcohol fraction was obtained by comparison of its infrared spectrum with the spectra of authentic samples of 3-cycloöcten-1-ol (described below, strong band at 705 $cm.^{-1}$) and 4-cycloöcten-1-ol (strong band at 725 $cm.^{-1}$). The infrared spectrum of the low-boiling material from the *cis*-cycloöctene oxide solvolysis could be accounted for by assuming it to be a mixture of the two alcohols. Finally, the presence of 4-cycloöcten-1-ol in the low-boiling material was confirmed by isolation of a *p*-nitrobenzoate prepared from the alcohol mixture, which was shown by mixed m.p. and infrared spectrum to be identical with the *p*-nitrobenzoate prepared from authentic 4-cycloöcten-1-ol.

Bicyclic Alcohol.—The presence in the low-boiling material of a small amount of a saturated alcohol isomeric with the cycloöctenols was demonstrated by isolation of the phenylurethan of the alcohol as follows. Distillation fractions 4 and 5 of the low-boiling material (5.94 g.) were treated with 35 ml. of 20% silver nitrate to remove unsaturated compounds. The insoluble saturated compounds were then extracted with ether (35 ml.), and the ether layer was washed twice with 5-ml. portions of 20% silver nitrate. Vapor phase chromatography (described below) of the ether layer showed the presence of at least three components in addition to a band that may have been due to cycloöctenols not removed by the silver nitrate. Evaporation of the ether gave 0.16 g. of a product that was warmed with 0.19 g. of phenyl isocyanate on a steam-bath. Removal of the excess phenyl isocyanate under reduced pressure and ozonolysis followed by reduction with sodium borohydride gave a product that was chromatographed on alumina (Merck, acid-washed). This is the procedure used previously,[6] except that treatment of the reduction product with phenyl isocyanate was omitted. The saturated phenylurethan which was eluted with 20% ether in petroleum ether (0.14 g.) was recrystallized from methanol and water, m.p. 118–119.5°.

Anal. Calcd. for $C_{15}H_{19}O_2N$: C, 73.44; H, 7.81; N, 5.71. Found: C, 73.36; H, 7.62; N, 5.75.

Cycloöctanone.—Distillation fractions 1 and 2 of the low boiling material from *cis*-cycloöctene oxide solvolysis gave several peaks upon vapor phase chromatography, in contrast to fractions 4 and 5, which gave a single major peak. The infrared spectrum of fraction 1 showed a carbonyl peak at 1688 cm.$^{-1}$. This unusually low frequency for carbonyl absorption suggested the presence of cycloöctanone (reported[15] carbonyl absorption at 1692 cm.$^{-1}$). The presence of cycloöctanone was confirmed by the preparation of a 2,4-dinitrophenylhydrazone, m.p. 171.0–173.2°, undepressed in mixed m.p. with authentic cycloöctanone 2,4-dinitrophenylhydrazone, m.p. 174.8–175.1°.

1,4- and 1,5-Epoxycycloöctanes and the Unidentified Component.—At this point the two remaining major components of fractions 1 and 2 which gave peaks upon vapor phase chromatography were isolated from the effluent gas stream of the vapor phase apparatus by attaching small collecting vessels as the fractions were eluted from the column. The column employed for this separation was a 12-mm. Pyrex tube with a 180-cm. length of packing consisting of 30% Dow-Corning Silicone oil no. 550 on a ground firebrick support (38–80 mesh). The column was heated to 180° and employed helium introduced under a pressure of about 60 cm. as the gas phase. Detection involved use of thermistors to measure changes in the thermal conductivity of the effluent gases. In preparative use, amounts up to 0.7 ml. were separated on the above column. The purity of the components collected in this manner was then checked by analysis on a column similar to the one described above, except that it was constructed of 8-mm. tubing.

One of the components separated in this manner was present in appreciable quantity only in distillation fraction 1, indicating that it had a relatively low boiling point. The infrared spectrum of this component showed that it was a mixture of 1,4- and 1,5-epoxycycloöctane.[5,8] The yield, estimated by vapor phase chromatography, was 0.1%. The other component appeared in fractions 1 and 2, indicating a somewhat higher boiling point, and no information concerning its structure has been obtained except the infrared spectrum, which indicates that it is an unsaturated alcohol. The estimated yield was 1%.

Cycloöctanediols.—The glycol fraction obtained when the *cis*-cycloöctene oxide solvolysis products were distilled yielded *trans*-1,2-cycloöctanediol as the isopropylidine ketal (5.6%) and *cis*-1,4-cycloöctanediol (23.6%), separated by methods that have been described.[4] In the present case a residue of 9.7% (calculated as diols) did not crystallize. However, the residue consisted mostly of *cis*-1,4-cycloöctanediol as shown by the fact that short-path distillation followed by crystallization yielded additional *cis*-1,4-cycloöctanediol (corresponding to 4.5%) plus non-crystalline material that was chromatographed to give still more crystalline *cis*-1,4-cycloöctanediol. The chromatogram yielded, in addition, several non-crystalline components that were not investigated further. It is estimated that none of the non-crystalline materials was present in over-all yield of as much as 1%.

3-Cycloöcten-1-ol.—Authentic 3-cycloöcten-1-ol, used in the identification of the alcohols formed in the solvolysis of *cis*-cycloöctene oxide, was obtained from the phenylurethan of m.p. 101.5–102.5°, isolated from the low-boiling *cis*-cycloöctene oxide solvolysis products, known to be 3-cycloöcten-1-yl phenylurethan by ozonolysis.[6] The phenylurethan (2.3 g.) was added to 50 ml. of tetrahydrofuran containing 0.4 g. of lithium aluminum hydride. The mixture was heated under reflux for 24 hr. during which time two additional 0.4-g. quantities of lithium aluminum hydride were added. The cooled reaction mixture was diluted with 100 ml. of ether to facilitate the subsequent filtration, and 3 ml. of water was added. Filtration, followed by drying and distillation of the solvent, gave a residual liquid that was distilled through a semi-micro column, yielding 0.45 g. (38%) of 3-cycloöcten-1-ol, b.p. 68° (1.5 mm.).

Anal. Calcd. for $C_8H_{14}O$: C, 76.14; H, 11.18. Found: C, 76.29; H, 11.04.

The infrared spectrum of the alcohol and of the crude phenylurethan prepared from it showed that little if any 4-cycloöcten-1-ol was present in the product. The crude phenylurethan melted at 100–102° and was shown by mixed melting point and infrared spectrum to be 3-cycloöcten-1-yl phenylurethan.

1,4-Cycloöctanedione from *cis*-1,4-Cycloöctanediol.—The oxidation of *cis*-1,4-cycloöctanediol to the corresponding diketone by benzoquinone in an Oppenauer-type oxidation is reported to give 15% yield.[4] The following procedure using N-bromosuccinimide[16] as the oxidizing agent gave 63% of the diketone. To *cis*-1,4-cycloöctanediol (10.5 g.) in 1500 ml. of acetone and 150 ml. of water was added 62.5 g. of N-bromosuccinimide followed by 5 ml. of glacial acetic acid. The mixture was cooled with a water-bath and allowed to stand for 2 hr. The solution was poured into 500 ml. of saturated sodium bicarbonate solution, and 200 ml. of 10% sodium thiosulfate was added. The mixture was filtered, and the filtrate was concentrated below 50° under reduced pressure and extracted with chloroform. The crude product was submitted first to short-path distillation at 1 mm. and then to fractionation through a semi-micro column, giving 6.41 g. (63%) of 1,4-cycloöctanedione, b.p. 73–76° (1 mm.). The diketone was a low-melting solid that had m.p. 46.8° after redistillation.

1,4-Cycloöctanedione Bis-2,4-dinitrophenylhydrazone.—The preparation of 1,4-cycloöctanedione was repeated on a small scale, except that the product from chloroform extraction was treated with 2,4-dinitrophenylhydrazine reagent. From 103 mg. of *cis*-1,4-cycloöctanediol, 361 mg. (101%) of 1,4-cycloöctanedione bis-2,4-dinitrophenylhydrazone was isolated. The product was recrystallized from nitrobenzene–ethanol to a constant melting point of 212° (introduced at 205°) and from mixed melting point and the infrared spectrum was identical with the derivative prepared from the pure diketone, although the melting point of the derivative by the latter route was higher (217.4°). Analytical data for a sample of 1,4-cycloöctanedione bis-2,4-dinitrophenylhydrazone prepared *via* oxidation of *cis*-1,4-cycloöctanediol with chromic anhydride–pyridine complex is reported elsewhere in this paper.

1,4-Cycloöctanedione Dioxime.—1,4-Cycloöctanedione (83 mg.) was heated under reflux with 0.5 ml. of absolute ethanol, 0.5 ml. of pyridine and 100 mg. of hydroxylamine hydrochloride for 2 hr. Evaporation of the solvent, followed by addition of water, gave 42 mg. (65%) of the dioxime, which after recrystallization from 95% ethanol melted at 169.5–170.2°.

Anal. Calcd. for $C_8H_{14}N_2O_2$: C, 56.45; H, 8.29. Found: C, 56.73; H, 8.30.

Hydrogenation of 1,4-Cycloöctanedione.—1,4-Cycloöctanedione (1.33 g.) in 4.3 ml. of 95% ethanol was hydrogenated over Raney nickel at 100° and 100 atmospheres. The crude product (1.03 g.) was chromatographed on 75 g. of neutral alumina of activity III, giving 229 mg. of *trans*-1,4-cycloöctanediol (eluted with 0.5% methanol in ether) and 231 mg. of *cis*-1,4-cycloöctanediol (eluted with 2% methanol

in ether), along with some intermediate fractions that contained both glycols.

4-Bromo-2-cycloöcten-1-yl Acetate.—In a typical preparation a mixture of 2-cycloöcten-1-yl acetate (8.02 g.), N-bromosuccinimide (8.50 g.), carbon tetrachloride (150 ml.) and benzoyl peroxide (0.04 g.) was heated under reflux for 20 min. After cooling, succinimide was separated by filtration, and the filtrate was washed with sodium bicarbonate solution. The solvent was removed without external heating and the residue was subjected to short-path distillation under reduced pressure followed by fractionation through a semi-micro column, giving 4-bromo-2-cycloöcten-1-yl acetate (5.08 g., 43%), b.p. 81.5° (0.27 mm.), $n^{25}D$ 1.5122.

Anal. Calcd. for $C_{10}H_{15}BrO_2$: C, 48.60; H, 6.12; Br, 32.35. Found: C, 48.39; H, 6.03; Br, 32.69.

Cycloöctenediol Diacetate. A. From Tetraethylammonium Acetate.—A solution of 4-bromo-2-cycloöcten-1-yl acetate (5.73 g.) in 75 ml. of dry acetone was heated under reflux for 20 hr. with 10 g. of tetraethylammonium acetate monohydrate. After filtration and removal of acetone under reduced pressure, water was added and the product was extracted with ether. The extract yielded 3.95 g. (75%) of cycloöctenediol diacetate upon distillation through a semi-micro column. An analytical sample had b.p. 90° (0.38 mm.), $n^{26}D$ 1.4700.

Anal. Calcd. for $C_{12}H_{18}O_4$: C, 63.68; H, 8.02. Found: C, 63.44; H, 8.15.

Selenious acid oxidation of *cis*-cycloöctene is reported to give 27% of cycloöctenediol diacetate of unknown stereochemistry.[17]

Cycloöctanediols from Method A.—Cycloöctenediol diacetate (6.32 g.) was hydrogenated over 0.21 g. of Adams platinum catalyst (which had been pre-reduced in 50 ml. of methanol) with absorption of 133% of one molar equivalent of hydrogen, indicating some hydrogenolysis of the allylic acetate. After saponification with 5 g. of sodium hydroxide and 10 ml. of water, the concentrated reaction mixture was extracted with chloroform. The dried chloroform extract yielded a glycol mixture (2.47 g., 62%, based on the unsaturated diacetate) which was crystallized from ethyl acetate. After seeding the ethyl acetate solution, 0.470 g. of *trans*-1,4-cycloöctanediol separated (19% based on the glycol mixture), m.p. 90.7–92°. Chromatography of the mother liquor resulted in isolation of cycloöctanol (10% by weight based on the glycol mixture) and additional *trans*-1,4-cycloöctanediol (4%).

Cycloöctanediol Diacetate. B. From Silver Acetate.—4-Bromo-2-cycloöcten-1-yl acetate (5.12 g.) was stirred overnight with 4 g. of silver acetate in 25 ml. of 100% acetic acid (prepared by adding acetic anhydride to glacial acetic acid). After separation of silver bromide, fractionation gave 2.44 g. (52.6%) of cycloöctenediol diacetate. This mixture was converted to saturated glycols as in method A. In order to separate any 1,2-cycloöctanediol that might be present, the glycol mixture was shaken with acetone and cupric sulfate.[4] Chromatography of the product on alumina resulted in isolation of *trans*-1,2-cycloöctanediol isopropylidene ketal, identified by its infrared spectrum, in a yield of 5%. A later series of chromatographic fractions consisted of *cis*- and *trans*-1,4-cycloöctanediols. The total amount of *trans*-1,4-cycloöctanediol was 0.565 g. (37% based on unsaturated diacetate), and as in the case of the 1,4-cycloöctanedione hydrogenation product, the separation of the epimeric glycols by chromatography was not complete.

Epimerization of *cis*-1,4-Cycloöctanediol.—*p*-Toluenesulfonyl chloride (3.8 g.) was added to a solution of *cis*-1,4-cycloöctanediol (2.88 g.) in pyridine (20 ml.). The crude monotosylate was isolated after the mixture stood overnight by pouring it into water, extracting with benzene and washing the extract with dilute hydrochloric acid and water. The crude monotosylate (5.3 g.) was allowed to react with tetraethylammonium acetate (4.5 g.) in acetone (150 ml.), first at room temperature (24 hr.) and then under reflux (24 hr.). The crude monoacetate was isolated and hydrolyzed with sodium hydroxide, giving 1.66 g. of a product that was chromatographed on alumina, separating an unsaturated alcohol fraction (270 mg.), *trans* 1,4-cycloöctanediol (605 mg., 21%) which was identified by its infrared spectrum, and *cis*-1,4-cycloöctanediol (145 mg., 5%).

Autoxidation of 1,3-Cycloöctadiene.—*cis-cis*-1,3-Cycloöctadiene[18] (22.3 g.) was placed in a flask connected to a gas buret and illuminated with a 275-watt sun lamp under a positive pressure of oxygen for 28 hr., with stirring. During this time 2.13 liters (40% of 1 molar equivalent) of oxygen was taken up, giving a viscous product that was reduced directly. A solution of the reaction mixture in 130 ml. of ether was added dropwise to a slurry of 7.82 g. of lithium aluminum hydride in 200 ml. of anhydrous ether, maintained below 20°. The excess lithium aluminum hydride was destroyed by addition of 40 ml. of ethyl acetate, followed by 60 ml. of saturated ammonium chloride solution. Filtration, followed by short-path distillation (0.3–0.7 mm., 90–180° bath temperature) gave 14.99 g. of low-boiling liquid and 7.79 g. of higher boiling material. The latter yielded 2.32 g. of crude glycols after redistillation and hydrogenation in the presence of pre-reduced platinum oxide. From the crude glycols there was obtained *trans*-1,2-cycloöctanediol isopropylidene ketal (0.43 g., 15%) by the method described previously under "Method B." Chromatography of the glycol residue yielded fractions amounting to 0.95 g. from which *trans*-1,4-cycloöctanediol bis-*p*-nitrobenzoate was prepared.

***trans*-2,3-Epoxycycloöctan-1-ol.**—Commercial 40% peracetic acid (12.0 ml.) to which sodium acetate trihydrate (2.4 g.) had been added to neutralize the sulfuric acid present was added to 2-cycloöcten-1-ol[13] (5.00 g.) maintained at 10–15°. The reaction mixture was made basic with excess sodium hydroxide and extracted with ether. Distillation through a semi-micro column gave 4.70 g. (84%) of *trans*-2,3-epoxycycloöctan-1-ol, b.p. 99–100° (1.8 mm.), $n^{25}D$ 1.4930.

Anal. Calcd. for $C_8H_{14}O_2$: C, 67.57; H, 9.93. Found: C, 67.65; H, 10.27.

Hydrogenation of *trans*-2,3-Epoxycycloöctan-1-ol.—Hydrogenation of a solution of 5.00 g. of *trans*-2,3-epoxycycloöctan-1-ol in ethanol in the presence of W-6 Raney nickel at 125° and 1300 p.s.i. gave 5.00 g. (99%) of a glycol mixture after short-path distillation of the product under reduced pressure. The 1,2-cycloöctanediol in the mixture was converted to the isopropylidene ketal,[4] and the latter compound (2.38 g., 75%) was isolated by distillation. The product, after chromatography on alumina, had an infrared spectrum identical with the spectrum of authentic *trans*-1,2-cycloöctanediol isopropylidene ketal and showed no bands attributable to *cis*-1,2-cycloöctanediol isopropylidene ketal. The ketal was further characterized by hydrolysis to the glycol[4] followed by conversion to the bis-*p*-nitrobenzoate.

***trans*-1,3-Cycloöctanediol.**—The glycol residue remaining after distilling the isopropylidene ketal from hydrogenation of *trans*-2,3-epoxycycloöctan-1-ol was recrystallized from benzene, giving 0.30 g. (12%) of *trans*-1,3-cycloöctanediol, m.p. 103–105°. An analytical sample that was recrystallized from benzene had m.p. 106.5–108°.

Anal. Calcd. for $C_8H_{16}O_2$: C, 66.62; H, 11.18. Found: C, 66.76; H, 11.11.

Lithium Aluminum Hydride Reduction of *trans*-2,3-Epoxycycloöctan-1-ol.—A slurry of lithium aluminum hydride (1.60 g.) in 30 ml. of ether was added to a solution of 1.5 g. of *trans*-2,3-epoxycycloöctan-1-ol in 25 ml. of ether. After 4 hr. the excess lithium aluminum hydride was destroyed by the addition of 5 ml. of ethanol, followed by concentrated sodium hydroxide. The ether layer was separated, and the aqueous layer was extracted with chloroform. Upon short-path distillation (100–130° at 1 mm.), 1.45 g. (96%) of a glycol mixture was obtained from the ether and chloroform extracts. The glycol mixture was separated in the manner described above for the hydrogenation products obtained from *trans*-2,3-epoxycycloöctan-1-ol, giving 0.65 g. (35%, based on glycols isolated) of *trans*-1,2-cycloöctanediol isopropylidene ketal, identified by its infrared spectrum, and 0.75 g. (50%) of *trans*-1,3-cycloöctanediol, m.p. 106.5–108°, undepressed on admixture with the glycol obtained by catalytic hydrogenation.

When the normal order of addition of reagents was employed, *i.e.*, when the epoxyalcohol was added to the lithium

aluminum hydride slurry, there was obtained 44% of *trans*-1,2-cycloöctanediol isopropylidene ketal and 31% of *trans*-1,3-cycloöctanediol, based on the weight of crude glycols, isolated in 82% yield.

2-Cycloöcten-1-one.—2-Cycloöcten-1-ol (5.00 g.) was dissolved in pure pentane (80 ml.) and active manganese dioxide[19] (23.5 g.) was added. After 6 hr. the slurry was filtered. The filtrate yielded 4.02 g. (82%) of a mixture of 2-cycloöcten-1-one and 2-cycloöcten-1-ol which was found to contain 59% of the ketone by comparison of the ultraviolet spectrum with the spectrum of the pure ketone.[13] Repetition of the oxidation gave 3.02 g. (62% over-all) of 2-cycloöcten-1-one of 98% purity as indicated by the ultraviolet spectrum.

2,3-Epoxycycloöctan-1-one.—In a modification of the method of Weitz,[20] sodium hydroxide (10 ml. of a 6 *N* solution) was added to a cooled mixture of 10 ml. of 30% hydrogen peroxide in 75 ml. of methanol. While maintaining a temperature of 0–5°, 2-cycloöcten-1-one (2.00 g.) in methanol (10 ml.) was added. After an hour the mixture was poured into 80 ml. of ice-water, and the solution was extracted with ether. The ether extract yielded 0.095 g. (5%) of recovered 2-cycloöcten-1-one, b.p. 83–84° (11 mm.), and 0.809 g. (36%) of 2,3-epoxycycloöctan-1-one, b.p. 115–116° (5 mm.). The latter compound was a solid which after sublimation had m.p. 92.0–93.0°.

Anal. Calcd. for $C_8H_{12}O_2$: C, 68.54; H, 8.63. Found: C, 68.46; H, 8.40.

Oxidation of *cis*- and *trans*-1,4-Cycloöctanediol with Chromic Anhydride–Pyridine Complex.—*cis*-1,4-Cycloöctanediol (0.100 g.) in dry pyridine (2 ml.) was added to the preformed complex[21] prepared from 0.555 g. of chromic anhydride and 6 ml. of pyridine. After stirring the mixture 30 minutes, it was allowed to stand overnight. The mixture was poured into 25 ml. of ice-water and extracted with four 40-ml. portions of chloroform. The extract was washed with dilute hydrochloric acid and dilute sodium bicarbonate and dried. Evaporation of the chloroform and treatment of the residue with 2,4-dinitrophenylhydrazine (0.270 g.) in ethanol (15 ml.) containing concentrated hydrochloric acid (5 drops) gave 1,4-cycloöctanedione bis-2,4-dinitrophenylhydrazone (0.250 g., 68%), m.p. 211.0–212.0° dec. after boiling the crude derivative with a large volume of ethanol. Recrystallization from nitrobenzene–ethanol gave an analytical sample, m.p. 211.8–212.0° (inserted at 205°).

Anal. Calcd. for $C_{20}H_{20}O_8N_8$: C, 48.00; H, 4.03. Found: C, 48.20; H, 4.15.

Oxidation of *trans*-1,4-cycloöctanediol (0.101 g.) by the same procedure gave 0.147 g. (42%) of 1,4-cycloöctanedione bis-2,4-dinitrophenylhydrazone, m.p. 211.3–211.5° after recrystallization from nitrobenzene–ethanol (1:1). No depression of melting point on admixture with an authentic sample was noted.

1,3-Cycloöctanedione Bis-2,4-dinitrophenylhydrazone.—Oxidation of *trans*-1,3-cycloöctanediol (0.100 g.) with chromic anhydride–pyridine complex followed by treatment with 2,4-dinitrophenylhydrazine as described for *cis*-1,4-cycloöctanediol gave 1,3-cycloöctanedione bis-2,4-dinitrophenylhydrazone (0.090 g., 26%), which had m.p. 233–234° (inserted at 225°) after recrystallization from nitrobenzene–ethanol.

Anal. Calcd. for $C_{20}H_{20}O_8N_8$: C, 48.00; H, 4.03. Found: C, 47.90; H, 4.16.

1,2-Cycloöctanedione Bis-2,4-dinitrophenylhydrazone.—Suberoin[4] (2.97 g.) was oxidized with cupric acetate monohydrate (8.36 g.) in methanol (2 ml.) and 50% aqueous acetic acid (20 ml.).[22] Distillation gave 1.76 g. (60%) of 1,2-cycloöctanedione, b.p. 58–60° (1 mm.), $n^{25}D$ 1.4699. Part of the diketone (0.276 g.) was treated with 2,4-dinitrophenylhydrazine reagent, giving 0.970 g. (99%) of 1,2-cycloöctanedione bis-2,4-dinitrophenylhydrazone. Recrystallization from nitrobenzene gave a sample with m.p. 216.0–216.5° (dec., inserted at 210°).

Anal. Calcd. for $C_{20}H_{20}O_8N_8$: C, 48.00; H, 4.03. Found: C, 48.32; H, 3.96.

***p*-Nitrobenzoates.**—The *p*-nitrobenzoates of the various cycloöctenols and cycloöctanediols prepared during this study were obtained by treating the alcohols with *p*-nitrobenzoyl chloride in pyridine at room temperature for 0.5 to 3.0 hr. followed by isolation in the usual manner,[23] except that in some cases *p*-nitrobenzoic acid and other impurities were removed by passing a solution of the crude *p*-nitrobenzoate through a column of neutral alumina. The melting points and analyses of the new derivatives appear in Tables I and II.

Di-*p*-toluenesulfonates.—The preparations of the new di-*p*-toluenesulfonates (Table II) were similar to the one reported for *cis*-1,4-cycloöctanediol di-*p*-toluenesulfonate.[4]

Proximity Effects. IX. Solvolysis of *trans*-Cycloöctene Oxide

BY ARTHUR C. COPE, ALBERT FOURNIER, JR., AND HOWARD E. SIMMONS, JR.[1]

RECEIVED MARCH 8, 1957

trans-Cycloöctene oxide has been prepared from *trans*-cycloöctene and peracetic acid. This oxide reacts exothermically with formic acid, forming a mixture of products that was isolated in 55% yield. Components of this mixture that have been isolated and the mole percentage of each include the following: first, products formed by a transannular hydride shift of the kind observed in previous work in this series: *trans*-1,4-cycloöctanediol, 33%; *trans*-1,3-cycloöctanediol, 1%; 4-cycloöcten-1-ol, 12%. In addition, three compounds formed by ring contraction were isolated. These were hexahydro-*o*-tolualdehyde (isolated as the acid), 25%; a liquid glycol $C_8H_{16}O_2$ (A) containing a C-methyl group, 16%; a second liquid glycol $C_8H_{16}O_2$ (B), also containing a C-methyl group, 13%.

trans-Cycloöctene oxide has been described by Ziegler and Wilms,[2] who prepared it from a sample of cycloöctene that is now known to be a mixture of *trans*- and *cis*-cycloöctene in a ratio of approximately 3:2.[3] In this work, *trans*-cycloöctene oxide was prepared from the pure *trans*-olefin and peracetic acid in 93% yield. Unlike *cis*-cycloöctene oxide, which is a crystalline solid, the *trans*-oxide is a liquid; differences in its infrared spectrum from the spectrum of the *cis*-oxide show that it is not contaminated by the *cis* isomer, and vapor phase chromatography indicated that the oxide prepared in this way is homogeneous.

Ziegler and Wilms heated *trans*-cycloöctene oxide with water at 120° and dilute aqueous sulfuric acid at 170–180°. No change in volume of the water-insoluble layer was noted in the absence of acid, while in the presence of acid a water-insoluble fraction was separated from the aqueous solution, but no products were isolated from either phase. We have found that *trans*-cycloöctene oxide reacts exothermically with formic acid to form a complex mixture. The products that were formed were separated into two fractions by distillation. A low-boiling fraction, b.p. 66–105° (22 mm.), was removed by distillation and contained 40% of the total product. The infrared spectrum of this mixture contained bands at 3000 and 1640 cm.$^{-1}$ (olefinic), 2700 cm.$^{-1}$ (aldehyde C–H), 1723 cm.$^{-1}$ (carbonyl) and 1180 cm.$^{-1}$ (formate ester). This mixture was treated with silver oxide and excess aqueous sodium hydroxide, in order to oxidize the aldehyde to an acid and at the same time to saponify the formate. Acidification of the alkaline solution formed a mixture of acids, $C_8H_{14}O_2$, which was saturated to permanganate and accordingly was composed of alicyclic acids. The infrared spectrum of the mixture contained an absorption band at 1375 cm.$^{-1}$, indicating the probable presence of a C-methyl group, and a Kuhn–Roth C-methyl determination (54% of one C-methyl group) indicated that one such group was present. The alicyclic carboxylic acids containing one C-methyl group that could be derived from *trans*-cycloöctene oxide with minimal ring contraction are *cis*- and *trans*-hexahydrotoluic acids. An amide prepared from the mixture of acids had m.p. 172.8–178.8°, a value consistent with the possibility that the mixture was composed of *cis*- and *trans*-hexahydro-*o*-toluic acids, whose amides melt at 151–153° and 181°, respectively.[4] *cis*-Hexahydro-*o*-toluic acid was prepared by the catalytic reduction of *o*-toluic acid[5] and converted to the *trans* isomer by heating with β-naphthalenesulfonic acid. The *p*-bromophenacyl ester of the *trans*-acid, m.p. 104–106°, proved to be identical with the corresponding derivative of the major component of the mixture of acids derived from the product obtained by rearrangement of *trans*-cycloöctene oxide. The mixture derived from the rearrangement product also contained some of the *cis*-acid, and an impure solid isolated from the mother liquors from recrystallization of the *p*-bromophenacyl ester prepared from the mixture contained characteristic bands at 1730, 1375, 890 and 758 cm.$^{-1}$ that are present in the spectrum of the *p*-bromophenacyl ester of *cis*-hexahydro-*o*-toluic acid, in addition to the bands present in the spectrum of the derivative of the *trans* isomer. Accordingly, the aldehyde formed from *trans*-cycloöctene oxide is hexahydro-*o*-tolualdehyde. It is uncertain from these results whether the aldehyde formed initially is the *cis* or *trans* isomer, for the *cis* isomer might be isomerized to the more stable *trans* form either in the formic acid solvolysis medium or in the presence of base during oxidation with silver oxide. Quite drastic conditions were required to isomerize the *cis*- to the *trans*-acid with β-naphthalenesulfonic acid, and vigorous acid treatment also has been used by others[6,7] to effect the isomerization. It was also shown that the *cis*-acid was affected relatively little if any by heating with aqueous sodium hydroxide at 180° for 8 hr. However, conversion of the *cis*- to the *trans*-aldehyde *via* an enol form would be expected to occur much more easily.

The alcohol formed by hydrolysis of the formate ester during treatment of the low-boiling fraction with alkaline silver oxide was shown to be composed principally of 4-cycloöcten-1-ol by preparation of the phenylurethan, which was compared with an authentic sample.[8] The alcohol was not examined in a manner that would detect the presence of 3-cycloöcten-1-ol unless it was the major component; both of these alcohols now are known to be formed in the solvolysis of *cis*-cycloöctene oxide.[9]

The high-boiling residue (60% by weight of the product) was saponified, and the alcohols that were formed were separated by chromatography on alumina. The first fraction contained 4-cycloöcten-1-ol, identified as the phenylurethan. The next fraction was a liquid glycol $C_8H_{16}O_2$ (A) that formed a bis-*p*-nitrobenzoate, m.p. 154–155°. Another liquid glycol $C_8H_{16}O_2$ (B) that formed a bis-*p*-nitrobenzoate, m.p. 175.5–180.4°, was eluted next. Both of these glycols were shown to be different from the eight isomeric cycloöctanediols by comparison of the infrared spectra of the bis-*p*-nitrobenzoates. Both glycols A and B gave negative periodate tests, indicating that they were not 1,2-glycols, and each contained one C-methyl group according to the Kuhn–Roth C-methyl determinations. From the broad melting range of the bis-*p*-nitrobenzoate, this derivative of glycol B may be a mixture of isomers, possibly stereoisomers. Further work is required to determine the structures of glycols A and B.

2-Hydroxy-2-methylcyclohexanemethanol was prepared from 2-hydroxymethylcyclohexanone and methylmagnesium iodide and shown not to be identical with either glycol A or B by conversion to the bis-*p*-nitrobenzoate, m.p. 214–215°. However, this synthesis apparently yielded predominantly one stereoisomer, and the structure of either glycol A or B may correspond to the other stereoisomer, or both may be position isomers of this formula or indeed may not have six-membered alicyclic rings.

The glycol eluted next from the chromatogram was *trans*-1,4-cycloöctanediol, identified as its bis-*p*-nitrobenzoate, m.p. 155.4–156.6°, which was identical with an authentic specimen. Finally, a small amount of crystalline *trans*-1,3-cycloöctanediol was eluted and identified by comparison with an authentic sample,[9] m.p. 109–111°.

The formation of *trans*-1,4- and *trans*-1,3-cycloöctanediol can be accounted for by hydride shifts across the eight-membered ring with concurrent attack by formic acid on the carbon atom from which the hydride shifts, as postulated for the con-

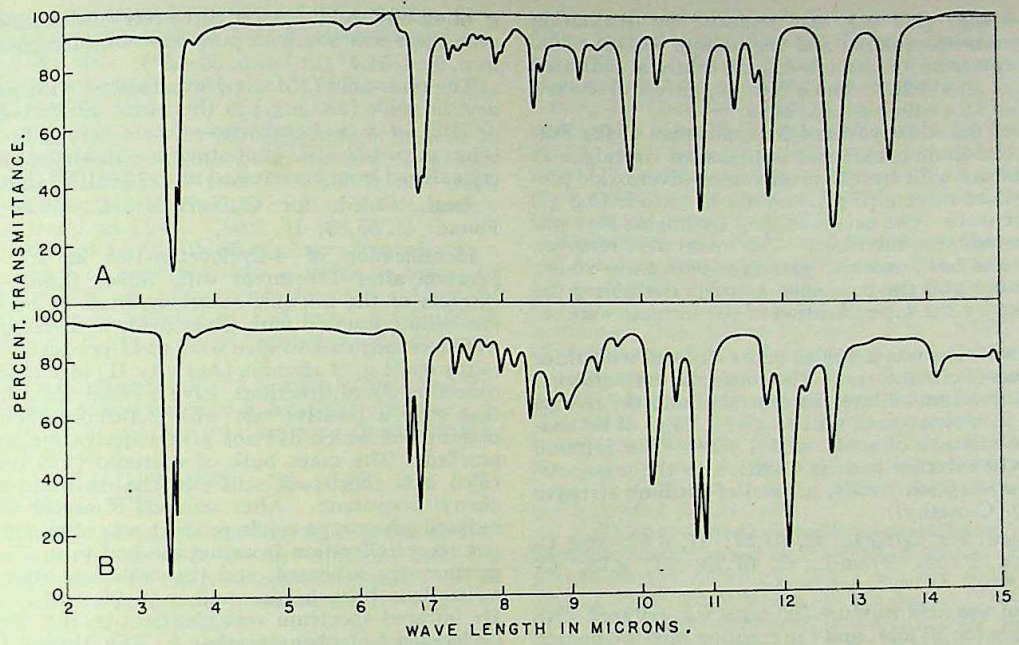

Fig. 1.—Infrared absorption spectra, determined with a Baird double beam infrared recording spectrometer, model B, fitted with a sodium chloride prism: curve A, *cis*-cycloöctene oxide; curve B, *trans*-cycloöctene oxide, both as solutions (100 mg./ml.) in carbon tetrachloride in the region 2–8μ and in carbon disulfide in the region 8–16μ, in a 0.1-mm. cell.

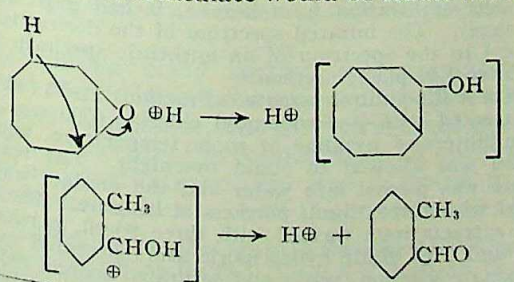
version of *cis*-cycloöctene oxide to *cis*-1,4-cycloöctanediol.[10] 4-Cycloöcten-1-ol may be formed in a similar manner, with loss of a proton accompanying the hydride shift,[9] or could be formed by the dehydration of *trans*-1,4-cycloöctanediol.

The formation of hexahydro-*o*-tolualdehyde in the solvolysis of *trans*-cycloöctene oxide is unusual in that ring contraction by two carbon atoms has occurred. Ring contraction of the oxides of cyclic olefins by one carbon atom has been described previously. For example, 1,4-dihydronaphthalene oxide on treatment with magnesium bromide yields 2-indanaldehyde in addition to β-tetralone.[11] 1-Methylcyclohexene oxide passed over kieselguhr at 220–230° forms 1-methylcyclopentanecarboxaldehyde as well as 2-methylcyclohexanone.[12] It seems likely that the spatial proximity of opposite sides of the eight-membered ring as well as the high degree of strain undoubtedly present in the *trans*-cycloöctene oxide are responsible for the unusual ring contraction that occurs in conversion of the oxide to hexahydro-*o*-tolualdehyde and glycols A and B. One reaction path by which the aldehyde could be formed is formulated below. It is quite possible that the bicyclo[4.2.0]cycloöctan-7-ol that is represented as an intermediate would be stable in formic acid under conditions used for the rearrangement. However, if such an intermediate is formed, cleavage of the four-membered ring could occur as formulated before the energy derived from cleavage of the strained *trans*-oxide was dissipated.



Work is in progress to determine the structures of glycols A and B.

Experimental[13]

trans-Cycloöctene Oxide.—*trans*-Cycloöctene (24.0 g.), purified by the aqueous silver nitrate extraction procedure,[3] was added dropwise during a period of 1 hr. with stirring to 65 ml. of commercial 40% peracetic acid[14] to which 13 g. of sodium acetate trihydrate had been added to neutralize the sulfuric acid present, with cooling to maintain a temperature of 0°. The mixture was stirred for 3 hr. at room temperature and then stored overnight at 5°. It was then placed in a separatory funnel containing crushed ice and neutralized to litmus by adding 30% sodium hydroxide solution. The aqueous solution was extracted with three 125-ml. portions of ether, and the combined extracts were washed with water and dried over magnesium sulfate. The solution was concentrated and the residue fractionated through a semi-micro column. The yield of *trans*-cycloöctene oxide, b.p. 85–86° (22 mm.), n^{25}D 1.4741, was 25.4 g. (93%). An analytical sample had b.p. 85.5° (22 mm.), n^{25}D 1.4740. Its infrared spectrum is shown in Fig. 1, together with the spectrum of *cis*-cycloöctene oxide.

Anal. Calcd. for $C_8H_{14}O$: C, 76.14; H, 11.18. Found: C, 75.95; H, 10.98.

Solvolysis of *trans*-Cycloöctene Oxide with Formic Acid.—A 100-ml. three-necked flask equipped with a dropping funnel, thermometer and stirrer was charged with 24 ml. of 88% formic acid heated to 48°. *trans*-Cycloöctene oxide (6.7 g.) was added dropwise with stirring in a nitrogen atmosphere, while the temperature was maintained at 48–51° by cooling with an ice-bath. The reaction mixture was heated at 90–95° for 1 hr., cooled and poured into 95 ml. of water. The product was extracted with four 80-ml. portions of ether, and the combined extracts were washed with saturated sodium bicarbonate solution, water and dried over Drierite. Material with b.p. 66–105° (22 mm.),

Digitized by Arya Samaj Foundation Chennai and eGangotri

$n^{25}D$ 1.4487–1.4657 (2.7 g.), was removed by distillation through a semi-micro column and the residue was set aside. An infrared spectrum of the low-boiling material indicated the presence of an aldehyde and a formate ester and showed the presence of an olefinic double bond.

Oxidation of the Aldehyde and Saponification of the Formate.—The low-boiling material was shaken overnight at room temperature with freshly precipitated silver oxide prepared from silver nitrate (9 g.), sodium hydroxide (5.3 g.) and 40 ml. of water (the excess sodium hydroxide also was present in the reaction mixture). The solids were removed by filtration, the basic solution extracted with three 20-ml. portions of ether and the combined extracts containing the alcohol formed by the saponification of the formate were set aside.

The basic solution was acidified and extracted with three 20-ml. portions of chloroform. The combined extracts were dried over magnesium sulfate, concentrated and the residue was distilled in a short-path still to give 1.03 g. of an analytically pure mixture of acids, $n^{25}D$ 1.4580. The infrared spectrum of the mixture had, in addition to the usual carboxylic acid absorption bands, a band of medium strength at 1375 $cm.^{-1}$ (C-methyl).

Anal. Calcd. for $C_8H_{14}O_2$: C, 67.57; H, 9.92; one C-methyl group, 10.55. Found: C, 67.79; H, 9.73; C-methyl, 5.78.[15]

A portion of the acid mixture (90 mg.) was refluxed with thionyl chloride for 30 min. and the reaction mixture poured into iced concentrated ammonium hydroxide. The product was filtered and a very poor yield of a mixture of amides was obtained. After two recrystallizations from water, it had m.p. 172.8–178.8°.

Anal. Calcd. for $C_8H_{15}NO$: C, 68.04; H, 10.70. Found: C, 68.19; H, 10.80.

Identification of *cis*- and *trans*-Hexahydro-*o*-toluic Acid.—The acid mixture (208 mg.) was treated with *p*-bromophenacyl bromide (408 mg.) according to the method of Shriner and Fuson.[16] A crude derivative was obtained (343 mg., 70%) with m.p. 80–96°. After four recrystallizations from hexane an analytical sample was obtained with m.p. 104–106° (hot-stage).

Anal. Calcd. for $C_{16}H_{19}BrO_3$: C, 56.66; H, 5.62. Found: C, 56.91; H, 5.62.

A mixture of this derivative with authentic *trans*-hexahydro-*o*-toluic acid *p*-bromophenacyl ester showed no depression and the infrared spectra of the two derivatives were identical.

The mother liquors from the recrystallization of the *p*-bromophenacyl ester of the acid mixture were concentrated to give a residue which after recrystallization from hexane had m.p. 52–90° (hot-stage). The infrared spectrum of this mixture indicated it to be mostly *cis*-hexahydro-*o*-toluic acid *p*-bromophenacyl ester, contaminated with the *trans* isomer.

***cis*-Hexahydro-*o*-toluic Acid *p*-Bromophenacyl Ester.**—A solution of *o*-toluic acid (15 g.) in glacial acetic acid (50 ml.) containing concentrated hydrochloric acid (0.5 ml.) was hydrogenated at room temperature in the presence of 3.3 g. of Adams platinum catalyst at 38–30 p.s.i. The reduction was complete in 2.5 hr. After filtration, the solvent was removed under reduced pressure and the product distilled to give 12.9 g. (81%) of *cis*-hexahydro-*o*-toluic acid, b.p. 83–85° (1 mm.), $n^{25}D$ 1.4620.

A portion of the acid was converted to the amide, which after two recrystallizations from water had m.p. 154.5–156° (lit.[4] m.p. 151–153°).

cis-Hexahydro-*o*-toluic acid (302 mg.) was converted to the *p*-bromophenacyl ester in 82% yield in the usual way.[16] After three recrystallizations from hexane, it had m.p. 83.0–84.2°.

Anal. Calcd. for $C_{16}H_{19}BrO_3$: C, 56.66; H, 5.62. Found: C, 56.54; H, 5.69.

***trans*-Hexahydro-*o*-toluic Acid *p*-Bromophenacyl Ester.**—*cis*-Hexahydro-*o*-toluic acid (4 g.) was refluxed for 30 min. with 200 mg. of β-naphthalenesulfonic acid. The residue was distilled in a short-path still at 120° (5 mm.) to give 3.8 g. of an oily solid. After three recrystallizations from benzene there was obtained pure *trans*-hexahydro-*o*-toluic acid, m.p. 52.4–54.4° (lit.[7] m.p. 50–52°).

The *trans*-acid (151 mg.) was treated with *p*-bromophenacyl bromide (280 mg.) in the usual way[16] to give 288 mg. or 80% of *trans*-hexahydro-*o*-toluic acid *p*-bromophenacyl ester, m.p. 102–103° (hot-stage). An analytical sample recrystallized from hexane had m.p. 104–106° (hot-stage).

Anal. Calcd. for $C_{16}H_{19}BrO_3$: C, 56.66; H, 5.62. Found: C, 56.88; H, 5.93.

Identification of 4-Cycloöcten-1-ol in the Low-boiling Fraction after Treatment with Silver Oxide.—The ether extracts of the alkaline solution obtained by treating the low-boiling fraction with silver oxide and sodium hydroxide were concentrated to give 0.67 g. of product. Chromatography on 21 g. of alumina (Activity II) in a 15-mm. column, collecting 20-ml. fractions, gave a small amount of material that gave a positive test with 2,4-dinitrophenylhydrazine reagent but which did not give a derivative that could be purified. The main bulk of material (115 mg.) was distilled in a short-path still and the distillate treated with phenyl isocyanate. After removal of excess reagent under reduced pressure, a crude product was obtained which after one recrystallization from hexane had m.p. 73–135°. The product was sublimed, and the sublimate after two recrystallizations from hexane had m.p. 92.0–94.5° (hot-stage). Its infrared spectrum was identical to the spectrum of 4-cycloöcten-1-ol phenylurethan.[8] The alcohol fraction was not examined in a way that would have detected the presence of 3-cycloöcten-1-ol as a minor component.

Saponification of the Residue of Diformates.—The residue (4.1 g.) from the distillation of the low-boiling product obtained by treating *trans*-cycloöctene oxide with formic acid was refluxed overnight with alcoholic potassium hydroxide (5.5 g.). The ethanol was removed under reduced pressure and replaced by 50 ml. of water. The product was extracted with three 40-ml. portions of chloroform, and the combined extracts were dried over magnesium sulfate. The solvent was removed under reduced pressure to give 3.2 g. of product which was chromatographed on 105 g. of Merck acid-washed alumina (Activity II) in a 22-mm. column, collecting 100-ml. fractions. Fractions 1, 8–10, 60, 61–62 and 68–70 were discarded.

Fraction	Eluent	Weight, mg.
2–7	Benzene	331
11–13	Benzene–ether (9:1)	94
14–15	Benzene–ether (9:1)	156
16–19	Benzene–ether (9:1)	432
20–30	Benzene–ether (3:2)	483
31–36	Benzene–ether (1:1)	51
37–42	Ether	34
43–48	Ether–methanol (66:1)	725
50–59	Ether–methanol (97:3)	633
65–67	Ether–methanol (17:3)	38

4-Cycloöcten-1-ol.—Fractions 2–7 were distilled in a short-path still to give 170 mg. of distillate with an infrared spectrum that was identical to the spectrum of authentic 4-cycloöcten-1-ol. It was treated with phenyl isocyanate overnight to give, after removal of excess reagent under reduced pressure, a crude phenylurethan with m.p. 81–94°. After recrystallization from hexane, it had m.p. 94–96° (hot-stage). The infrared spectrum of the derivative was identical to the spectrum of an authentic specimen of 4-cycloöcten-1-yl phenylurethan.[8]

Glycol A Bis-*p*-nitrobenzoate.—Fractions 11–13 (96 mg.) were treated with *p*-nitrobenzoyl chloride (500 mg.) in a few milliliters of pyridine at room temperature, and the solution was allowed to stand overnight. The reaction mixture was poured into water and the product was extracted with three 10-ml. portions of benzene. The combined extracts were washed with three 80-ml. portions of water and with dilute hydrochloric acid, saturated sodium bicarbonate solution, water and saturated sodium chloride solution. The benzene solution was dried by concentrating to about 5 ml. at atmospheric pressure and passed over 5 g. of Activity II alumina. There was obtained after elution with benzene 201 mg. (68%) of a bis-*p*-nitrobenzoate with An analytical sample had m.p. 154–155°

after four recrystallizations from ethanol. A mixture with authentic *trans*-1,4-cyclooctanediol bis-*p*-nitrobenzoate[9] was depressed to 133–148°.

Anal. Calcd. for $C_{22}H_{22}N_2O_8$: C, 59.72; H, 5.01. Found: C, 60.08; H, 5.15.

A portion of fractions 14–15 (69 mg.) was converted in 83% yield to the corresponding bis-*p*-nitrobenzoate as above. After three recrystallizations from ethanol it had m.p. 154.0–155.2° and did not depress the m.p. of the derivative prepared from fractions 11–13.

An aliquot of fractions 16–19 (86 mg.) was treated with a 100% molar excess of *p*-nitrobenzoyl chloride as before to give 233 mg. or 87% of a bis-*p*-nitrobenzoate. After six recrystallizations from ethanol it had m.p. 154.0–155.2° and did not depress the m.p. of the derivative obtained from fractions 11–13.

Glycol B Bis-*p*-nitrobenzoate.—A portion of fractions 20–30 (137 mg.) was converted into a bis-*p*-nitrobenzoate in 78% yield. After seven recrystallizations from ethanol, it had m.p. 175.5–180.4°.

Anal. Calcd. for $C_{22}H_{22}N_2O_8$: C, 59.72; H, 5.01. Found: C, 59.89; H, 5.22.

A comparison of infrared spectra showed that the derivative prepared from fractions 20–30 was different from the bis-*p*-nitrobenzoates of the isomeric cyclooctanediols and of glycol A. A mixture of the bis-*p*-nitrobenzoates of glycol A and glycol B had m.p. 140–170°.

Fractions 31–36 (51 mg.) were treated with 280 mg. of *p*-nitrobenzoyl chloride in pyridine to give a derivative in 71% yield. After five recrystallizations from ethanol, it had m.p. 172–180°. A mixture with the derivative prepared from fractions 20–30 had m.p. 171.0–179.5°.

Periodate Tests and C-Methyl Determinations on Glycols A and B.—Both glycols A and B gave negative reactions with periodic acid (see ref. 16, p. 115). C-methyl determinations[15] gave the following values: glycol A, 9.57; glycol B, 8.98; calcd. for one C-methyl group, 10.55.

***trans*-1,4-Cyclooctanediol Bis-*p*-nitrobenzoate.**—A portion of fractions 43–49 (116 mg.) was treated overnight with a 100% excess of *p*-nitrobenzoyl chloride in a few milliliters of pyridine. There was obtained 284 mg. or 83% of crude *trans*-1,4-cyclooctanediol bis-*p*-nitrobenzoate, which after four recrystallizations from ethanol had m.p. 155.4–156.6°. A mixture with an authentic specimen[9] had m.p. 155.5–157.0°.

An aliquot of fractions 50–59 (169 mg.) was converted in 79% yield into a bis-*p*-nitrobenzoate in the same manner. After four recrystallizations from ethanol, it had m.p. 155.5–157.0°. A mixed m.p. with the derivative prepared from fractions 43–49 showed no depression.

***trans*-1,3-Cyclooctanediol.**—Fractions 65–67 (38 mg.) were sublimed at 70° (1 mm.) to give (after two recrystallizations from ethyl acetate) *trans*-1,3-cyclooctanediol, m.p. 109–111° (hot-stage). A mixture with an authentic specimen[9] showed no depression, and the infrared spectra of the two samples were identical.

Derivatives of 2-Hydroxy-2-methylcyclohexanemethanol.—A solution of methylmagnesium iodide was prepared from 6.9 g. of methyl iodide and 1.2 g. of magnesium in 30 ml. of ether. A solution of 2.4 g. of 2-hydroxymethylcyclohexanone[17] (b.p. 82° at 2.6 mm., $n^{25}D$ 1.4767) in 30 ml. of ether was added dropwise over a period of 20 min., and the mixture was refluxed for 1 hr. Water was added to the cooled mixture, followed by iced dilute hydrochloric acid. The ether layer and chloroform extracts of the aqueous layer were dried over magnesium sulfate and distilled, yielding 1.7 g. of 2-hydroxy-2-methylcyclohexanemethanol, b.p. 79° (0.15 mm.), $n^{25}D$ 1.4814, which was converted to the following derivatives.

2-Hydroxy-2-methylcyclohexanemethanol bis-*p*-nitrobenzoate was prepared by treating the glycol (402 mg.) with *p*-nitrobenzoyl chloride (1.6 g.) in a few milliliters of pyridine at room temperature for 1.5 days. The product was isolated in the usual manner and yielded 467 mg. (36%) of a derivative (calculated as the bis-*p*-nitrobenzoate). An analytical sample obtained after four recrystallizations from ethyl acetate had m.p. 214–215°.

Anal. Calcd. for $C_{22}H_{22}N_2O_8$: C, 59.72; H, 5.01. Found: C, 59.69; H, 5.08.

2-Hydroxy-2-methylcyclohexanemethanol mono-*p*-nitrobenzoate was prepared by treating 204 mg. of the glycol with 1.05 molar equivalent of *p*-nitrobenzoyl chloride in pyridine at 5° overnight. The product amounted to 382 mg. (92%) of a derivative (calculated as the mono-*p*-nitrobenzoate). After four recrystallizations from cyclohexane, it had m.p. 91.5–92.5°.

Anal. Calcd. for $C_{15}H_{19}NO_5$: C, 61.42; H, 6.52. Found: C, 61.09; H, 6.72.

Structures of the Adducts of Cyclopentadiene and Methacrylic Acid and Some of its Derivatives[1]

BY JOHN S. MEEK AND WALTER B. TRAPP[2]

RECEIVED JUNE 4, 1956

The condensation of methacrylic acid and some of its derivatives with cyclopentadiene was studied in an effort to ascertain whether the methyl group or the negative group such as the carboxyl would be in the *endo* position in the major adduct. It was found that the carboxyl and the amide group showed a preference for the *exo* position. The aldehyde group showed an increasing tendency to prefer the *endo* position with longer reaction times and higher temperatures.

Methacrylic acid,[3] methyl methacrylate[3] and methacrolein[4,5] have been reported to give adducts with cyclopentadiene, but their structures were not proven. Recently the condensation of cyclopentadiene and methacrylic acid was reported to give both isomeric adducts I and II and the major product was tentatively assigned structure I[6] in accordance with Alder and Stein's orientation rule of diene syntheses.[7] However, we have found that the major adduct of cyclopentadiene and methacrylic acid is II.

Beckmann, Schaber and Bamberger attempted to prove structures of I and II by treatment with 50 volume per cent. sulfuric acid for 16 hours to see which acid would give a lactone. They re-

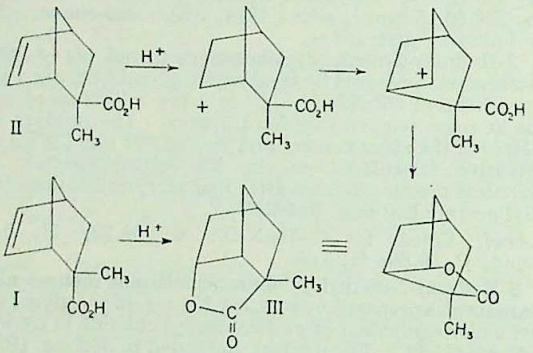
ported the major isomer gave a 9% yield of a lactone melting at 122–123° plus a 66% yield of an hydroxy acid. Their minor isomer gave a different lactone and hydroxy acid in unspecified yield. Prior to the appearance of their work we had tried to lactonize our isomers with 75% sulfuric acid at 25° and found that the major isomer gave a 43% yield of a compound melting at 124–125°. The infrared spectrum showed this compound to have a five-membered lactone ring and structure III was assigned to it. Our minor isomer also gave this same lactone in a yield of only 10% although this isomer appeared to react more rapidly when treated with sulfuric acid. A Wagner–Meerwein rearrangement of the *exo*-acid should give the same lactone as the *endo*-acid as

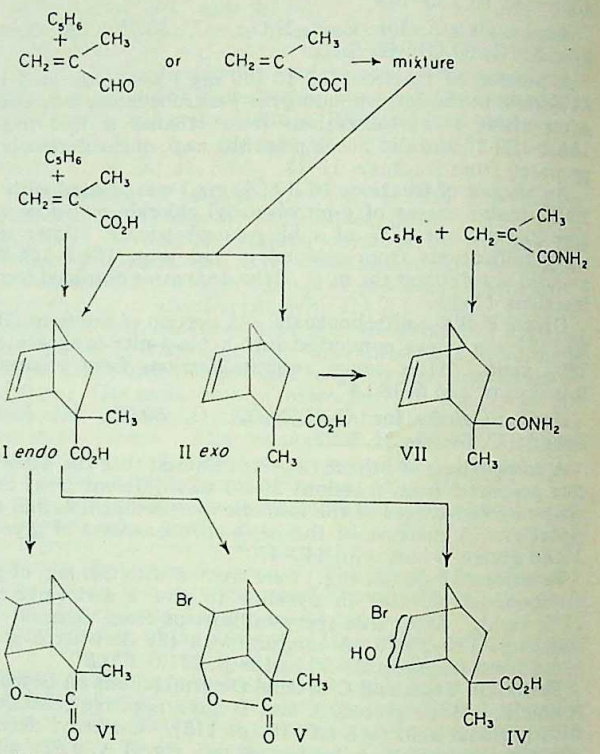


Hence, a structure proof by this method is not satisfactory.

Our assignment is based on the observations that the major isomer formed a bromohydrin IV under the same conditions that led to a bromolactone V from the minor isomer. The major isomer was unreactive toward iodine stock solution[8] while the minor isomer gave an iodolactone VI.

The melting point of our major isomer was 79–80° and that of the minor isomer was 94–95°. Beckmann, Schaber and Bamberger reported melting points of 83 and 109°. Bicyclic compounds frequently have large melting point depressions and our lower melting point for the minor isomer may be explained by this and by the fact that material melting at 92–95° was found by iodine titration to be approximately 94% pure.

Methacrylic acid and cyclopentadiene when heated for 10 minutes at 93° in acetic acid gave a 24% yield of the *endo* isomer I and a 46% yield of isomer II (*exo*). Longer heating at the same temperature or at 150° increased the yield of the *endo* isomer only slightly. When the *exo*-acid was heated at 115° for two hours in a sealed tube no odor of methacrylic acid or cyclopentadiene was noted upon opening the tube. The melting point of the acid was not lowered significantly and recrystallization led only to the recovery of starting material. Therefore, the predominance of II is not due to an equilibrium between the isomers. The *exo*/*endo* ratio was approximately two to one which is not in accordance with Alder's rule of the maximum accumulation of double bonds.[9]



Methacrylamide and cyclopentadiene at 120° gave a 16% yield of crude product which on recrystallization gave only one adduct (VII). This compound was shown to be the *exo* isomer since it could also be prepared from the *exo*-acid II.[6]

Methacrylyl chloride and cyclopentadiene condensed readily at room temperature to give an oil. This was hydrolyzed to a mixture of I and II in which the *endo*-acid predominated.

The cyclopentadiene adduct of methyl methacrylate upon saponification is reported to give almost entirely the *exo*-acid.[6] It is to be noted that there is no α-hydrogen atom in the ester and thus ready epimerization is excluded.

Methacrolein and cyclopentadiene gave evidence of forming increasing amounts of the *endo* isomer with increasing severity of conditions. Beckmann, Schaber and Bamberger found that heating for two to three hours on a water-bath at reflux temperature gave an oil which after several distillations melted at 56–58° and upon purification through the semicarbazone melted at 67–68°. Oxidation by silver oxide gave only the *exo*-acid.[6] Reaction temperatures of 150° for 11 hours gave us material which after distillation was separated into a fraction, m.p. 55–60°, an intermediate fraction and a third fraction, m.p. −5 to +13°. The first fraction on oxidation with silver oxide gave the *exo*-acid. The third and largest fraction gave the *endo*-acid.

Heating the aldehyde adduct at 195° gave cyclopentadiene and methacrolein. It seems likely that at low temperatures the product composition is largely *exo* due to kinetic control while at higher

(8) This reagent was used after C. S. Rondestvedt, Jr., and C. D. Ver Nooy (THIS JOURNAL, **77**, 4878 (1955)) showed that quantitative yields of iodolactones were obtained with adducts of cyclopentadiene and various *trans*-cinnamic acids where the carboxyl group was *endo* while the isomers with *exo*-carboxyl groups were inert.

temperatures the reaction is reversible and the product composition is under thermodynamic control. Generally *exo* isomers predominate under severe conditions and are thermodynamically more stable.[10] In these cases the isomers differ in the positions of a carbon-containing moiety and a hydrogen atom. In the present case the isomers differ in the location of a methyl and a formyl group which are comparable sterically.

Experimental

2-Methylbicyclo[2.2.1]-5-heptene-2-carboxylic Acid (I and II).—Glacial methacrylic acid (17.2 g., 0.2 mole) and freshly distilled cyclopentadiene (13.2 g., 0.2 mole), 0.1 g. of *p-t*-butylcatechol and 25 ml. of toluene were heated in a sealed glass tube for 2 hours at 150–157°. Distillation gave 3 g. of methacrylic acid and 20.8 g. (68%) of product, b.p. 113° (4.5 mm.), m.p. 41–57°. Upon recrystallization from 50% acetic acid, 80% of the material was separated manually into needles of I, m.p. 94–95°, and granules of II, m.p. 79–81.

Anal. Calcd. for $C_9H_{12}O_2$: C, 71.02; H, 7.95. Found for isomer I: C, 70.94; H, 7.94. Isomer II: C, 70.97; H, 8.16.

Lactonization of I and II.—Equal quantities (0.89 g.) of I and II were placed in glass-stoppered flasks along with 10 ml. of 75% sulfuric acid and shaken at 25°. After ten minutes all of I had dissolved, but 40 minutes was required for II. At that time both samples were diluted with 500 vol. per cent. of water. Unchanged II (0.02 g.) precipitated and the remaining solution was ether extracted to obtain the product. With sample I no unchanged acid appeared. The ether extracts were shaken with sodium bicarbonate and the product from I after removal of the ether and recrystallization from ethanol gave 90 mg. (10%) of III, m.p. 121–122°. The product from II after sublimation weighed 0.37 g. (42%) and melted at 124–125° and its melting point was not depressed when mixed with the product from I. The analytical sample melting point was not depressed when mixed with the product from I. The analytical sample melted at 125–126° after recrystallization from aqueous ethanol; reported[6] 122–123°.

Anal. Calcd. for $C_9H_{12}O_2$: C, 71.02; H, 7.95; sapn. equiv., 152. Found: C, 71.30; H, 7.92; sapn. equiv., 152.

Bromolactone V.—To a solution of 0.400 g. (2.62 mmoles) of I in 10 ml. of 5% sodium carbonate was added bromine water containing a trace of potassium bromide. The temperature was maintained below 10° and the addition was stopped when the color persisted. On standing, 0.40 g. (66.5%) of V precipitated, m.p. 74–75°. The material was insoluble in 10% sodium bicarbonate, and had a peak at 5.58 μ in its infrared spectrum which indicated a five-membered lactone ring.

Anal. Calcd. for $C_9H_{11}BrO_2$: C, 46.77; H, 4.80. Found: C, 46.64; H, 4.84.

Bromohydrin of II.—Compound II when treated similarly gave no precipitate on standing. However, acidification resulted in a 73% yield of IV, m.p. 141–147°; recrystallization from acetone–petroleum ether, raised the melting point to 150–151.5°.

Anal. Calcd. for $C_9H_{13}BrO_3$: C, 43.43; H, 5.22. Found: C, 43.32; H, 5.42.

Dibromide of II.—Five grams (0.033 mole) of II was dissolved in 70 ml. of 5% sodium bicarbonate and agitated at 5–10°. Bromine dissolved in petroleum ether (30–60°) was added dropwise until color persisted. A white dibromide precipitated, weighing 1.58 g. (21%), m.p. 198–199°. The dibromide was soluble in 5% sodium bicarbonate and the infrared spectrum showed a carboxylic carbonyl peak at 5.87 μ.

Anal. Calcd. for $C_9H_{12}Br_2O_2$: C, 34.64; H, 3.88. Found: C, 34.52; H, 4.00.

Iodolactone VI.—One gram of I gave 1.30 g. of iodolactone, m.p. 83–86°, when treated with iodine in basic solution.[8]

Anal. Calcd. for $C_9H_{11}IO_2$: C, 38.87; H, 3.99. Found: C, 39.13; H, 3.83.

(10) R. B. Woodward and H. Baer, THIS JOURNAL, 66, 645 (1944).

A 0.2263-g. sample of I, m.p. 92–95° absorbed 94% of the calculated amount of iodine stock solution. When II was similarly treated with a small amount of iodine no discharge of color occurred and acidification precipitated 88% of unchanged II.

Formation of I under Various Conditions.—A series of samples of 43 g. gross weight containing 0.2 mole each of methacrylic acid and cyclopentadiene in acetic acid (12 ml.) with *p-t*-butylcatechol were exposed to varying conditions of time and temperature. Aliquots were then assayed for I with iodine stock solution.

Time	Temp., °C.	Mole % endo
0 min.	25	0
10 min.	93	24
45 min.	93	27
8 hr.	93	27
2.5 hr.	150	29

Hydrolysis of V and VI.—One-half gram (2.16 mmoles) of V was added to a solution of 1.0 g. of potassium hydroxide in 15 ml. of water and 15 ml. of 95% ethanol and the mixture was heated on a steam-bath for 30 minutes. The solution was cooled, filtered and extracted with ether. Acidification of the aqueous solution followed by a fourfold ether extraction, drying over sodium sulfate and evaporation of the solvent gave 260 mg. (71.7%) of hydroxy lactone, m.p. 124–128°. Recrystallization from water raised the melting point to 129–130°.

Anal. Calcd. for $C_9H_{12}O_3$: C, 64.27; H, 7.19. Found: C, 64.21; H, 7.07.

The compound gave a positive periodate test, indicating a vicinal diol was formed by hydrolysis in the reagent. The infrared spectrum showed the following in hexachlorobutadiene and Nujol mulls: carbonyl at 5.78 μ, hydroxyl at 3.02 μ (sharp, indicates either intramolecular bonding or intermolecular bonding where the bonding plays a prominent part in the crystal structure), carboxyl type stretch absent; in CCl_4 solution: 2.79 μ free OH, 2.94 μ bonded OH, 5.60 μ unbonded lactone carbonyl, 5.70 μ bonded lactone carbonyl. Upon dilution the ratio of the intensities of the unbonded peaks to the bonded peaks increased, showing intermolecular bonding. From chemical and spectral evidence the assignment of **2-methylbicyclo[2.2.1.]-5,6-di-endohydroxyheptane-2-endocarboxylic acid 2,6-lactone** was made.

A 396-mg. sample of VI was similarly treated with base, and 175 mg. (73%) of product was obtained, m.p. 124–129°. There was no melting point depression when mixed with the hydroxy lactone prepared from V.

2-Methylbicyclo[2.2.1.]-5-heptene-2-carboxamide (VII).—One-tenth of a mole (8.5 g.) of methacrylamide, 13.2 g. (0.2 mole) of cyclopentadiene, 0.1 g. of *p-t*-butylcatechol and 12 ml. of methanol were heated together at 120° for 4.5 hours in a sealed glass tube. The methanol was evaporated and the residue was extracted with water to remove methacrylamide. Extraction with ethanol left 5 g. of polymeric material which was removed by filtration. Upon standing three weeks the alcoholic solution afforded 2.5 g. (16.5%) of crystals, m.p. 110–120°. Sublimation at 92° gave 1.9 g. (12.6%) of VII, m.p. 154–155°; reported[3] 152–153°.

A 4.6-g. sample of II was treated with thionyl chloride in ether and gave 4.5 g. (76%) of acid chloride, b.p. 57° (4.5 mm.), $n^{20}D$ 1.4950, $n^{25}D$ 1.4929, d^{25}_4 1.1266.

Anal. Calcd. for $C_9H_{11}ClO$: C, 63.34; H, 6.50; *MR*, 43.78. Found: C, 63.05; H, 6.76, *MR*, 43.85.

Ten ml. of cold concentrated ammonium hydroxide was added dropwise to 150 mg. of the acid chloride of II. The mixture was diluted with 20 ml. of water and filtered, yielding 120 mg. (93%) of solid amide, m.p. 157–157.5°. Purification by sublimation raised the m.p. to 157.5–158°. When this material was mixed with VII it melted at 154–155°.

A 460-mg. sample of I gave 80 mg. of acid chloride, $n^{20}D$ 1.4910.

Anal. Calcd. for $C_9H_{11}ClO$: C, 63.34; H, 6.50. Found: C, 63.23; H, 6.53.

Since the acid chlorides from I and II differed significantly in their refractive index, attempts to thermally isomerize the acid chloride of II were made. However, no change in the refractive index was noted after 51 days at room temperature in the dark, 60 hours at 80°, 2 hours at 150° or one hour at

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

175° although slight discoloration occurred in the latter two cases.

Condensation of Methacrylyl Chloride and Cyclopentadiene.—A mixture of 5.0 g. (0.048 mole) of methacrylyl chloride, prepared from glacial methacrylic acid and thionyl chloride, 6.6 g. (0.1 mole) of cyclopentadiene and 0.1 g. *p-t*-butylcatechol was kept in a sealed glass tube for a week at room temperature. Distillation of the black oil gave a 61% yield of heart fraction, b.p. 126° (95 mm.), $n^{22}D$ 1.4930, d^{29}_4 1.1227; lit.[3] for the chloride prepared from mixed acid adducts $n^{20}D$ 1.4950.

A mixture of 10 ml. of 10% aqueous potassium hydroxide and 1.12 g. (6.6 mmoles) of the acid chloride adduct was heated at 55–60° for 10 minutes. A small amount of tar was removed by filtration, and acidification gave 1.07 g. of acid, m.p. 60–63°. Recrystallization gave 0.85 g. of mixed crystals which were separated manually; 60% (0.51 g.) melted at 93–94° and this melting point was not depressed with samples of I previously obtained. The remaining 40% (0.34 g.) melted at 78–79° and showed no melting point depression when mixed with II.

2-Methylbicyclo[2.2.1]-5-heptene-2-carboxaldehyde.—A mixture of 285 g. (4.06 moles) of methacrolein, 225 g. (3.4 moles) of cyclopentadiene and 1 g. of *p-t*-butylcatechol was heated in a 2-l. steel bomb at 150–155° for 11 hours. An exothermic reaction occurred at about 95° when the reactants were heated. Distillation through an 18″ Vigreux column gave 388.8 g. (84%) of adduct, b.p. 80–85° (31 mm.). Cooling and decantation gave three fractions: 22%, m.p. 55–60°; 28%, m.p. 20–45°, and 50%, m.p. −5 to +13°.

Anal. Calcd. for $C_9H_{12}O$: C, 79.37; H, 8.88. Found for the first fraction: C, 79.42; H, 8.80. For the last fraction: C, 79.41; H, 8.66.

Other preparations conducted at slightly higher temperatures gave products containing less of the higher melting (*exo*) isomer while runs conducted under less severe conditions gave increased amounts of this isomer.

When the crude product was heated at atmospheric pressure to a temperature of 180–195°, a distillate consisting of both methacrolein and cyclopentadiene came over at a head temperature of 58°.

A 2.72-g. (0.02 mole) sample of the third fraction above was oxidized with silver oxide, and 1.95 g. (65%) of crude I was obtained, m.p. 88–91°. Recrystallization from 50% acetic acid gave 1.4 g. (46%), m.p. 95–96°, which gave no melting point depression with I obtained previously.

Oxidation of the first fraction gave 2.3 g. of crude II, m.p. 70–76°. Recrystallization raised the melting point to 79–80°, yield 1.8 g. (60%). A mixed melting point with II was not depressed.

When 21 g. of methacrolein, 24 g. of cyclopentadiene and a tenth gram of inhibitor were heated in a sealed tube at 170° for 10 hours, more than the usual amount of methacrolein was recovered and a relatively small amount of adduct was obtained. In addition 3 g. of product was obtained, b.p. 170–178° (50 mm.), $n^{20}D$ 1.5242, d^{20}_4 1.0718. This was believed to be **2-methyl-1,2,3,4,5,8,9,10-octahydro-1,4,5,8-dimethanonaphthalene-2-carboxaldehyde.**

Anal. Calcd. for $C_{14}H_{18}O$: C, 83.12; H, 8.97; *MR*, 57.62. Found: C, 83.93; H, 8.71, *MR*, 57.75.

A 2,4-dinitrophenylhydrazone formed in 86% yield, m.p. 208–210°. After two recrystallizations from ethanol the m.p. was raised to 218–219°, yield 75%.

Anal. Calcd. for $C_{20}H_{22}N_4O_4$; N, 14.65. Found: N, 14.49.

Acknowledgment.—The analyses were performed by Galbraith Laboratories. The methacrylamide and methracylic acid were gifts of the Rohm and Haas Co. The authors wish to thank Dr. W. J. Potts of the Dow Chemical Co. for running and interpreting the spectrum of the hydroxy lactone.

Reactions of α,α-Diphenyl-β-propiolactone with Amines and Thiols

BY H. E. ZAUGG, H. J. GLENN, R. J. MICHAELS, R. U. SCHOCK AND L. R. SWETT

RECEIVED FEBRUARY 11, 1957

The reactions of α,α-diphenyl-β-propiolactone with four heterocyclic secondary amines, two primary amines, with the sodium salts of ethyl mercaptan and of thiophenol and with thiourea are described and compared with analogous reactions of β-propiolactone itself. The conversion of products of these reactions to compounds of potential pharmacological interest is reported.

The seemingly capricious nature of the aminolysis reaction of β-propiolactone has been demonstrated by Gresham and co-workers.[1] Three principal factors, namely, solvent, mode of combination of the reactants and nature of the amine used, were found to be operative in determining whether hydroxy amides (carbonyl–oxygen bond fission) or β-amino acids (alkyl–oxygen bond fission) are formed. Hurd and Hayao[2] later showed that aromatic amines tend to react with β-propiolactone to give almost exclusively the corresponding amino acids. In contrast, a more recent study[3] with β-(*p*-nitrophenyl)-β-propiolactone showed that this β-hindered lactone reacts with most amines, regardless of conditions, to give β-hydroxy amides. Only benzylamine and cyclohexylamine give appreciable yields of the corresponding amino acids, and then only under carefully controlled conditions.

The present work extends the study of these reactions to the α-hindered lactone, α,α-diphenyl-β-propiolactone (I).[4] Reaction of I with excess N-(γ-aminopropyl)-morpholine at room temperature without solvent gave the amino acid IIa in 60% yield and the hydroxy amide IIIa in 12% yield. From the reaction with *n*-butylamine, only the hydroxy amide IIIb could be isolated albeit in only 45% yield. The four heterocyclic amines piperidine, morpholine, pyrrolidine and N-methylpiperazine gave the corresponding amino acids, IIb, c, d and e, as the only isolable products, the first three in high yields (80–90%) but the last in only 46% yield. Employment of acetonitrile as solvent seemed to have little influence on the course of these amine reactions. However, non-polar media such

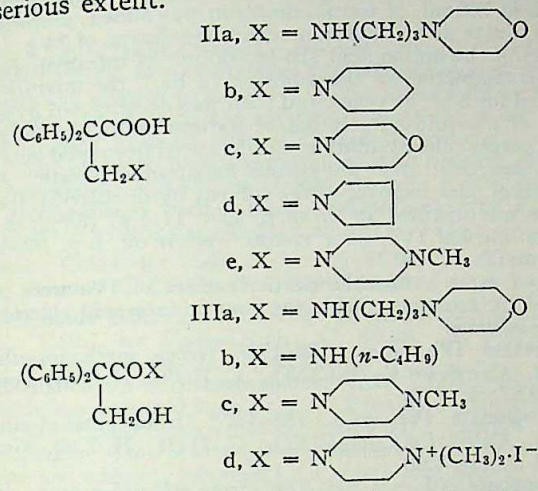
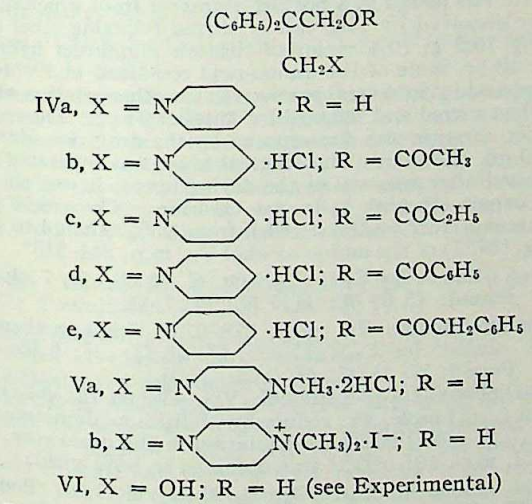
as ether or even boiling benzene, retarded them to a serious extent.

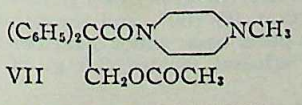


For the purpose of pharmacological evaluation, the two amino acids IIb and IIe were reduced with lithium aluminum hydride to the amino carbinols IVa and Va, respectively. The four O-acyl derivative IVb, c, d, and e were then prepared from IVa, and the methiodide Vb was made from Va.



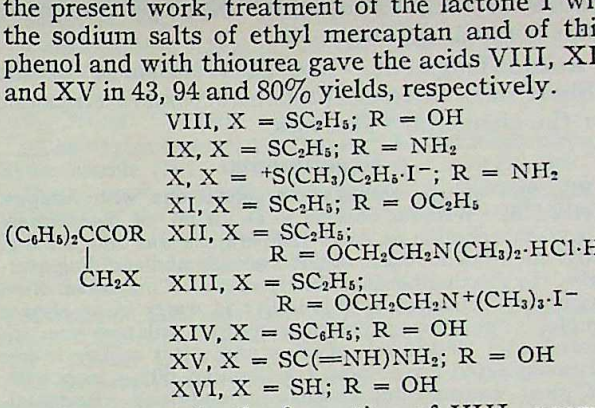
VI, X = OH; R = H (see Experimental)

The hydroxy amide IIIc and its monomethiodide IIId were prepared from α-phenyltropic acid[5] by acetylation of the hydroxyl group followed by conversion to the acid chloride and reaction with N-methylpiperazine to give the acetoxy amide VII which readily hydrolyzed to IIIc. All attempts to prepare the acid chloride of O-acetyl-α-phenyltropic acid directly from the β-lactone I by treatment with acetyl chloride failed. Mild conditions gave only recovered lactone; and heating the reactants at 100° in an autoclave in the presence of a few drops of concentrated sulfuric acid as catalyst seemed to result in some reaction, but treatment of the crude product with N-methylpiperazine gave none of either amide VII or IIIc. In contrast, β-propiolactone itself reacts with acetyl chloride at only slightly elevated temperatures to give β-acetoxypropionyl chloride in 67% yield.[6]



VII

All reactions between β-propiolactone and organic sulfur compounds which have been reported thus far[7] involve alkyl–oxygen bond fission to give derivatives of β-thiolpropionic acid. Likewise, in the present work, treatment of the lactone I with the sodium salts of ethyl mercaptan and of thiophenol and with thiourea gave the acids VIII, XIV and XV in 43, 94 and 80% yields, respectively.



As by-product in the formation of VIII, appreciable quantities of ethyl diphenylacetate, $(C_6H_5)_2CHCOOC_2H_5$, were formed. It might seem that this ester was produced primarily by reaction of the lactone I with the ethanol solvent to give ethyl α-phenyltropate, which readily would undergo aldol-reversal in alkaline medium to give the above cleavage product.[5] However, another possible route for this degradation reaction could involve initial carbonyl–oxygen bond fission of the lactone I to give the ethylthiol ester of α-phenyltropic acid, isomeric with VIII. This thiol ester would be expected to undergo aldol-reversal even more readily than the corresponding oxygen ester because its anionic fission product $[(C_6H_5)_2CCOSC_2H_5]^{\ominus}$, is a weaker base than is the anion $[(C_6H_5)_2CCOOC_2H_5]^{\ominus}$, formed initially by cleavage of ethyl α-phenyltropate. Once formed, the thiol ester would readily undergo ester interchange in the basic ethanolic medium to give the corresponding oxygen ester. The latter route for this cleavage reaction is given some credence by the fact that when water was substituted for ethanol as the solvent in the reaction of I with sodium ethyl mercaptide, a 42% yield of ethyl diphenylthiolacetate, $(C_6H_5)_2CHCOSC_2H_5$ (XVII), actually was isolated. At any rate, formation of XVII shows that a β-lactone can react with an organic sulfur compound by carbonyl–oxygen bond fission.

The thioacid VIII readily formed an acid chloride which gave the amide IX and the two esters XI and XII on treatment with the appropriate reactants. Reaction of the amide IX with methyl iodide gave, with difficulty, the sulfonium salt X. Treatment of the ester XII with methyl iodide likewise gave a methiodide, which is presumed to be the ammonium salt XIII rather than the sulfonium salt because of its relatively facile formation.

By the action of concentrated sulfuric acid on the thioacid XIV, ring-closure to the thiachromanone XVIII readily was effected.

Finally alkaline hydrolysis of the acid XV formed the thiolpropionic acid XVI.

Many of the products reported above were submitted for testing as potential analgesics, antispasmodics or local anesthetics. None showed more than minimal activity.

Acknowledgment.—Mr. E. F. Shelberg of the Abbott microanalytical laboratory was responsible for the elementary analyses.

Experimental

Reaction of α,α-Diphenyl-β-propiolactone with Amines. Method A. Without Solvent.—To 10 ml. of N-(γ-aminopropyl)-morpholine at room temperature was added 2.5 g. (0.011 mole) of I. After slight warming and standing overnight, the mixture became homogeneous. Completion of reaction was indicated by miscibility in water of an aliquot sample. The viscous colorless reaction mixture was triturated with 50–100 ml. of ether and, after cooling in ice, the precipitated amino acid IIa (2.45 g., 60%), m.p. 186–187° dec., was collected by filtration and dried. Recrystallization from methanol did not change the melting point.

Anal. Calcd. for $C_{22}H_{28}N_2O_3$ (IIa): C, 71.71; H, 7.66; N, 7.60. Found: C, 72.03; H, 7.68; N, 7.74.

The ether filtrate was washed with water and then extracted with dilute hydrochloric acid. The aqueous extract was made alkaline with sodium hydroxide, and the precipitated oil was taken up in ether, dried and concentrated. The hydroxy amide IIIa (0.50 g., 12%), m.p. 133–134°, slowly crystallized from the concentrated ether solution. Recrystallization from methanol did not raise the melting point.

Anal. Calcd. for $C_{22}H_{28}N_2O_3$ (IIIa): C, 71.71; H, 7.66. Found: C, 71.83; H, 7.34.

In like manner reaction of I with *n*-butylamine gave only the hydroxy amide IIIb, m.p. 70–72° (from hexane), in 45% yield.

Anal. Calcd. for $C_{19}H_{23}NO_2$: C, 76.73; H, 7.80. Found: C, 76.79; H, 7.84.

Reaction of I with piperidine gave only the amino acid IIb in 87% yield, m.p. 137–139° (from acetone). When mixed with an authentic specimen of IIb,[8] m.p. 137–138°, it produced no melting point depression.

Reaction of I with morpholine gave a 95% yield of the morpholinium salt of the amino acid IIc, m.p. 173° dec.

Anal. Calcd. for $C_{23}H_{30}N_2O_4$: C, 69.32; H, 7.59; N, 7.03. Found: C, 69.53; H, 7.45; N, 7.23.

When this salt was heated for 5 hr. at 110° under reduced pressure (20 mm.), the free amino acid IIc, m.p. 163–164°, was obtained.

Anal. Calcd. for $C_{19}H_{21}NO_3$: C, 73.29; H, 6.80; N, 4.50. Found: C, 73.19; H, 7.03; N, 4.63.

Method B. In Acetonitrile.—The reaction of I with piperidine did not take place in ether solution at room temperature nor even in refluxing benzene to give IIb. A more polar solvent seemed necessary.

To a stirred solution of 2.65 g. (0.0307 mole) of piperidine in 10 ml. of acetonitrile was added 4.6 g. (0.0205 mole) of the lactone I. In about an hour at room temperature, the reaction mixture set to a solid mass. After standing overnight, the solid was collected and washed with pentane. There was obtained 5.5 g. (87%) of the amino acid IIb, m.p. 138–139° dec.

In like manner, the reaction of I with pyrrolidine gave the amino acid IId in 83% yield, m.p. 133°.

Anal. Calcd. for $C_{18}H_{21}NO_2$: C, 77.26; H, 7.17; N, 4.74. Found: C, 77.08; H, 7.34; N, 4.81.

Similarly, N-methylpiperazine with I in acetonitrile gave the amino acid IIe in 46% yield, m.p. 175–176° (from 95% ethanol).

Anal. Calcd. for $C_{20}H_{24}N_2O_2$: C, 74.04; H, 7.46; N, 8.64. Found: C, 74.28; H, 7.58; N, 8.56.

A crude by-product also was obtained from this reaction, possibly the hydroxy amide IIIc, but it could not be purified.

2,2-Diphenyl-3-piperidinopropanol (IVa).—To a stirred suspension of 9.4 g. (0.25 mole) of lithium aluminum hydride in 700 ml. of tetrahydrofuran was added, dropwise at such a rate as to maintain reflux, a solution of 34 g. (0.11 mole) of the amino acid IIb in 500 ml. of tetrahydrofuran. After completion of the addition (1 hr.), the mixture was stirred for 2 hr. at reflux and then was decomposed by addition of a saturated solution of sodium potassium tartrate. The purple colored solution was decanted from solid salts and was then dried over anhydrous magnesium sulfate. After filtration, and removal of the solvent by distillation, the residue was distilled *in vacuo* to give 11.4 g. (35%) of the amino alcohol IVa, as a viscous yellow oil, b.p. 165–166° (0.7 mm.).

Four ester hydrochloride derivatives of IVa were prepared by treatment with the appropriate acid chloride in ether solution:

Acetate IVb, m.p. 173–175° (from methanol–ether). *Anal.* Calcd. for $C_{22}H_{28}ClNO_2$: C, 70.66; H, 7.55. Found: C, 70.87; H, 7.40.

Propionate IVc, m.p. 155–157° (from ethanol–ether). *Anal.* Calcd. for $C_{23}H_{30}ClNO_2$: C, 71.21; H, 7.80. Found: C, 71.25; H, 7.68.

Benzoate IVd, m.p. 218–219° (from ethanol–ether). *Anal.* Calcd. for $C_{27}H_{30}ClNO_2$: C, 74.38; H, 6.94. Found: C, 74.32; H, 6.66.

Phenylacetate IVe, m.p. 174–176° (from ethanol–ether). *Anal.* Calcd. for $C_{28}H_{33}ClNO_2$: C, 74.73; H, 7.17. Found: C, 74.47; H, 7.13.

2,2-Diphenyl-3-(N-methylpiperazino)-propanol (Va).—Twenty-two and four-tenths grams (0.1 mole) of the amino acid IIe was placed in a Soxhlet extractor from which it was slowly dissolved by 1500 ml. of stirred refluxing ether containing 15.2 g. (0.4 mole) of lithium aluminum hydride. After 48 hr. some of the amino acid remained undissolved, so it was added in several portions to the ether solution which was then stirred and refluxed for another 24 hr. The cooled reaction mixture was decomposed by the dropwise addition of 200 ml. of water. The ethereal layer was separated and dried and after removal of the drying agent, it was treated with excess ethereal hydrogen chloride. The crude precipitate was recrystallized twice from 95% ethanol to give 21.7 g. (57%) of the amino alcohol Va, m.p. 244–246°.

Anal. Calcd. for $C_{20}H_{28}Cl_2N_2O$: C, 62.66; H, 7.36; N, 7.31. Found: C, 62.63; H, 7.55; N, 7.43.

Monomethiodide Vb, m.p. 278–279° (from methanol). *Anal.* Calcd. for $C_{21}H_{29}IN_2O$: C, 55.75; H, 6.46; N, 6.19. Found: C, 55.97; H, 6.58; N, 6.19.

2,2-Diphenyl-1,3-propanediol (VI).—When the β-lactone I (22.5 g., 0.1 mole) was reduced with lithium aluminum hydride (0.25 mole) in ethereal solution in the usual way, the diol VI, m.p. 101–103°,[9] was obtained in 84% yield.

Anal. Calcd. for $C_{15}H_{16}O_2$: C, 78.92; H, 7.06. Found: C, 78.77; H, 7.15.

N-Methylpiperazides of Acetyl-α-phenyltropic Acid (VII) and of α-Phenyltropic Acid (IIIc).—A mixture of 6.9 g. (0.03 mole) of α-phenyltropic acid[6] and 5.5 g. (0.07 mole) of acetyl chloride was refluxed on the steam-bath for 3 hr., and the excess acetyl chloride was removed by distillation. Then 7.1 g. (0.06 mole) of thionyl chloride was added, and the mixture was refluxed for 4 hr. The excess thionyl chloride was also removed by distillation and the residual oil (acetoxy acid chloride) was taken up in 50 ml. of dry ether. This solution, previously chilled in ice, was then added slowly to an ice-cold solution of 7.0 g. (0.07 mole) of N-methylpiperazine in 50 ml. of dry ether. After standing at room temperature overnight, the reaction mixture was extracted with excess dilute hydrochloric acid. The separated aqueous extract was made alkaline with cold 40% sodium hydroxide solution, and the precipitated oil was taken up in chloroform. Removal of the chloroform gave an oily free base which could not be crystallized. This material was dissolved in ether and the hydrochloride was fractionally precipitated by the slow addition of a solution of hydrogen chloride in isopropyl alcohol. Two fractions of the hydrochlorides were obtained. The first (hygroscopic) gave a crude crystalline base (3.5 g.), m.p. 95–100°, and the second hydrochloride fraction gave a purer base, which after two recrystallizations from aqueous ethanol yielded 2.3 g. of VII, m.p. 111–112°.

Anal. Calcd. for $C_{22}H_{26}N_2O_3$: C, 72.10; H, 7.15; N, 7.65; O, 13.10. Found: C, 71.93; H, 6.88; N, 7.80; O, 13.80.

The 3.5 g. of crude base (m.p. 95–100°) was dissolved in a solution of 25 ml. of concentrated hydrochloric acid in 25 ml. of water and allowed to stand for 60 hr. After heating for 1 hr. on the steam-bath, the mixture was cooled in ice and made strongly alkaline with 40% sodium hydroxide solution. The liberated base was extracted with benzene, which was removed by distillation to leave a solid residue which was recrystallized from aqueous ethanol to give 2.5 g. (80%) of the hydroxy amide IIIc, m.p. 141–142°.

Anal. Calcd. for $C_{20}H_{24}N_2O_2$: C, 74.04; H, 7.46; N, 8.64. Found: C, 74.35; H, 7.63; N, 8.82.

Methiodide IIId, m.p. 234–235° (from methanol–ether). *Anal.* Calcd. for $C_{21}H_{27}IN_2O_2$: C, 54.08; H, 5.84; N, 6.01. Found: C, 54.37; H, 5.78; N, 6.07.

2,2-Diphenyl-3-ethylthiopropionic Acid (VIII).—Sodium ethoxide was prepared from 4.6 g. (0.2 mole) of sodium in 40 ml. of dry ethanol. A solution of 12.4 g. (0.2 mole) of ethyl mercaptan in 10 ml. of ethanol was then added dropwise with cooling and stirring, followed by a solution of 33.6 g. (0.15 mole) of α,α-diphenyl-β-propiolactone in 100 ml. of ethanol. After standing at room temperature for 48 hr., the mixture was refluxed for 20 hr., cooled and poured into 200 ml. of water. Non-acidic material was eliminated by an ether extraction, and the aqueous layer was acidified with hydrochloric acid. The liberated acid was taken up in ether and dried. Removal of the ether by distillation gave the crude product, which after one recrystallization from dilute ethanol yielded 18.5 g. (43%) of VIII, m.p. 146–147°.

Anal. Calcd. for $C_{17}H_{18}O_2S$: C, 71.30; H, 6.33. Found: C, 71.07; H, 6.30.

From the neutral fraction was obtained 2.4 g. of ethyl diphenylacetate, m.p. 55–57°, identified by analysis and by mixed melting point with an authentic specimen.

When the β-lactone was treated with sodium ethylmercaptide in aqueous rather than alcoholic solution, the desired acid VIII was obtained in very poor yield together with a 42% yield of ethyl diphenylthiolacetate (XVII), m.p. 48–49°.

Anal. Calcd. for $C_{16}H_{16}OS$: C, 74.97; H, 6.29; S, 12.51. Found: C, 75.11; H, 6.33; S, 12.51.

Mixed with an authentic specimen, m.p. 49°,[10] there was no depression of melting point.

2,2-Diphenyl-3-ethylthiopropionamide (IX).—To a solution of 6.3 g. (0.031 mole) of the acid VIII in 40 ml. of dry benzene was added 4.8 g. of thionyl chloride dissolved in 10 ml. of dry benzene. After refluxing for 3 hr., the excess thionyl chloride and benzene were removed under reduced pressure. To the cooled residue of acid chloride was added 30 ml. of concentrated ammonium hydroxide. The oil which resulted was taken up in ether. Removal of the ether by distillation left a solid which after two recrystallizations from 75% ethanol gave 3.4 g. (54%) of the amide IX, m.p. 84–85°. (In another experiment a second dimorph, m.p. 95–96° was obtained.)

Anal. Calcd. for $C_{17}H_{19}NOS$: C, 71.56; H, 6.71; N, 4.91. Found: C, 71.53; H, 6.46; N, 5.04.

Methiodide X, m.p. 158–160° (from ethanol), was obtained by the reaction of methyl iodide with IX in refluxing acetone.

Anal. Calcd. for $C_{18}H_{22}INOS$: C, 50.59; H, 5.19; N, 3.28. Found: C, 51.10; H, 5.22; N, 3.41.

(10) H. Staudinger, G. Rathsam and F. Kjelsberg, *Helv. Chim. Acta*, **3**, 853 (1920).

Ethyl 2,2-Diphenyl-3-ethylthiopropionate (XI).—By substituting ethanol for the ammonium hydroxide in the above procedure, the ester XI, b.p. 202° (2.5 mm.), $n^{26}D$ 1.5685, was obtained in 52% yield.

Anal. Calcd. for $C_{19}H_{22}O_2S$: C, 72.59; H, 7.05. Found: C, 72.40; H, 6.92.

A methiodide of XI, m.p. 125–126°, was obtained, but it could not be purified completely.

Anal. Calcd. for $C_{20}H_{25}IO_2S$: C, 52.63; H, 5.52; S, 7.02. Found: C, 54.07; H, 5.70; S, 6.68.

β-Dimethylaminoethyl 2,2-Diphenyl-3-ethylthiopropionate Hydrochloride (XII).—Treatment of the acid chloride of VIII with excess β-dimethylaminoethanol in benzene gave a 46% yield of the ester XII in the form of the monohydrate, m.p. 117–119° (from acetone–ether).

Anal. Calcd. for $C_{21}H_{30}ClNO_3S$: C, 61.22; H, 7.34; N, 3.40. Found: C, 61.39; H, 7.57; N, 3.45.

Methiodide XIII, m.p. 151–152° (from isopropyl alcohol). *Anal.* Calcd. for $C_{22}H_{30}INO_2S$: C, 52.90; H, 6.05; N, 2.81. Found: C, 52.83; H, 6.19; N, 2.95.

2,2-Diphenyl-3-phenylthiopropionic Acid (XIV).—To a solution of 2.20 g. (0.02 mole) of thiophenol in 50 ml. of dry methanol containing sodium methoxide (prepared from 0.46 g. of sodium) was added 4.48 g. (0.02 mole) of the lactone I. After standing at room temperature for two weeks (a shorter time probably would suffice), the methanol was removed under reduced pressure and the residue was taken up in 75 ml. of water. After extraction with two 50-ml. portions of ether, the aqueous solution was acidified with concentrated hydrochloric acid. The precipitated oil crystallized slowly, was removed by filtration and washed with water to give 6.33 g. (94%) of the acid XIV, m.p. 95–100°. Two recrystallizations from hexane (Skellysolve B) raised the melting point to 103–104°.

Anal. Calcd. for $C_{21}H_{18}O_2S$: C, 75.42; H, 5.42. Found: C, 75.57; H, 5.54.

3,3-Diphenylthiachromanone (XVIII).—To 5 ml. of concentrated sulfuric acid at room temperature was added 0.97 g. of 2,2-diphenyl-3-phenylmercaptopropionic acid. After constant swirling for 10 minutes, the deep red solution was poured onto ice, the resulting solid was collected at the filter and washed with water. The crude dry product (0.9 g.) was recrystallized twice by dissolving in acetone and adding hexane (Skellysolve B) to the warm solution. The pure thiachromanone XVIII melted at 163–164°.

Anal. Calcd. for $C_{21}H_{16}OS$: C, 79.72; H, 5.10. Found: C, 79.94; H, 5.36.

Reaction of the β-Lactone I with Thiourea. Preparation of XV.—To a boiling solution of 0.40 g. (0.0053 mole) of thiourea in 10 ml. of dry ethanol was added 1.12 g. (0.005 mole) of the lactone I. Refluxing for 3 hr. resulted in the precipitation of a colorless, crystalline solid, which after refrigeration overnight was collected at the filter and dried. There was obtained 1.20 g. (80%) of XV, m.p. 159.5–162°.

Anal. Calcd. for $C_{16}H_{16}N_2O_2S$: C, 63.97; H, 5.37; N, 9.33; S, 10.67. Found: C, 63.96; H, 5.57; N, 8.51; S, 10.37.

2,2-Diphenyl-3-thiolpropionic Acid (XVI).—Approximately 13.3 g. of crude XV was warmed with a 10% sodium hydroxide solution until most of it dissolved. After filtering and allowing to stand several hours, the alkaline solution was acidified and the precipitated product (7.3 g., m.p. 180–190°) was dried. Two recrystallizations from methanol gave colorless prisms of XVI, m.p. 200–202.5°.

Anal. Calcd. for $C_{15}H_{14}O_2S$: C, 69.74; H, 5.46; S, 12.39. Found: C, 69.91; H, 6.02; S, 12.68.

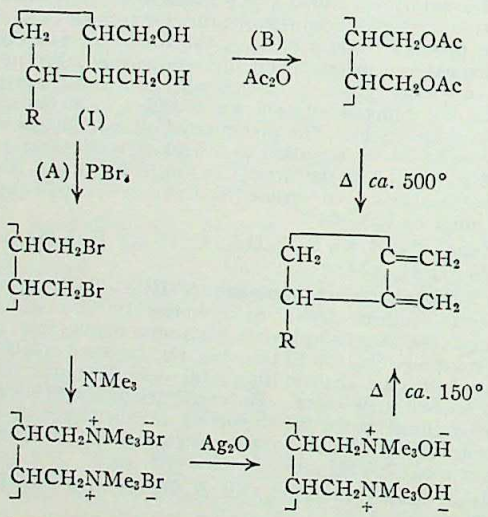
1,2-Dimethylenecyclohexane. Synthesis and Polymerization[1]

BY A. T. BLOMQUIST AND D. T. LONGONE

RECEIVED FEBRUARY 6, 1957

1,2-Dimethylenecyclohexane has been obtained by the thermal decomposition of 1,2-bis-(dimethylaminomethyl)-cyclohexane dimethohydroxide. The syntheses of the precursors for the diene involved standard classical transformations starting with diethyl phthalate. The over-all yield was 27%. A number of polymerizations utilizing several systems and for various reaction times showed that the monomer was much less reactive than its smaller ring homologs, 1,2-dimethylenecyclobutane and 1,2-dimethylenecyclopentane. Polymers obtained were either oils or highly crystalline non-rubbery solids. On the basis of infrared spectra the polymers appeared to be comprised of all *cis*-1,4-units. The polymerization characteristics of this diene appear to be due, at least in part, to its six-membered ring structure.

Previous investigations carried out in this Laboratory concerning the study of conjugated exocyclic dienes have utilized two quite different preparative methods. Both methods may be viewed as starting with the same appropriate glycol I and proceeding as



Path A involves the Hofmann degradation of the appropriate bis-quaternary ammonium hydroxide and path B the pyrolytic decomposition of the requisite diacetate.

On comparing the two methods of preparation it has been found that the Hofmann elimination affords a product of greater purity and in higher yield. It also gives a single product, whereas with acetate pyrolysis a large forerun must be carefully removed in the purification of the diene.

The high pyrolytic temperatures (*ca.* 500°) required in the latter method may lead to ring cleavage in more sterically strained cyclic systems. Thus it has been shown that pyrolysis of 1,2-bis-(acetoxymethyl)-cyclobutane at 485° gives only 2-vinyl-1,3-butadiene while the desired product, 1,2-dimethylenecyclobutane, may be obtained *via* the Hofmann method in 28% yield.[2]

More recently[3] a direct comparison of both methods was made in the synthesis of 1,2-dimethylenecyclopentane and its 3-methyl homolog. Yields and product purity were superior using the Hofmann method.

Because of the encouraging results obtained in these earlier studies it seemed desirable to restudy the synthesis of 1,2-dimethylenecyclohexane (II). This diene has been prepared previously in this Laboratory *via* the acetate pyrolysis at 525° in 29% yield.[4] Emulsion polymerization of the diene, using potassium persulfate as initiator, was carried out at 53° and gave a 53% conversion to a highly crystalline polymer with no rubber characteristics whatsoever. The synthesis and polymerization of II also has been reported by two other groups of investigators. Wicklatz and Short[5] first prepared this diene by dehydrohalogenation of 1,2-bis-(iodomethyl)-cyclohexane and by diacetate pyrolysis at 300–500°; while Bailey and Golden[6] repeated the diacetate pyrolysis at 520°.

Wicklatz and Short[7] obtained a homopolymer of II and described the product as a brittle resin. They also report the ionic polymerization of II using aluminum trichloride at −70° to produce "oily polymers." Bailey and Golden[6] obtained a white crystalline homopolymer melting at 165° using a peroxide-catalyzed emulsion system, an identical polymer from ionic polymerization using boron trifluoride etherate, and a viscous oil using boron trifluoride gas.

The physical properties of the homopolymers of II obtained in the work summarized above are in marked contrast to those of the homopolymers of the smaller ring homologs prepared in this Laboratory. 1,2-Dimethylenecyclobutane[2] and 1,2-dimethylenecyclopentane[3] readily gave elastomeric homopolymers using a persulfate emulsion system. Both monomeric dienes were prepared *via* the Hofmann method. Of further interest is the fact that Bailey obtained only a highly crystalline, non-rubber homopolymer of 1,2-dimethylenecyclopentane using monomer prepared *via* the acetate pyrolysis.[8]

These anomalies led us to suspect that traces of impurities might be present in the monomeric dienes prepared *via* the more drastic acetate py-

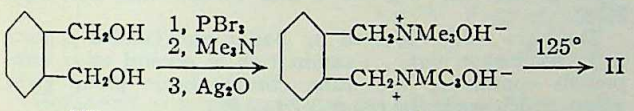
rolysis. Olefinic impurities, inherent in the latter method of preparation, would be expected to affect the polymerization of the dienes in a number of possible ways—retarder or inhibitor action, etc.

Since, 1,2-dimethylenecyclohexane (II) had not been prepared by the Hofmann method and information was available concerning its preparation *via* acetate pyrolysis and subsequent polymerization, this investigation was initiated.

The immediate goal was to determine whether the highly crystalline, non-rubber characteristics of the homopolymer II were due to impurities in the monomer prepared *via* the acetate pyrolysis or were unique to this particular six-membered ring system.

1,2-Dimethylenecyclohexane (II).—The synthesis of II was achieved as indicated below.



III IV

The glycol 1,2-bis-(hydroxymethyl)-cyclohexane (III) was made by lithium aluminum hydride reduction of diethyl 1,2-cyclohexanedicarboxylate obtained from the catalytic reduction of diethyl phthalate. The over-all yield of III from diethyl phthalate was 84%. Treatment of III with phosphorustribromide gave 1,2-bis-(bromomethyl)-cyclohexane in 90% yield. Conversion of the dibromide to the bis-quaternary ammonium hydroxide IV was effected by treatment with methanolic trimethylamine followed by reaction with freshly prepared moist silver oxide.

Thermal decomposition of IV at 120–125° gave II (40%). After one distillation under nitrogen and reduced pressure the pure diene showed b.p. 73–74° (139 mm.), n^{25}D 1.4717, and an ultraviolet spectrum maximum (in isoöctane) at 220 mμ with log ε 3.82.

Polymerization of II.—Freshly prepared and purified diene was subjected to a number of free radical initiated polymerizations using conventional emulsion and oxidation–reduction recipes and one typical Ziegler recipe. The rate of polymerization in all cases was very slow and homopolymer products were either oils or brittle, powdery solids depending upon extent of polymerization time.

The solid homopolymers were highly crystalline as evidenced by their complete insolubility in all common organic solvents and high melting points. The comparatively narrow melting point ranges indicate absence of extensive crosslinking. The polymerization results are summarized in Table I.

Infrared spectra of the solids (KBr) show the absence of terminal methylene groups and indicate all *cis*-1,4-units in the polymers. Molecular weight estimations either by the Signer—Barger ebullioscopic method, applicable to molecular weights of about 5000, or by intrinsic viscosity measurements could not be made because of solvent difficulties.

The homopolymers reported here are thus very similar to the oils and brittle resins of Wolinsky[9] and Short and the high-melting crystalline solids of Bailey and Golden.

TABLE I

Since the diene II was prepared and purified by the same methods used for 1,2-dimethylenecyclopentane and 3-methyl-1,2-dimethylenecyclopentane, its extremely slow rate of polymerization appears to be peculiar to the six-membered ring system. In addition to the increased steric effect present in going from the five-carbon to the six-carbon cyclic monomer a more significant structural difference is the spatial relationship of the exocyclic double bonds. In 1,2-dimethylenecyclobutane and the 1,2-dimethylenecyclopentanes, which polymerize rapidly, the exocyclic double bonds are forced to be coplanar by the steric requirements of the cyclobutane and cyclopentane rings. In 1,2-dimethylenecyclohexane, however, there is a large deviation from coplanarity of the double bond system when the cyclohexane ring is in the chair conformation. The angle between the planes of the double bonds approaches 60° in this conformation. Cyclohexane is known to exist predominantly in the chair form at moderate temperatures and only at elevated temperatures is the boat form important. The ultraviolet absorption maxima of the dienes are a measure of the relative coplanarity of the double bond system. 1,2-Dimethylenecyclohexane has a maximum absorption about 30 mμ lower than the corresponding four- and five-membered ring dienes.

This non-coplanarity of the conjugated system would be expected to decrease the reactivity of the monomer toward 1,4-addition. Free radical addition to one of the exocyclic methylene groups and resultant formation of the endocyclic double bond (1,4-addition) requires twisting the ring system so that the originally non-planar methylene carbon atoms become coplanar. In the smaller ring analogs no such ring contortions are required in the formation of the internal double bond.

Whether this factor is significant enough to account entirely for the marked decrease in the reactivity of the monomer cannot be ascertained at the present time. It is pertinent, however, to mention the extreme difficulty Laughlin[9] encountered in attempting to polymerize 4-neopentyl-1,2-dimethylenecyclohexane in a wide variety of systems; and the low conversions (29–75%) Wolinsky[10] obtained on polymerization of 1,2-dimethylene-4-methylcyclohexane.

Experimental Part

Diethyl 1,2-Cyclohexanedicarboxylate (V).—In a stainless steel hydrogenation bomb diethyl phthalate, 236 g. (1.06 moles), was reduced over Raney nickel at 170° to give crude V. The crude was fractionated through a 60-cm. Vigreux column to give pure diester (94%), b.p. 124–125° (5.4 mm.), $n^{25}D$ 1.4503 (Bailey and Golden[6] reported b.p. 150–152° (23 mm.), $n^{25}D$ 1.4505).

1,2-Bis-(hydroxymethyl)-cyclohexane (III).—Lithium aluminum hydride reduction of 122 g. (0.53 mole) of V carried out in the usual way gave 67 g. (89%) of III, b.p. 142–143° (3.8 mm.), $n^{25}D$ 1.4905 (Haggis and Owen[11] reported b.p. 110–130° (0.3 mm.), $n^{20}D$ 1.4914; Bailey and Golden[6] found b.p. 134–136° (3 mm.), and Wicklatz and Short[5] reported b.p. 145–146° (5 mm.), $n^{25}D$ 1.4880).

Anal. Calcd. for $C_8H_{16}O_2$: C, 66.63; H, 11.18. Found: C, 66.73; H, 11.13.

1,2-Bis-(bromomethyl)-cyclohexane (VI).—Using the procedure described for the preparation of 1,2-bis-(bromomethyl)-cyclopentane,[3] from 76 g. (0.53 mole) of III there was obtained pure dibromide (90%), b.p. 112–113° (2.5 mm.), $n^{25}D$ 1.5413, d^{25}_4 1.6276; MD calcd. for $C_8H_{14}Br_2$ 52.5, found 52.2 (no correction for exaltation due to the six-membered ring).

Anal. Calcd. for $C_8H_{14}Br_2$: C, 35.58; H, 5.23; Br, 59.19. Found: C, 35.63; H, 5.32; Br, 59.33.

1,2-Bis-(dimethylaminomethyl)-cyclohexane Dimethobromide (VII).—A mixture of 59 g. (1.00 mole) of trimethylamine, 44 g. (0.16 mole) of VI and 10 ml. of methanol was kept in a sealed Pyrex bomb at room temperature until separation of solid precipitate was complete. Evaporation of the reaction mixture to dryness *in vacuo* gave the bis-quaternary ammonium bromide (88%). Attempted recrystallization of the crude salt was unsuccessful. A portion of it was converted to the quaternary ammonium picrate which was recrystallized from 95% ethanol. Two picrates were obtained: A, difficultly soluble in hot ethanol and B, very soluble in hot ethanol. Picrate A had m.p. 192–194° and B a m.p. of 166–167°.

Anal. Calcd. for $C_{26}H_{36}O_{14}N_8$: C, 45.61; H, 5.30; N, 16.37. Found: A: C, 45.28; H, 5.11; N, 16.41; B: C, 45.35; H, 5.13; N, 16.18.

1,2-Dimethylenecyclohexane (II).—The crude quaternary ammonium bromide VII (38.2 g., 0.098 mole) was dissolved in a minimum amount of water. Freshly prepared silver oxide was added to the aqueous solution in small portions with stirring. The reaction vessel was cooled with an ice-bath. An immediate exothermic reaction occurred with the formation of yellow silver bromide. The addition of silver oxide was continued until the formation of silver bromide ceased, as was evidenced by the persistence of the dark brown color due to excess oxide. The solid mixture of silver bromide and silver oxide was filtered off and the filtrate, an aqueous solution of 1,2-bis-(dimethylaminomethyl)-cyclohexane dimethohydroxide, was transferred directly into a 200-ml. round-bottomed flask for pyrolysis. The flask was equipped with a Vigreux head and condenser take-off which led to a receiver immersed in an ice-bath. The cold receiver had an outlet leading to a trap immersed in Dry Ice. Hydroquinone was added to the pyrolysis flask and the receiver and the entire system purged with nitrogen. The flask was heated slowly with an oil-bath and under reduced pressure (142–146 mm.). At bath temperature from 90 to 115° mostly water came over at a vapor temperature 66–68°. In the range 115 to 125° oil and water co-distilled at *ca.* 68°. The oil-bath was kept at 125° until the decomposition was complete. The ice-bath receiver contained all the crude diene (upper layer) and it was separated from the water layer and washed with 10% hydrochloric acid to convert the trimethylamine, formed during pyrolysis, to its ammonium salt. After washing with water, until neutral to litmus, and drying over magnesium sulfate the crude diene was distilled from a 25-ml. pear-shaped flask. Distillation was carried out in an atmosphere of nitrogen and in the presence of hydroquinone. Pure diene (5.0 g., 40%) showed b.p. 73–74° (136 mm.), $n^{25}D$ 1.4717 (Wicklatz and Short[5] reported b.p. 48.8–49.4° (55 mm.), $n^{25}D$ 1.4710; Bailey and Golden[6] found b.p. 60–61° (90 mm.), 124° (740 mm.), $n^{25}D$ 1.4718; Verdol[4] gave b.p. 80–81° (130 mm.), $n^{20}D$ 1.4741).

Anal. Calcd. for C_8H_{12}: C, 88.82; H, 11.18. Found: C, 88.85; H, 11.30.

Reaction of II with Maleic Anhydride.—Maleic anhydride (1.42 g., 0.0145 mole) and 25 ml. of ether were placed in a 50-ml. round-bottomed flask equipped with a reflux condenser. After the addition of 1.57 g. (0.0145 mole) of pure diene II the mixture was allowed to stand overnight during which time a white crystalline solid separated. The ether was evaporated, using a water aspirator, and the crude product recrystallized from ether to give pure $\Delta^{9,10}$-octahydronaphthalene-2,3-dicarboxylic acid anhydride, m.p. 139.5–140.0° (Bailey and Golden[6] reported m.p. 139–140° and Verdol[4] gave m.p. 142–143°).

Absorption Spectra of II.—The infrared spectrum of II was similar to those reported for the smaller ring analogs.[3] Strong absorption is present at 3.26 and 6.08 μ indicative of unsaturation and at 11.35 μ characteristic of the terminal methylene group.

The ultraviolet spectrum of II shows only one peak, λ_{max} (isoöctane) 220 mμ, log ϵ 3.82 (Bailey and Golden[6] reported λ_{max} 220, log ϵ 4.00 and Verdol[4] λ_{max} 220, log ϵ 3.74).

The log ϵ value reported by Bailey and Golden appears to be somewhat high. Examination of several other compounds containing the same chromophoric group gives values which are in the range 3.7 to 3.8.

Diene	λ_{max}, mμ	log ϵ	Reference
	220	3·82	This work
	220	4·00	6
	220	3·74	4
	218 (Ethanol)	3·80	10
	217 (Isoöctane)	3·77	10
	221	3·69	9

NP = neopentyl

Homopolymerization of II.—All polymerizations were carried out on about one-gram samples of freshly prepared and purified diene in sealed glass tubes. All polymerizations but one were at 50° in a rotating constant-temperature water-bath. The oxidation–reduction charge at 5° was kept in a refrigerator and frequently hand-agitated. In all cases before sealing, the glass tubes were purged with purified nitrogen to remove oxygen.

The recipes used were

(a) Emulsion

Monomer, 1.0 g.
Ivory soap, 0.1 g.
Initiator solution, 0.1 ml. (3% potassium persulfate soln.)
Water, 2.5 ml.

(b) Oxidation–reduction emulsion

Monomer	1.0 g.
Water	3.3 ml.
Ivory soap	0.03 g.
Catalyst ($K_2S_2O_8$)	.33 ml. (3% soln.)
Activator (Na_2SO_3)	.00., g.

(c) Mass

Monomer	1.0 g.
Benzoyl peroxide	0.01 g.

(d) Ziegler[12]

Benzene	21.5 ml.
Triisobutylaluminum	0.063 ml. (added as 10% soln. in benzene)
Titanium tetrachloride	0.027 ml. (5% soln. in benzene)

Digitized by Arya Samaj Foundation Chennai and eGangotri

hours at 50°. Addition of 50 ml. of methanol did not precipitate polymer; only a trace of flocculent white solid separated. On standing overnight in an open heater, the solvent evaporated off, leaving a clear yellow sticky wax, evidently very low molecular weight polymer or air oxidation product of monomer.

All other reactions were quenched by chilling the tubes before opening and pouring the contents into a 2% sol. of PBNA in absolute ethanol. Where solid polymers were obtained, they precipitated as gummy particles which on stirring balled up into one mass. After drying at room temperature *in vacuo* the solids were hard, brittle white resins. They were found to be completely insoluble and generally unswollen in all common organic solvents.

Where oils were obtained, unreacted monomer could be recovered as its maleic anhydride adduct from an ether extract of the coagulating solution. The presence of monomer rather than dimer, even after heating at 50° for 50 hours (see Table I), indicates further the decreased activity of this diene. 1,2-Dimethylenecyclopentane, in comparison, dimerizes very readily above 90° or on contact with silica gel to form a self Diels–Alder adduct.[3]

The homopolymers obtained as oils were not further investigated.

Anal. of polymer (solid). Calcd. for $(C_8H_{12})_x$: C, 88.82; H, 11.18. Found: C, 89.09; H, 10.98.

Preparation and Properties of Some Hexadecyl Hydrogen Esters of Dibasic Acids

BY W. FREDERICK HUBER AND E. S. LUTTON

RECEIVED MARCH 4, 1957

Hexadecyl hydrogen esters of the dibasic acids succinic, glutaric, pimelic, maleic and itaconic were prepared and their crystallization behavior studied by means of X-ray diffraction. The compounds melt in the range of 59–77° and show only one crystal form whether from solvent or melt. Each appears to crystallize in double chain-length structure; each shows rather individualistic diffraction behavior except the similar homologous pair, the glutarate and the pimelate.

Introduction

Little is known of the preparation and properties of the longer monoalkyl hydrogen esters of dibasic acids. The preparation of hexadecyl hydrogen succinate by the reaction of succinic anhydride with hexadecanol has been reported.[1] Herein are reported the preparation and X-ray diffraction patterns of the hexadecyl hydrogen esters of succinic, glutaric, pimelic, maleic and itaconic acid.

Experimental

M.p.'s and analyses of the products appear in Table I.

TABLE I

M.P.'S AND ANALYSES OF HEXADECYL HYDROGEN ESTERS

n-Hexadecyl hydrogen ester	M.p., °C.	Analyses, % Neut. equiv. Calcd.	Neut. equiv. Found	Sapn. equiv. Calcd.	Sapn. equiv. Found
Succinate	63.5–64.5	342.5	340.0	171.3	172.2
Maleate	70–71.5	340.5	338.8	170.3	172.1
Itaconate	76–76.5	354.5	356.0	177.3	175.8
Glutarate	68.5–69.5	356.5	356.7	178.3	177.7
Pimelate	58–59	384.6	382.5	192.3	191.4

The succinate, maleate and itaconate were prepared by heating molar equivalents of the requisite acid anhydride with hexadecyl alcohol at 130–140° for 10 minutes. Hexadecyl hydrogen glutarate and pimelate were obtained by refluxing hexadecanol with excess dibasic acid for about 10 hr. in benzene with *p*-toluenesulfonic acid as a catalyst. The products were purified by recrystallization from hexane. In the case of the pimelate it was necessary to wash the hexane solution with warm water to remove pimelic acid. The structure of the products is unequivocal with the exception of hexadecyl hydrogen itaconate. In this case, esterification can open the anhydride to form either hexadecyl hydrogen α-methylenesuccinate or hexadecyl β-methylenesuccinate. The chemical structure of the itaconate was not explored.

Thermal and X-Ray Diffraction Technique.—Rapid complete m.p.'s and regular complete m.p.'s[2] were determined, the latter on both melted-chilled and solvent-crystallized samples. The single melting-level has been reported under sample preparation. "Rod pellets" of both solvent-crystallized and melted-chilled samples were X-rayed and found to have substantially identical patterns. Flat-film patterns were obtained with a General Electric XRD-1 unit employing nickel-filtered CuKα radiation and a 0.025-in. pinhole system. Sample-to-film distance was normally 10 cm.

X-Ray diffraction data are listed in the following order: compound; long spacing, L.S. (in Å.); short spacings, S.S. (in Å.). Relative intensities of diffraction lines are indicated by (V.S.) = very strong, (S) = strong, (M) = medium, (W) = weak.

Hexadecyl H succinate: L.S. 42.8; S.S. 4.54(S+), 3.98(S), 3.77(W), 3.63(S+)
Hexadecyl H glutarate: L.S. 45.2; S.S. 4.63(W), 4.4(W), 4.11(V.S.), 3.76(S)
Hexadecyl H pimelate: L.S. 50.8; S.S. 4.60(W), 4.14(V.S.), 3.79 (S)
Hexadecyl H maleate: L.S. 29.4; S.S. 5.28(W), 4.64(S), 3.78(V.S.)
Hexadecyl H itaconate: L.S. 40.7; S.S. 4.68(M), 4.44(W), 4.16(V.S.), 3.74(S)

Discussion

While the dibasic acids from which these hexadecyl monoesters were made show a range of m.p.'s covering 90°, the esters show a spread of only 18° with little correlation between relative melting level in the acid and ester series. Each ester shows the same single solid phase whether from solvent or from melt. The several compounds are quite individualistic in X-ray diffraction behavior except for the glutarate and pimelate which are adjacent odd homologs; they show a beta prime-type of pattern rather similar to those exhibited by palmitic and stearic acids. It is a little surprising that the higher homolog melts 10° lower, especially when the acid m.p.'s are in the reverse order.

The chain lengths of these hexadecyl esters should be of the order 28–30 Å. The long spacings which mostly run from 40–50 Å. bespeak tilted [illegible] structures. The maleate long

spacing is remarkably short at 29 Å. and may signify a single-chain-length structure, but the fact that the intensities of various orders of long spacing follow a sequence similar to those of the succinate suggests a double-chain-length structure.

CINCINNATI 31, OHIO

COMMUNICATIONS TO THE EDITOR

THE STRUCTURE OF RUSCOGENIN[1]

Sir:

Ruscogenin, isolated by Lapin and Sannié[2] in 1955 from *Ruscus aculeatus L.*, was identified as 19-hydroxydiosgenin.[3] However, we wish to report recent evidence which invalidates the structure proposed by the French workers. For purpose of clarity we shall assume that this new sapogenin is x-hydroxydiosgenin and later in this communication arrive at the most probable structure.

Recrystallized ruscogenin[4] diacetate (m.p. 191–194°, $[\alpha]^{25}D$ −80.5°, 1.03% in $CHCl_3$; diol,[5] m.p. 205–211°, $[\alpha]^{25}D$ −118°, 1% in $CHCl_3$) was degraded[6] by methods well established in the sapogenin field[3,7] to the oily diacetate of 5,16-pregnadiene-x,3-diol-20-one I in 70% yield. Beckmann rearrangement[8] of the oxime (m.p. 188–197° dec.; C, 69.82; H, 8.02), followed by mild acid treatment yielded x-acetoxydehydroepiandrosterone acetate II (m.p. 97–99°) and 147–149°; C, 71.44; H, 8.31), which on vigorous alkaline hydrolysis afforded x-hydroxydehydroepiandrosterone III (m.p. 195–197°; C, 74.71; H, 8.99). Diol III was stable to acid and reverted to II on acetylation. Controlled acid-catalyzed methanolysis of the diacetate II led, after chromatography, to x-acetoxydehydroepiandrosterone IV (m.p. 136.5–138°; C, 72.91; H, 8.97) in about 65% yield.

When the diol III was treated with aluminum isopropoxide and cyclohexanone in refluxing toluene, 1,4-androstadiene-3,17-dione[9] (m.p. 139.5–140.5°; λ_{max}^{MeOH} 243 mμ, ε 16,000) was obtained in approximately 30% yield, as shown by comparison (infrared and mixed m.p.), with an authentic sample prepared according to Djerassi and Scholz.[9b] The monoacetate IV was carefully oxidized with chromic acid in acetone[10] to an oily ketone V, which on treatment with potassium acetate in refluxing ethanol or aqueous potassium hydroxide in methanol at room temperature, again afforded 1,4-androstadiene-3,17-dione (m.p. 139–140.5°) in approximately 40% and 50% yield respectively. These results could best be rationalized by assuming the additional hydroxyl to be situated on carbon 1 of the steroid nucleus.

In order to obtain additional information as to the position and configuration of the functional groups, the diol III was reduced with sodium borohydride in methanol to 5-androstene-1,3β,17β-diol VIa (m.p. 275–280° dec.; C, 74.24; H, 9.97; triacetate VIb, m.p. 145–147°; C, 69.24; H, 8.57), which on catalytic hydrogenation in presence of Adams catalyst in ethanol containing a trace of hydrochloric acid, afforded in 93% yield androstane-1,3β,17β-triol VII (m.p. 217–219°; C, 74.01; H, 10.47). Triol VII was found to be different (infrared and mixed m.p.) from authentic androstane-1α,3β,17β-triol (m.p. 236–238°; C, 73.71; H, 10.54), obtained from 1-androstene-3,17-dione by α-epoxidation with alkaline hydrogen peroxide, followed by stepwise reduction with sodium borohydride and lithium aluminum hydride.[11]

Conclusive proof of structure was finally obtained when the triol VIa and its triacetate VIb were compared with authentic samples[12] of 5-androstene-1β,3β,17β-triol, m.p. 270–278° dec. and its triacetate m.p. 147.5–148.5°. They were respectively found to be identical in all respects (infrared and mixed m.p.).

The positions of the two hydroxyl groups and of the double bond in ruscogenin are thus firmly established. In light of our results and the conversion of ruscogenin to diosgenin by Lapin and Sannié,[2] we conclude that this new sapogenin is very likely 1β-hydroxydiosgenin.

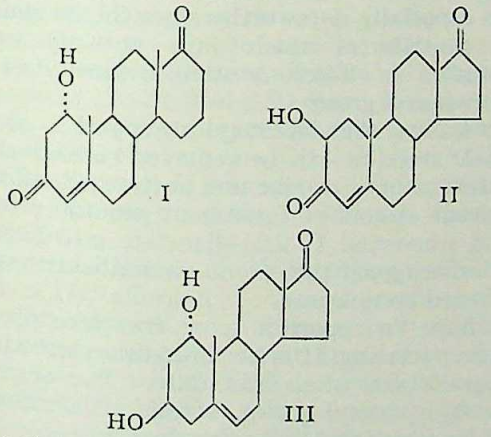
MICROBIOLOGICAL HYDROXYLATION OF C_{19}-STEROIDS AT POSITIONS C-1 AND C-2

Sir:

Extensive studies[1] have shown that steroids can be hydroxylated by microörganisms at positions 6β, 7α, 7β, 8- and/or 9-, 10, 11α, 11β, 14α, 15α, 15β, 16α, 17α and 21. We now wish to report the preparation of 1α-hydroxy-4-androstene-3,17-dione (I); m.p. 218–221°; $[\alpha]D$ +184° ($CHCl_3$); $\lambda_{max}^{methanol}$ 240 mμ (15,000); (found: C, 75.32; H, 8.46); and 2β-hydroxy-4-androstene-3,17-dione (II); m.p. 143–145°; $[\alpha]D$ −36.8° ($CHCl_3$); $\lambda_{max}^{methanol}$ 242 mμ (14,200); (found: C, 75.80; H, 8.71); by the microbiological action of a species of *Penicillium*, isolated from local soil, on 4-androstene-3,17-dione. By subjecting dehydroepiandrosterone to the same oxidative fermentation, we obtained, besides I, 1α-hydroxydehydroepiandrosterone (III); m.p. 275–277.5°; $[\alpha]D$ +10.6° ($CHCl_3$); (found: C, 74.92; H, 9.21). The hydroxylated steroids were prepared by the fermentation and extraction techniques previously described,[2] and, in the case of the hydroxylated androstenediones, were purified by chromatography on silica gel. 1α-Hydroxydehydroepiandrosterone (III) was readily obtained by direct crystallization on concentration of the methylene chloride extract.



The structure of II was indicated by the contribution of the new hydroxyl to the molecular rotation of the compound (ΔM_D −658),[3a] by a positive "blue tetrazolium" test, and by the characteristic change of ultraviolet spectra with time in 0.1 *N* methanolic potassium hydroxide.[4] The structure was established by converting II to its acetate, m.p. 157–158°; $[\alpha]D$ −5.9° ($CHCl_3$); $\lambda_{max}^{methanol}$ 243 mμ (15,300); (found: C, 73.47, H; 8.04); and epimerizing II acetate, by heating with anhydrous potassium acetate in glacial acetic acid,[5] to the known 2α-acetoxy-4-androstene-3,17-dione,[3b] m.p. 209–211°; $[\alpha]D$ +146.8° ($CHCl_3$); $\lambda_{max}^{methanol}$ 239.5 mμ (15,500).

The structure of I was established by the conversion of I acetate, m.p. 112.5–113.5°; $[\alpha]D$ +191.7° ($CHCl_3$); $\lambda_{max}^{methanol}$ 239.5 mμ (16,500); (found: C, 72.71; H, 8.07); by means of dilute methanolic sodium hydroxide to 1,4-androstadiene-3,17-dione,[6] m.p. and mixed m.p. 139–140°. Comparison of the infrared spectrum with that of an authentic sample confirmed identity. Oppenauer oxidation of III to 1,4-androstadiene-3,17-dione[6] established the structure of III.

The configuration of the 1-hydroxyl group in both I and III was initially assigned on the basis of molecular rotatory contributions.[7] The structure of III was definitively confirmed by its catalytic reduction to 1α,3β-dihydroxyandrostan-17-one (IV), m.p. 202–203.5°; $[\alpha]D$ +88.2° ($CHCl_3$); (found: C, 74.32; H, 9.74); followed by reduction of IV with sodium borohydride to 1α,3β,17β-androstanetriol (V), m.p. 238–239°; $[\alpha]D$ +20.2° ($CHCl_3$); (found: C, 73.99; H, 10.47). This compound (V) was identical in all respects with that prepared by Benn, Colton, and Pappo[8] by the reduction of 1α,2α-oxidoandrostane-3,17-dione.

Reduction of III with sodium borohydride or lithium aluminum hydride gave 5-androstene-1α,3β,17β-triol (VI), m.p. 212–213°; $[\alpha]D$ −54.8° ($CHCl_3$); (found: C, 74.41; H, 10.22); triacetate, m.p. 179–181°; (found: C, 69.11; H, 8.24). Cautious acetylation of III produced 1α-hydroxy-3β-acetoxy-5-androsten-17-one (VII), m.p. 243–244°; $[\alpha]D$ −6.7° ($CHCl_3$); (found: C, 72.58; H, 8.83); which was oxidized with chromium trioxide in pyridine to 3β-acetoxy-5-androstene-1,17-dione (VIII), m.p. 156–157.5°; $[\alpha]D$ +40.7° ($CHCl_3$); (found: C, 73.27; H, 8.27). The reduction of VIII with sodium borohydride yielded VI and 5-androstene-1β,3β,17β-triol (IX), m.p. 270–278°; triacetate, m.p. 147.5–148.5°; $[\alpha]D$ −32.4° ($CHCl_3$); (found: C, 69.11; H, 8.54). Compound IX and its triacetate were identical in all respects (m.p., mixed m.p., and infrared) with the corresponding triol and triacetate obtained from Ruscogenin by Benn, Colton, and Pappo.[8]

MICROBIOLOGICAL TRANSFORMATION OF STEROIDS. 2β-HYDROXYLATION

Sir:

It has become increasingly evident that enzymatic hydroxylations of steroid occurring in the mammalian tissues will inevitably find their counterparts in microbially-induced transformations of the same or similar substrates. Of the hydroxylation processes occurring in mammals the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

reactions at 2α[1], 2β[2], 6α[3], 18-[4] and 19-[4] have not as yet been duplicated by incubations with microorganisms.[4a]

We wish to report that microbiological 2β-hydroxylation of 4-pregnene-17α,21-diol-3,20-dione (I, Reichstein's Compound S) has now been achieved with the aid of several unidentified *Streptomyces* species isolated from soil (Schering collection numbers FC7-206, FC6-53S, DS 81-B). Incubation of Compound S (600 mg.) in a peptone–soybean meal–yeast extract–cerelose medium with a 72-hour growth culture of *Streptomyces* sp. DS-81-B with rotary shaking at 28° for 48 hours afforded, after chloroform extraction and chromatography, 35 mg. of 4-pregnene-2β,17α,21-triol-3,20-dione (II), m.p. 215–220° dec. Further recrystallization from acetone–hexane raised the m.p. to 225.5–228° dec. and gave II with the following constants: $[\alpha]^{25}D$ −58° (dioxane), λ_{max}^{MeOH} 243 mμ (ϵ = 14,500), λ_{max}^{Nujol} 3.01 μ (OH), 5.81 μ (20-carbonyl), 5.94 μ (3-carbonyl) and 6.18 μ (Δ^4); three hydroxyl groups by integration of the OH band. Calcd. for $C_{21}H_{30}O_5$: C, 69.58; H, 8.34. Found: C, 69.81; H, 8.76. A polymorphic modification of II exists which possesses an altered infrared spectrum, λ_{max}^{Nujol} 2.87 μ (OH), 5.82 μ (20-carbonyl), 5.89 μ and 6.02 μ (3-carbonyl) and 6.20 μ (Δ^4). The latter polymorph is converted to the former by recrystallization from acetone–hexane and seeding with the former. The infrared spectra of the two forms differed in considerable detail from the 6β, 11α, 11β, 15α and 15β-hydroxy derivatives of I. The 2,21-diacetate of II, prepared with acetic anhydride and pyridine melts at 218–219°, $[\alpha]^{25}D$ +9° (dioxane), λ_{max}^{MeOH} 244 mμ (ϵ = 16,200), λ_{max}^{Nujol} 2.73, 2.83, 2.97 μ (OH), 5.71 μ (acetate carbonyl), 5.78 μ (20 carbonyl), 5.95 μ (3-carbonyl), 6.16 μ (Δ^4), 8.06 μ and 8.25 μ (C–O–C of acetate). Calcd. for $C_{25}H_{34}O_7$: C, 67.24; H, 7.68. Found: C, 66.99; H, 7.74. The 21-monoacetate of II, prepared with one equivalent of acetic anhydride in pyridine solution, melted at 234–235°, $[\alpha]^{25}D$ −24° (dioxane), λ_{max}^{MeOH} 243 mμ (ϵ = 14,300), $\lambda_{max}^{CHBr_3}$ 2.86 μ (OH), 5.71 μ (acetate carbonyl), 5.76 μ (20-carbonyl), 5.95 μ (3-carbonyl), 6.17 μ (Δ^4) and 8.12 μ (C–O–C of acetate). Calcd. for $C_{23}H_{30}O_6$; C, 68.29; H, 7.97. Found: C, 68.00; H, 7.63.

The structure of II has been assigned on the basis of the following arguments and experiments. Appearance of the conjugated carbonyl band at 5.94 μ is interpreted as indicating a hydrogen bond interaction between the carbonyl at 3- and an hydroxyl group on an adjacent carbon atom. This is further substantiated by the observed interaction of the neighboring acetate with the 3-carbonyl) in the 2,21-diacetate of II as well. The observed ultraviolet maximum of II excludes 4- as a site for neighboring hydroxyl since enols of α,β-diketones absorb in the region of 280 mμ. Measurement of the ultraviolet absorption in alkaline solution, according to Meyer,[5] after heating at 60° for 4 hours, afforded a curve which corresponded exactly in location of maxima with the highly characteristic curve from 2α-hydroxy-4-androstene-3,17-dione.[5] The rotation of the 2,21-diacetate of II differs markedly from that reported for 4-pregnene-2α,17α,21-triol-3,20-dione 2,21-diacetate[6] ($[\alpha]^{25}D$ +122° (chloroform), m.p. 200–202°, 215–217° (polymorphs)). In like fashion II contrasts with the 4-pregnene-2α,17α,21-triol-3,20-dione, $[\alpha]^{25}D$ +130° (chloroform), m.p. 219–221°. Since 2β-hydroxyl reaches equilibrium with 2α-hydroxyl in mildly alkaline solution,[7] it is obvious that the same alkaline ultraviolet spectrum must result for both configurations in a given pair of 2-hydroxy-3-keto-Δ^4-steroids.[5] Hence, II must contain a 2β-hydroxyl group.

The assignment is corroborated by the fact that the predicted shift in molecular rotation (ΔM-581)[7] based on the only 2β-hydroxy-3-keto-Δ^4-steroid known previously, 2β-hydroxytestosterone 2,17-diacetate[7] (2β-hydroxytestosterone itself[2] is characterized incompletely), is in reasonable agreement with the observed values of the shift for 21-acetate of I *vs.* 2,21-diacetate of II (ΔM-500). This is especially noteworthy since the 2β-hydroxyl group contributes much more strongly to the levorotation of 3-keto-Δ^4-steroids than does any other hydroxyl group.

It is known that hydroxyl groups at 2- or 6- in 3-keto-Δ^4-steroids can be removed reductively by mild treatment with zinc and acetic acid, affording the parent steroid.[7] Treatment according to this method converted II 2,21-diacetate into I 21-acetate, indistinguishable from an authentic sample by infrared comparison.

We hope to report a more complete proof of structure, relating II with 2β-hydroxytestosterone by degradation, at a later date. The chemistry of the 2β-hydroxyl group, heretofore a rather inaccessible function, is being studied.

We wish to acknowledge the helpful advice of Dr. André Meyer in the interpretation of the alkaline ultraviolet spectra.

TRANSFORMATION OF STEROIDS BY FUNGI. INTRODUCTION OF 1ξ AND 2β-HYDROXYL GROUPS INTO REICHSTEIN'S COMPOUND S.

Sir:

Heretofore, no unambiguous microbiologically induced hydroxylation of steroid substrates has

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

been observed.[1] In the preceding communication[2] we have described the first 2β-hydroxylation of Compound S with *Streptomyces* sp. We wish now to report the microbiological hydroxylation of 4-pregnene-17α,21-diol-3,20-dione (I, Reichstein's Compound S) in the 1ξ and 2β positions by *Rhizoctonia ferrugena* (CBS, Holland). The fermentation of I (3.0 g.) by *R. ferrugena* was carried out in a medium containing corn steep liquor, ammonium dihydrogen phosphate, yeast extract, dextrose, soybean oil and calcium carbonate. In the fermentation stage a forty-eight hour culture was incubated with the steroid substrate (introduced in ethanolic solution) on a rotary shaker for five days at 23°. The culture filtrate was extracted with chloroform and chloroform–methanol (4:1), and the extracts were concentrated to dryness in vacuo below room temperature. The residue was redissolved in dry, acid and alcohol-free chloroform and the solution was chromatographed on a silicic acid adsorption column. A methanol–chloroform gradient elution[3] was utilized to separate the two steroidal transformation products and residual substrate. The steroid substrate, I, was collected in the first fractions, the 2β-hydroxylated product, II, in the middle fractions and the 1-hydroxylated product, III, in the last fractions. Homogeneity was indicated by paper chromatography.

Crystallization of the middle fractions from chloroform–ether mixture afforded 101 mg. of 4-pregnene-2β,17α,21-triol-3,20-dione (II), m.p. 214–220° dec. Further recrystallization from acetone–hexane raised the m.p. to 220–222° dec. The infrared spectrum of II was identical with that of an authentic sample,[2] and the mixed m.p. showed no depression.

The crystallization of the last group of fractions (Product III) afforded 163 mg. of crystalline solid, m.p. 180–200° dec. Cautious recrystallization from acetone–hexane without application of heat, raised the m.p. to 193–207° dec. (with a transition of about 170°), $[\alpha]^{25}D$ +89 (dioxane) (corrected for acetone of solvation), λ_{max}^{MeOH} 241 mμ (ϵ = 16,500 —corrected for acetone of solvation), λ_{max}^{Nujol} 2.83 μ (OH), 5.81 μ (20-carbonyl), 6.04 μ (3-carbonyl), 6.18 μ (Δ^4) (one additional polymorphic variety has been observed.) Calcd. for $C_{21}H_{30}O_5 \cdot C_3H_6O$: C, 68.54; H, 8.63. Found: C, 68.41; H, 8.66.

The identity of III was established in the following manner. Integration of the hydroxyl bands of the infrared spectrum confirmed the presence of three hydroxyl groups. Measurement of the ultraviolet spectrum of III in alkaline solution[4] showed a shift in the maximum to 245 mμ but no peak in the 380 mμ region after two hours at 60°. This is consistent with the conversion of a 1-hydroxy-3-keto-Δ^4-steroid into a $\Delta^{1,4}$-diene-3-keto-steroid, which transformation would be expected to occur under these conditions. Also the ultraviolet spectrum of III was strikingly different from that of a 2-hydroxy-3-keto-Δ^4-steroid in alkaline solution.[2,4] The presence of the dienone among the products from the alkaline treatment of III was further substantiated by the measurement of the polarographic reduction potential of the solution.[5] A shift in the half-wave potential from 1.46 volts (III) to 1.31 volts (after alkaline treatment) corresponds well to the shifts observed for cortisone *vs.* prednisone (0.16 volt) and cortisol *vs.* prednisolone (0.17 volt). Furthermore, pyrolysis of a sample of III at the melting point for ten minutes afforded a mixture of products whose infrared spectrum contained the characteristic $\Delta^{1,4}$-diene-3-one bands.

Finally, a solution of III in glacial acetic acid was refluxed for one hour. Upon concentration of the solution *in vacuo*, chromatography of the residue on Florisil and recrystallization from acetone–hexane there was obtained 1,4-pregnadiene-17α,21-diol-3,20-dione, m.p. 237–240°, whose infrared spectrum was identical with that of an authentic sample.[6] From this evidence we conclude that the structure of III is clearly 4-pregnene-1ξ,17α,21-diol-3,20-dione. The configuration of the 1-hydroxyl group remains to be fixed.

With cortisol, cortisone, corticosterone, desoxycorticosterone, progesterone and testosterone transformations occur upon incubation in the presence of *R. ferrugena* as determined by paper chromatographic examination of the product. The structure of the transformation products in these instances remains to be elucidated.

Other species of *Rhizoctonia* have effected the transformation of I into cortisol, cortisone and 11-epicortisol; a more detailed account of these findings will be published subsequently. Additional conversion products obtained with organisms of this genus are now under investigation.

We wish to make the following acknowledgments. From the Schering Corporation we acknowledge the helpful advice of Drs. André Meyer and Alexander Nussbaum, the assistance of Dr. P. Kabasakalian and Mr. J. McGlotten who carried out the polarographic reductions, of Dr. J. Y. Chen who interpreted the infrared spectra, and of Mrs. M. J. Gentles. From the Institute of Microbiology we acknowledge the technical assistance of Mr. A. Chernov. We also wish to thank Dr. C. M. Haenseler for his helpful advice and for various cultures of *Rhizoctonia*.

CYCLOPENTENE-3,5-DIONE

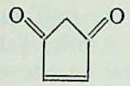
Sir:

The synthesis of many substituted and unsubstituted cyclopentenone derivatives of theoretical

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

and practical importance is hindered by the lack of readily available intermediates. With few exceptions, substituted cyclopentadienes are too unstable to be isolated, and these exceptions have not proved useful for further synthetic work.[1,2] We wish to report the synthesis of cyclopentene-3,5-dione (I),



I

a yellow, stable, crystalline, highly reactive molecule which promises to provide an entry into many new synthetic fields.

Cyclopentene-3,5-dione can be prepared easily from cyclopentadiene by bromination,[3] and treatment of the resultant 3,5-dibromocyclopentene with tetraethylammonium acetate in dry acetone.[4] Hydrolysis affords cyclopentene-3,5-diol which can be oxidized to I in 50% yield with chromic acid in acetic acid. After crystallization from ether–pentane and two sublimations it showed m.p. 36–37°. *Anal.* Calcd.: mol. wt., 96. Found: C, 62.3; H, 4.0; mol. wt., 96; ultraviolet: λ_{max} 222 (4.16), 322 (1.30), 367 (1.30); infrared: 5.73, 5.83.

We shall report on the details of several of its reactions later, but the following will indicate their scope. (1) It is readily reduced to 1,3-cyclopentanedione (m.p. 150–151°, reported[5] 151–152°) and this sequence may provide the best synthesis of this useful compound. (2) The enedione is highly reactive in the Diels–Alder reaction, and readily gives adducts with cyclopentadiene, anthracene and other dienes. (However, it is *less* reactive than maleic anhydride. We consider this difference significant, and will discuss it in due course.) (3) Cyclopentene-3,5-dione condenses rapidly with aldehydes and ketones in the presence of weak bases. These and other reactions are being explored.

The dione is an acid (*p*H of a 0.1 *N* aqueous solution, 4.5) which is rapidly destroyed by base. Despite its acidity, the molecule appears to be completely ketonic. It does not give a ferric chloride test. In its enolic form it would be a derivative of cyclopentadienone and as such perhaps partake of the unfavorable electronics which have been suggested to explain the lack of existence of that molecule. In addition to its interest for its own sake, we believe that this unique molecule, containing as it does three different types of functional groups and with each of its carbon atoms potentially reactive, will be a useful intermediate in the synthesis of many hitherto unavailable molecules.

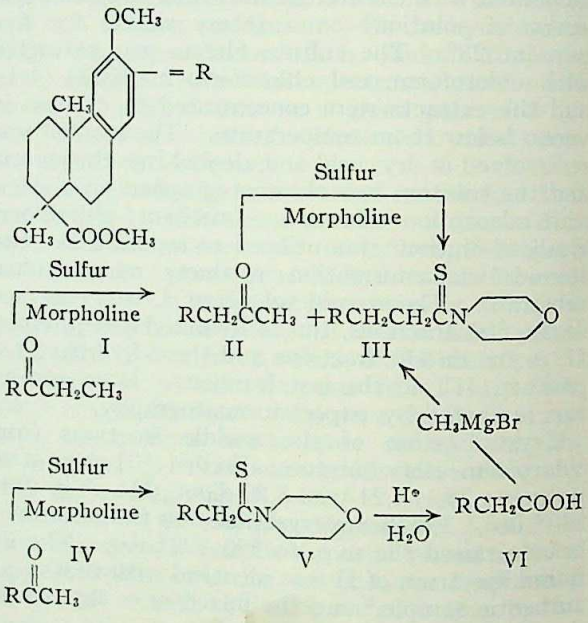
A NEW TYPE OF PRODUCT FROM THE WILLGERODT REACTION

Sir:

We wish to report the migration of a keto group to an adjacent carbon atom during a Willgerodt reaction. Methyl O-methyl-7-propionylpodocarpage (I) under Willgerodt conditions is converted (10% yield) to methyl O-methyl-7-acetonylpodocarpate (II). Since this new ketone is also converted to the thiomorpholide (III) under Willgerodt conditions, it is probable that at least part of the material goes through II as an intermediate.



The reaction of methyl O-methylpodocarpate[1] and propionyl chloride in the presence of aluminum chloride gave methyl O-methyl-7-propionylpodocarpate [I, m.p. 103.5–105°, λ max 255 mμ (ε = 10,500)[2] and 315 mμ (ε = 4,090), 5.82 and 5.98 μ μ(CHCl₃); $[\alpha]^{25}D$ +134° (ethanol); calcd. for $C_{22}H_{30}O_4$: C, 73.71; H, 8.44. Found: C, 74.04; H, 8.54]. Chromatography of I on silica under conditions which were shown to separate I and II failed to reveal the presence of any II.

A mixture of methyl O-methyl-7-propionylpodocarpate (107.5 g.), sulfur (14.4 g.), and morpholine (39.2 g.) was heated at reflux for 10 hr. The reaction mixture was dissolved in benzene, filtered, and the solvent was removed. The expected thiomorpholide, (III, 85.6 g., m.p. 172–177°) crystallized when an ether solution was concentrated. Further recrystallization from a mixture of chloroform and methanol gave the pure thiomorpholide [m.p. 177–178.5, λ max 281 μ (ε = 18,000), $[\alpha]^{25}D$ +110° (chloroform); calcd. for $C_{26}H_{37}NO_4S$: N, 3.05; S, 6.98; OCH_3, 13.50. Found: N, 3.08; S, 6.94; OCH_3 13.02]. The material in the mother liquors from this reaction was chromatographed over silica (1700 g.). Among the compounds eluted with 2% ethyl acetate in benzene was methyl O-methyl-7-acetonylpodocarpate (II) which crystallized from aqueous methanol as

(1) I. R. Sherwood and W. F. Short, *J. Chem. Soc.*, 1006 (1938).

(2) The analytical determinations were made by the Analytical Laboratory under the direction of Dr. Robert T. Dillon.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

colorless platelets [11.1 g., m.p. 105.5–107.5°, λ_{max} 281 mμ (ε = 3,160) and 287 mμ (ε = 3,140), 5.82, 6.18, 6.37, and 7.37 μ (chloroform): $[\alpha]^{25}D$ +122°; calcd. for $C_{22}H_{30}O_4$: C, 73.71; H, 8.44; OCH_3, 17.32. Found: C, 73.93; H, 8.43; OCH_3, 17.05]. Compound II formed a bright yellow 2,4-dinitrophenylhydrazone [m.p. 203.5–207.5°, λ_{max} 3.04, 5.83, 6.23, 6.33, and 7.61 μ; calcd. for $C_{28}H_{34}N_4O_7$: C, 62.44; H, 6.36. Found: C, 62.64; H, 6.46].

To confirm the structure assigned to II, methyl O-methyl-7-acetonylpodocarpate was synthesized in the following manner: methyl O-methyl-7-acetylpodocarpate[3] (IV) was converted by a Willgerodt reaction to the corresponding thiomorpholide [V, m.p. 177–180.5°, λ_{max} 281 mμ (ε = 17,600), 5.81, 6.20, 6.37 and 6.71 μ (chloroform); $[\alpha]^{25}D$ +101° (ethanol); calcd. for $C_{25}H_{35}NO_4S$: S, 7.20; N, 3.14. Found: S, 7.20; N, 3.17]. Hydrolysis of V with sulfuric acid in acetic acid gave the corresponding monobasic acid [VI, m.p. 144.5–147°, presoftened, λ max 281 mμ (ε = 2,690) and 287 mμ (ε = 2,630), 5.82, 6.18, 6.35, and 6.66 μ (KBr); calcd. for $C_{21}H_{28}O_5$: C, 69.97; H, 7.83; OCH_3, 17.22; COOH, 12.49. Found: C, 70.23; H, 8.03; OCH_3, 16.87; COOH, 12.33]. Addition of an ether solution of VI to an excess of methylmagnesium bromide gave II which was identical [melting point, no depression on mixing: ultraviolet and infrared spectra] with the compound derived from the Willgerodt reaction on methyl O-methyl-7-propionylpodocarpate.

When heated with sulfur and morpholine, methyl O-methyl-7-acetonylpodocarpate (II) was converted to III (41% yield).

RECEIVED JUNE 3, 1957

THE PREPARATION OF BERYLLIUM AMALGAM[1]

Sir:

The preparation of a beryllium amalgam by electrolysis of concentrated solutions of $BeCl_2$ into a mercury cathode has been claimed by Prytz[2] but this method is not confirmed elsewhere. A new and novel method, involving electrolysis of beryllium from a NaCl–$BeCl_2$ fused salt mixture into a mercury cathode has been developed in this laboratory and applied to the preparation of beryllium metal.[3]

Procedure.—Equimolar quantities of NaCl and $BeCl_2$ are melted together (224°)[4] to form an electrolyte. Beryllium chloride can be prepared by hydrochlorination of beryllium metal at 500°.

The electrolysis cell consists of a 4-liter resin reaction flask with a cylindrical inner sleeve to facilitate removal of the electrolyte at the conclusion of the electrolysis. Heat is supplied by an electric heating mantle.

Mercury (5000 g.) is placed in the cell and chunks of electrolyte are added quickly. The cell is closed and the electrolyte is melted down in an atmosphere of argon. A carbon anode is then inserted and the electrolysis commenced at about 5 volts and 6 amperes at temperatures of 300–350°.

Amalgam tends to climb through the salt to the anode. Therefore it is desirable to stir the cathode during electrolysis to avoid premature termination of the experiment. At the conclusion of the electrolysis (50–100 amp.-hr.) the cell is opened and the inner sleeve removed with the electrolyte within it. The amalgam, which varies in viscosity from a free flowing liquid to a semi-solid paste, depending on beryllium concentration, is found floating on the mercury at the bottom of the cell. The current efficiency of the electrolysis is approximately 65%.

The formation of amalgam evidently is sensitive to small traces of oxygen. Rigorous purification of the argon cover is required and it is essential that the cell be leak tight if amalgam is to be formed.

It is evident from this description that it also might be possible to prepare a beryllium amalgam by a displacement reaction with sodium amalgam and the fused-salt mixture used in electrolysis.

Properties of the Amalgam.—The amalgam is unstable in air, decomposing spontaneously with the formation of a black powder which is approximately 75% Be by weight. Dilute amalgams can be concentrated to about 2% beryllium by pinholing. The 2% amalgam is a thick pasty material from which additional mercury can be removed by such methods as pressing in a die or heating *in vacuo*.

Surprisingly, the room temperature X-ray diffraction pattern of the amalgam is the same as solid (−78°) mercury. The exact nature of the amalgam is not known. By analogy with the Mg–Hg system the compound $BeHg_2$ (2.2% Be) is suspected. It is hoped this information will assist in further investigation of the Be–Hg system.

cyclization,[6] *without rearrangement*, has not yet been detected in nature. In addition, numerous attempts to effect the synthesis of pentacyclosqualene by acid-catalyzed cyclization of squalene have failed.[7]

We outline here a total synthesis of this substance, heretofore obtained only by partial synthesis from α-onoceradienediol[8] (II, R = OH), and, incidentally, the synthesis of both α-onoceradiene (II, R = H)[8] and β-onoceradiene (III).[8,9]

Acid-catalyzed cyclization of either α- or β-monocyclohomofarnesic acid (IV) leads to a mixture of lactones from which the (±)-lactone V has been isolated.[10,11] Hydrolysis of the (−)-lactone in methanolic potassium hydroxide followed by careful acidification and ammonolysis gave the ammonium salt VI in high yield. Oxidative electrolytic coupling of VI in refluxing methanol at a smooth platinum anode[12] gave after chromatography the diol IX (m.p. 185–186.5°, $[\alpha]_D$ +420; found: C, 80.58; H, 12.29). Cyclization of IX with perchloric acid in benzene-acetic acid yielded (+)-pentacyclosqualene, I (m.p. 275–276.5° (sealed capillary), $[\alpha]_D$ +86°) identical in all respects with "γ-onocerene" prepared from α-onoceradienediol (II, R = OH).[8] Dehydration of the diol IX with phosphorus oxychloride–pyridine gave β-onoceradiene (m.p. 159–161°, $[\alpha]_D$ +140°) identical with an authentic sample.

Similarly, the (+)-lactone VII led to the diol VIII (m.p. 270-271°, $[\alpha]_D$ +13°; found: C, 80.41; H, 12.34) which on cyclization also gave (+)-pentacyclosqualene (I). α-Onoceradiene (II, R = H; m.p. 199.5–201°, $[\alpha]_D$ +25°) was obtained from VIII by $POCl_3$ dehydration.[13]

It is a pleasure to thank Drs. D. H. R. Barton, G. Lucius and M. Stoll for gifts of materials and Dr. Sherlock Swann, Jr., and Mr. W. Garrison for valuable aid with the electrolytic experiments.

MACROLIDE ANTIBIOTICS. VI. A STANDARD OF ABSOLUTE CONFIGURATION AMONG MACROLIDE ANTIBIOTICS

Sir:

As pointed out in a recent review,[1] the macrolide group of antibiotics represents a therapeutically and biogenetically important class of natural products. Knowledge concerning the absolute configuration of these substances is limited to a single center (C-10) of magnamycin[1] and this is of no direct applicability to the other antibiotics of this class since magnamycin follows the "acetate" rather than "propionate" pattern so common among macrolide antibiotics. Attempts to use rotation rules such as Hudson's lactone rule for the determination of the absolute configuration in the erythromycin series[2] have led to ambiguous results. We should now like to report certain reactions with neomethymycin (Ia)[3] which establish the absolute

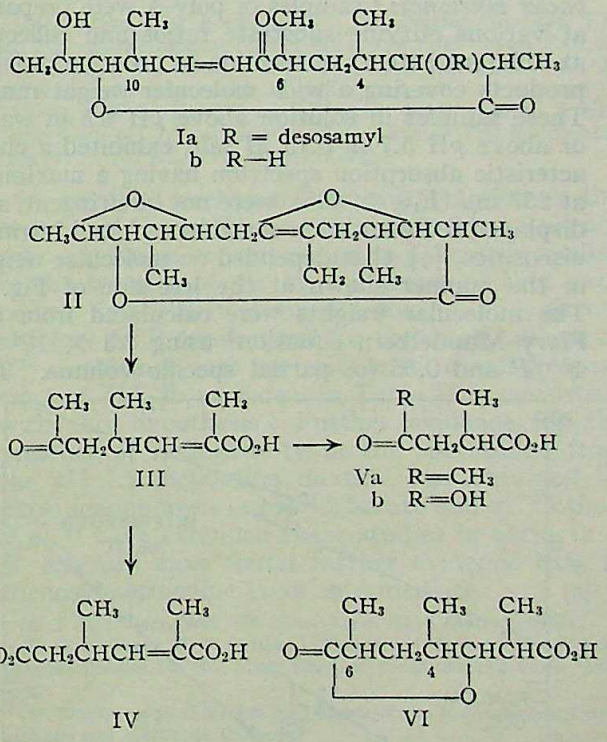
configurations of C-4 and C-6 of neomethymycin (Ia) as well as of methymycin,[4] pikromycin[5,6] and narbomycin[7] (see ref. 15).

When neomethymycin (Ia)[3,8] was boiled for 10 min. with 5 *N* sulfuric acid, extracted with ether and the *unwashed* ether extracts dried and distilled at 200° and 40 mm., there was isolated in over 70% yield the cyclic enol ether II[9] (m.p. 168–170° (from dilute methanol), $[\alpha]_D$ +124.5° (dioxane),[10] no high u.v. maximum, $\lambda_{max}^{CHCl_3}$ 5.75 μ (lactone) and 5.88 μ (enol ether) but no hydroxyl absorption, negative iodoform test; found for $C_{17}H_{26}O_4$: C, 69.15; H, 9.03; O, 22.22, OCH_3, 0.0; (5)C-CH_3, 23.84).[11] Ozonolysis of II at −80° in methylene chloride solution, decomposition of the ozonide with boiling water, saponification with 5% sodium hydroxide solution and purification of the acid fraction by silica gel chromatography and distillation yielded 6-oxo-2,4-dimethyl-2-heptenoic acid (III) (b.p. 100° at 0.001 mm., $[\alpha]_D$ +46° (chloroform), 11 $\lambda_{max}^{CHCl_3}$ 5.80, 5.88 and 6.02 (m) μ and broad "acid absorption" in 3.4 μ region, positive iodoform test; found for $C_9H_{14}O_3$: C, 62.96; H, 8.37) which formed a bright yellow 2,4-dinitrophenylhydrazone (m.p. 142–144°; found for $C_{15}H_{18}N_4O_6$: C, 51.46; H, 5.57; N, 16.05; neut. equiv., 340). Brief warming of the keto acid III with sodium hypoiodite solution in aqueous dioxane gave iodoform and crystalline 1,3-dimethyl 1-butene-1,4-dioic acid (IV), which may be a mixture of *cis–trans* isomers since it could not be obtained sharp melting after distillation at 120° and 0.001 mm. and recrystallization from ether–hexane (m.p. 130–155°, $[\alpha]_D$ +41° (chloroform), λ_{max}^{EtOH} 215 mμ, log ϵ 4.05; found for $C_8H_{12}O_4$: C, 55.60; H, 7.09; neut. equiv., 88). Ozonolysis of the unsaturated keto acid III followed by permanganate oxidation produced α-methyllevulinic acid (Va), $[\alpha]_D$ −5.6° (chloroform), which was characterized as the yellow 2,4-dinitrophenylhydrazone (m.p. 194–196° with sublimation from 165°; found for $C_{12}H_{14}N_4O_6$: C, 46.69; H, 4.64; N, 17.94; neut. equiv., 306). Hypoiodite oxidation of α-methyllevulinic acid (Va) furnished iodoform and (−)-methylsuccinic acid (Vb) (m.p. 111.5–113°, $[\alpha]_D$ −17.5° (*c* 0.97 in ethanol), $[\alpha]_D$ −9° (*c*, 1.0 in H_2O) found for $C_5H_8O_4$; C, 45.32; H, 6.03; neut. equiv., 65) identified by infrared comparison with an authentic sample kindly provided by Dr. E. J. Eisenbraun.[12] By proceeding without isolation of intermediates, a 20% over-all yield of (−)-methylsuccinic acid (Vb) could be realized from the enol ether II.

Since (−)-methylsuccinic acid has been related with L-glyceraldehyde,[12,13] the absolute configuration of C-4 in neomethymycin (Ia) has been established. In view of the fact that neomethymycin[3] as well as methymycin,[4] pikromycin,[14] and narbomycin[14] have been transformed into the identical lactonic acid VI, which still retains C-4 and C-6 of the parent compounds, and since the acid VI has been converted[14] into meso-α,α'-dimethylglutaric acid, the absolute configuration of C-4 and C-6[15] in all four antibiotics has been related experimentally to L-glyceraldehyde.



We are indebted to the Squibb Institute for Medical Research and the National Heart Institute (grant No. H-2574) of the National Institutes of Health, U. S. Public Health Service for financial assistance. The microanalyses were performed by

(4) Papers III and IV, C. Djerassi and J. A. Zderic, THIS JOURNAL, **78**, 2907, 6390 (1956).

(8) In our earlier communication (ref. 3) bearing on the structure proof of neomethymycin, we neglected to state that the methyl group was placed at C-10 rather than the equally plausible C-11 position because successive treatment of dihydroneomethynolide (Ib with double bond reduced) with lithium aluminum hydride, periodate oxidation, steam distillation of acetaldehyde and finally treatment of the residue with sodium hypoiodite did *not* yield any iodoform.
(9) The same product was obtained when neomethynolide (Ib) or cycloneomethynolide (VIa in ref. 3) was shaken with acidified ether and then distilled at 40 mm.
(10) The substance showed a positive plain dispersion curve (*cf.* C. Djerassi and W. Klyne, *Proc. Chem. Soc.*, 55 (1957))—in contrast to the three starting materials—thus demonstrating the disappearance of the ketone function.
(11) Single positive Cotton-effect curve in methanol solution (peak $[\alpha]_{315}$ + 560°).

(13) For a summary of Fredga's work see J. A. Mills and W. Klyne in W. Klyne's "Progress in Stereochemistry," Academic Press, Inc., New York, N. Y., 1954, Vol. I, p. 203.
(14) R. Anliker, D. Dvornik, K. Gubler, H. Heusser and V. Prelog, *Helv. Chim. Acta*, **39**, 1785 (1956).
(15) Provided pikromycin and narbomycin possess a hydroxyl group at C-3. If the hydroxyl group is located at C-5—as has been suggested as a preferred structural alternative for pikromycin (ref. 5, 6)—then it should be noted that C-4 and C-6 as marked in formula VI correspond to C-2 and C-4 of pikromycin and since the sterochemical convention is then changed, the absolute configuration of these two centers in pikromycin would correspond to the D-series. This point will obviously not be settled until the constitution of pikromycin (and narbomycin) has been established unambiguously at which time it will be known which carbon atoms of the antibiotics correspond to those of the lactone acid VI. In any event, the latter represents the standard of absolute configuration for this portion of these macrolide antibiotics.

POLYNUCLEOTIDES. I. MOLECULAR PROPERTIES AND CONFIGURATIONS OF POLYRIBOADENYLIC ACID IN SOLUTION[1]

Sir:

We wish to report the discovery of two configurations of polyriboadenylic acid (poly-A): one a flexible, randomly coiled, molecularly dispersed form and the other a rigid, presumably helical form composed of variable numbers of poly-A molecules.

Using polynucleotide phosphorylase from *Azotobacter vinelandii*,[2] samples of poly-A were prepared at various enzyme–substrate ratios and collected at different extents of reaction in order to provide products covering a wide molecular weight range. These samples in solution above *p*H 6.5 in water or above *p*H 5.7 in 0.15 *M* salt, exhibited a characteristic absorption spectrum having a maximum at 257 mμ ($E_{1\%} \cong 295$), were not birefringent, and displayed sedimentation constants, s^0, and intrinsic viscosities, $[\eta]$, that depended on molecular weight in the manner shown at the left side of Fig. 1. The molecular weights were calculated from the Flory–Mandelkern equation[3] using 2.3×10^6 for $\Phi^{1/3}/P$ and 0.55 for partial specific volume. The

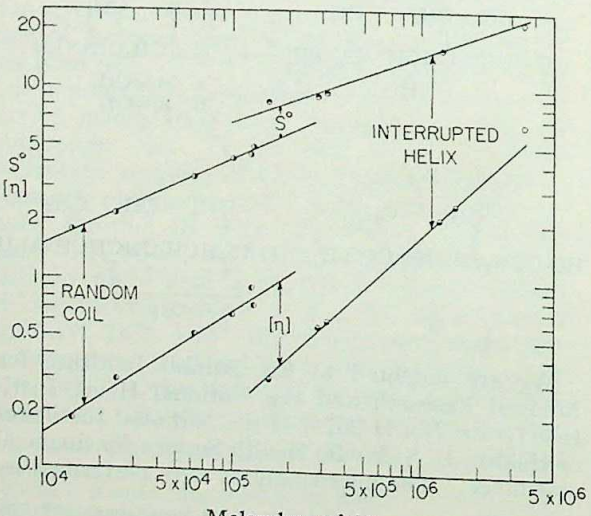

Fig. 1.—Molecular weight dependence of sedimentation constant, S^0_{20} in svedbergs and intrinsic viscosity $[\eta]_{25}$, in dl./g., of the two configurations of poly-A. For the curves on the left, the solvent was 0.15 *M* NaCl, 0.015 *M* citrate, *p*H 7.1; for those on the right it was 0.15 *M* acetate, *p*H 4.9. The open circle (○) represents measurements at *p*H 3.7 with no added salt present.

slopes, 0.45 and 0.65, respectively, are typical of randomly coiled chains: we conclude that this is the configuration under these conditions.

However, below *p*H 5 in 0.15 *M* salt and below *p*H 6.5 in water the poly-A samples displayed a different spectrum having a maximum at 252 mμ ($E_{1\%} \cong 255$) and had values of s^0 and $[\eta]$ that depended on the concentration and the temperature at which the transition had been brought about by lowering the *p*H.

By varying the concentration of poly-A (0.2 to 1.5 g./100 cc. for the sample having a molecular weight of 126,000) prior to lowering the *p*H to 4.9 (acetate buffer of ionic strength 0.15) the solutions were found to exhibit systematic variations in s^0 and $[\eta]$ that were clearly indicative of the formation of stable aggregates. The weights of these aggregates increased with the concentration of poly-A at which the transition was induced. Calculating the molecular weights (or particle weights) as before, it was found that the s^0 and $[\eta]$ varied with weight as shown in the right side of Fig. 2. The linear relations that result and the values of the slopes, 0.36 and 0.92, respectively, indicate that the species are homologous in structure and that the differences in weight are the result of different extents of linear growth. Unlike the randomly coiled configuration, this form does not show a marked increase in specific viscosity upon removal of salt. This and the behavior in flow birefringence lead to the conclusion that the structure is relatively rigid and rod-like, but not quite to the extent found for deoxyribonucleic acid (DNA). The stability of this structure appears to result from the lowering of the electrostatic energy brought about by titrating about half of the adenine groups. The failure to find spectra intermediate in character between the two described further suggests that the transition is abrupt and complete and that practically all the chromophoric groups (adenine) undergo the same change in environment. Moreover, at *p*H 4.9 in 0.15 *M* acetate, the transition to the randomly coiled form occurs in a very narrow temperature range near 75°, only a few degrees below the transition temperature observed for DNA. This coöperative behavior indicates a highly ordered arrangement of secondary bonds for the acid-stable form.

These observations are compatible with a structure in which poly-A molecules are associated through hydrogen-bonded base-pairing in a double stranded helix,[4] each strand of which has gaps where one poly-A molecule ends and another begins. This would resemble the interrupted helical model once proposed for DNA,[5] but the gaps in our case may be larger. The increased rotational freedom at the gaps would account for the smaller space filling properties exhibited by this configuration

relative to DNA. If this structural proposal is the correct one, it may be possible for ribonucleic acid, also, to assume a double-stranded configuration in solution through pairing of only the adenine nucleotides.[6]

(6) We are very much indebted to Mrs. Elizabeth Klemperer who was reponsible for many of the measurements in this investigation.

INCORPORATION OF THE CARBON CHAIN OF METHIONINE INTO SPERMIDINE[1,2]

Sir:

The cumulative work of several laboratories has indicated the metabolic importance of the polyamines putrescine, spermidine and spermine in diverse biological systems. Tabor, *et al.*,[3] have shown that putrescine is the source of the four-carbon chain of spermidine and spermine. Recent results obtained by the author show that the side chain of methionine is an efficient precursor of the three carbon chain of spermidine in *Neurospora crassa*.

Neurospora crassa strains 74A-3b (wild type) and 38706 (blocked in the conversion of homocysteine to methionine) were grown at room temperature on Fries minimal medium supplemented with 50 μg./ml. of DL-methionine-2C^{14}. The spermidine was isolated by grinding the mold with sand and 5% TCA[4] and chromatography of the extract on 0.6 × 20 cm. columns of Dowex 50-X2 using an HCl gradient. The spermidine containing fractions were combined and dried; spermidine trihydrochloride was crystallized from methanolic hydrogen chloride and ethyl acetate. The specific activities of the added methionine and the isolated spermidine are compared in Table I. Amine concentrations were determined as described by Rosenthal and Tabor.[5] Radiopurity of the isolated spermidines was checked by paper ionophoresis in *p*H 8.2 borate buffer and by descending paper chromatography (3 parts 1-propanol:1 part 0.2*M* sodium acetate buffer). In all cases the radioactivity moved in one spot and was in the same position as added authentic spermidine trihydrochloride.

TABLE I

Strain	Specific Activities: Methionine (initial) c.p.m./μmole	Spermidine (isolated) c.p.m./μmole	Ratio Spermidine/ Methionine
74A-3b	6.36×10^4	3.38×10^4	0.53
38706	11.4×10^4	6.34×10^4	0.56

Spermidine was degraded by oxidation with alkaline permanganate. The small yield of succinate, from the four carbon chain, was isolated by chromatography on Dowex 1[6] and on paper using aqueous phenol.[7] The succinate isolated from the oxidation product of synthetic spermidine,[8] labeled in the four carbon chain, contained about 33% of the radioactivity put on the Dowex 1 column, while less than 0.5% of the radioactivity was found in the succinate from the oxidation products of isolated spermidine and synthetic spermidine[8] labeled in the three carbon chain. The low level of activity in the succinate shows that the isolated spermidine is not labeled in the four carbon chain and is consistent with labeling in the three carbon chain.

TABLE II

*p*H	Total radioactivity in spermidine fractions, c.p.m. + ATP	− ATP
7.2	2.1×10^4	520
8.2	2.5×10^3	795

Incubation, four hours at 37°; incubation mixture, 100 μg. 2C^{14}-DL-methionine (3.8×10^5 c.p.m.) per vessel, 0.01 *M* putrescine, 0.008 *M* glutathione, 0.003 *M* $MgCl_2$, 0.00001 *M* pyridoxal phosphate, 0.1 *M* buffer, 2.5 ml. 1:1 extract of 74A-3b, 0.02 *M* K_4ATP as indicated, total volume 5 ml.; buffers are *p*H 7.2, potassium phosphate + Tris hydrochloride (1:1), *p*H 8.2, Tris hydrochloride.

A possible mechanism for this reaction is the transfer of the methionine side chain from S-adenosyl methionine to putrescine in a manner similar to the transfer of the methyl group of this compound first observed by Cantoni.[9] The almost absolute ATP requirement for the incorporation of C^{14} methionine into spermidine by a cell free extract of 74A-3b as shown in Table II is consistent with this hypothesis. Further evidence for the presence of radioactivity in the spermidine from the *p*H 7.2 incubation mixture was obtained by paper ionophoresis in *p*H 8.2 borate buffer. Tabor, *et al.*,[10] have extended these studies in extracts of *E. coli* and have found further evidence that S-adenosylmethionine is an intermediate.

THE HETEROGENEITY OF POLYSACCHARIDES AS REVEALED BY ELECTROPHORESIS ON GLASS-FIBER PAPER

Sir:

Glass-fiber paper[1] has been used in conjunction with a borate buffer *p*H 9–10 for the electrophoretic separation[2] of a wide variety of organic substances

including polysaccharides[3] and it has been reported that the method can be used for differentiating certain specimens of glycogen from various sources[4]; dextrans and other bacterial polyglucosans also may be distinguished.[4] The advantage of using the glass-fiber paper rather than cellulose paper is that complexes between the polysaccharide and the fiber are avoided[5] and the location of polysaccharides of all types is no longer a problem.[3,4] While it is possible to separate certain polysaccharides such as fructans, glucans and pentosans which have entirely different structures, using a borate buffer,[6] the inhomogeneity of a single polysaccharide cannot be ascertained in the same way, probably because of molecular association. We have found, however, that by replacing the borate buffer with 2*N* sodium hydroxide considerable information can be obtained. By this technique it has been shown that many polysaccharides hitherto assumed to be essentially homogeneous can be separated into two or more components.

All glycogen specimens from a wide variety of sources[7] thus far encountered have been found to be composed of two fractions, the major one moving at about ten times the rate of the other. In all cases the slow-moving component moved at the same rate but some of the glycogen specimens can be differentiated by the rate of movement of the faster moving component. Thus a specimen of liver glycogen obtained from a pregnant rabbit[8] can be distinguished by the fact that the faster moving component moves more slowly than the corresponding component of normal rabbit liver glycogen.

Amylopectins from a wide variety of starches have not only been found to be heterogeneous but also to differ from one another; three components have been detected in corn amylopectin, one of which corresponds to one of the components of corn amylose which is likewise heterogeneous. Repeated precipitation fails to separate all the amylose component(s) from amylopectin and both corn and potato amylose display heterogeneity even after repeated crystallization. The reason for this is not yet clear, but it is of interest to note that amylitol, obtained from corn amylose by sodium borohydride reduction,[9] moves on the glass paper largely as a single component and shows a mobility quite distinct from that of amylose.

Gums from *Acacia arabicum, A. pychnantha, A. senegal, A. seyal, Anogeissus latifolia* (gum ghatti) and gum tragacanth (*Astragalus sp.*) were all found to be heterogeneous whereas Black Wattle gum from *A. decurrens* and mesquite gum from *Prosopis juliflora* appeared to be homogeneous. Immunological examination has recently indicated the heterogeneity of gum arabic.[10]

The gums from the seeds of guar (*Cyamopsis tetragonaloba*), locust bean (*Ceratonia siliqua L.*), Kentucky coffee bean (*Gymnocladus dioica*), ivory nut (*Phytelephas macrocarpa*), tara (*Caesalpinia spinosa*), and those from flat (*Linum usitatissimum*) and *Plantago lanceolata*, all proved to be heterogeneous, two components being detected in each case.

The hemicelluloses separated from corn hulls, wheat straw, flax straw and ramie grass, and the so-called hemicelluloses from aspen wood, slash pine, loblolly pine and Western Hemlock all proved to be heterogeneous in nature. On the other hand the crystalline xylans[11] prepared from birch wood and barley straw by partial hydrolysis and also a specimen of the galactoaraban of sugar beet pulp proved to be homogeneous. These two crystalline xylans had almost identical mobilities on glass-fiber paper while the galactoaraban moved most rapidly, probably because of the more readily ionizable character of the primary alcoholic groups. Potassium hydroxide has been found to be a better electrolyte than sodium hydroxide for the separation of certain hemicelluloses; this observation may be related to the long-established fact[12] that it is better to use potassium hydroxide than sodium hydroxide for methylating hemicelluloses by the methyl sulfate method.

The fructans from rye flour (graminin), dahlia and perennial rye grass which have relatively low molecular weights were found to be homogeneous while the fructans from the ti (*Cordyline terminalis*) root, and from cocksfoot (*Dactylis glomerata*) contained small amounts of a second slow moving component.

Carraggenin already recognized as being heterogeneous[13] was found to consist of several components; one of the components corresponded to the K-fraction precipitated with potassium chloride, which was found to be homogeneous. Similarly agar has been found to be a mixture, a result in agreement with the recent report[14] that it consists of a neutral (agarose) and an acidic (agaropectin) component. Floridean starch also exhibits heterogeneity as also does laminarin from both *Laminaria digitata* and *L. cloustoni*. The reduced ($NaBH_4$) laminarin from *L. cloustoni* displays homogeneity.

Glass-fiber paper electrophoresis has also shown that yeast mannan and the glucomannans from Konjak mannan and Iles mannan are heterogeneous while the three mucopolysaccharides, heparin, hyaluronic acid, and chondroitin sulfate which individually behave as homogeneous polymers can be separated from each other with relative ease.

The movement of carbohydrate polymers on the glass paper appears to depend on the ionization of the alcoholic groups under the influence of the alkaline electrolyte. This is supported by the

fact that the non-reducing neutral oligosaccharides, sucrose, raffinose, stachyose, and the α- and β-Schardinger dextrins display considerable mobility, and like the free sugars, glucose and maltose, show no evidence of heterogeneity.

Electrophoretic separations were carried out on strips of glass-fiber paper (7 × 40 cm.) at 120 volts and 110 milliamperes for 10 hours:[15] The mobilities of the polysaccharide components are expressed conveniently as the ratio of the distance of migration of the component from the origin to the distance moved by the faster and major component of calf liver glycogen whose mobility is taken as 100. In a typical experiment the two components of glycogen moved 4.0 and 0.4 cm., thus having mobilities of 100 and 10, respectively. Likewise the three components of the seaweed polysaccharide from *Laminaria cloustoni* had mobility values of 10, 105 and 130 whereas the apparently homogeneous polysaccharides, birch wood xylan, sugar beet galactoaraban, Dahlia inulin and levosine (from rye flour) have mobility values of 110, 160, 130 and 140, respectively.

The components of a number of the above polysaccharides are now being separated on a larger scale with the object of ascertaining the structural significance of the phenomenon of heterogeneity as revealed by glass paper electrophoresis. It seems evident even at this early stage of the work that heterogeneity in polysaccharides especially those of fairly high molecular weight may be the rule rather than the exception. It is also conceivable that this phenomenon is analogous to the heterogeneity already recognized in proteins[16] and it may have some bearing on the specificity of the chemical components of the various species of plants and animals.

THE ACID DENATURATION OF FERRIHEMOGLOBIN[1]

Sir:

A series of important studies by Steinhardt and Zaiser[2] has demonstrated that hemoglobin undergoes a drastic configurational change below *p*H 4. The reaction is slow enough to permit spectroscopic and titrimetric observation of both the native and the altered form near *p*H 3.5. It is characterized by a change in absorption spectrum, and by the binding of about 36 protons per molecule (mol. wt., 67,000); *i.e.*, near *p*H 3.5 the "denatured" form contains about 36 more bound protons than the native form.

This communication reports the viscosity change accompanying the reaction. Figure 1 shows the

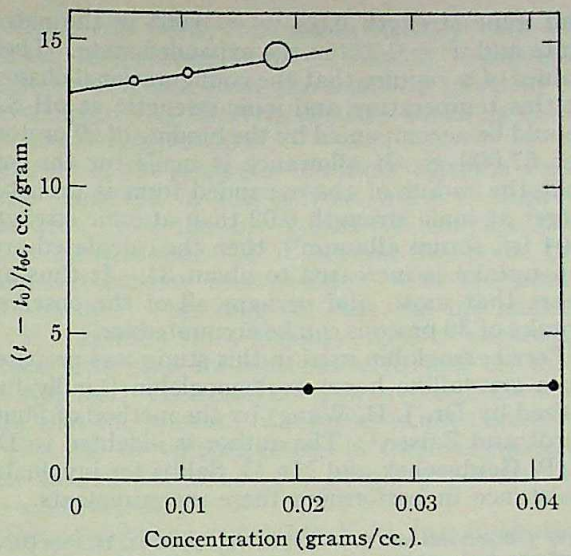

Fig. 1.—Viscosity data for native ferrihemoglobin (●) and for the same protein exposed to *p*H 3.5 for about 10 to 15 minutes (O). t represents flow time for the solution of concentration c, and t_0 flow time for solvent. All measurements were performed at ionic strength 0.04 at 25°.

data obtained from flow times in an Ubbelohde viscometer. To obtain intrinsic viscosities ($[\eta]$) from these data one must add 0.5 to the limiting value of the ordinate at zero concentration, so as to correct for the density difference between solution and solvent[3] and for the kinetic energy of the effluent solution. One obtains $[\eta]$ = 3.5 cc./gram for the native protein in neutral solution, in good agreement with a determination by Cohn and Prentiss.[4] At *p*H 3.5, after the configurational change has occurred, $[\eta]$ = 13.5 cc./gram. The configurational change thus clearly involves a marked expansion of the protein molecule, much like that observed for serum albumin.[5] Hemoglobin dissociates into half-molecules, at a *p*H much higher than that at which the configurational change occurs.[6] If this dissociation is assumed to occur without appreciable change in $[\eta]$, then, by Einstein's equation, the radius of an equivalent sphere (for half-molecules) is 26.5 Å. in the native state and 41.5 Å. in the expanded state.

The finding here reported is of special interest because it suggests a simple explanation for the uptake of protons observed by Steinhardt and Zaiser.[2] For expansion implies penetration of solvent into the molecular domain, which profoundly affects the titration curve by reducing all electrostatic interactions.[7] Specifically, the factor w, which occurs in the usual equation for the titration curve,[5,7] becomes much smaller and the titration curve itself becomes steeper. Equations derived earlier[7] enable this effect to be calculated if a spherical model is assumed. For spherical half-molecules with the radii given above we get, at 25°

and ionic strength 0.02, $w = 0.065$ in the native state and $w = 0.023$ in the expanded state. These values of w require that the configurational change, at this temperature and ionic strength, at pH 3.5, should be accompanied by the binding of 29 protons per 67,000 g. If allowance is made for the fact that the radius of the expanded form is probably larger at ionic strength 0.02 than at ionic strength 0.04 (*cf.* serum albumin[5]), then the calculated proton uptake is increased to about 34. It thus appears that most, and perhaps all of the observed uptake of 36 protons can be accounted for.

Ferrihemoglobin used in this study was prepared from crystalline horse oxyhemoglobin (kindly furnished by Dr. J. H. Wang) by the method of Steinhardt and Zaiser.[8] The author is indebted to Dr. E. P. Geiduschek and Mr. G. Saliba for invaluable assistance in performing these measurements.

CHARLES TANFORD[9]

RECEIVED JUNE 3, 1957

S-(DICHLOROVINYL)-L-CYSTEINE: AN AGENT CAUSING FATAL APLASTIC ANEMIA IN CALVES[1]

Sir:

We are reporting the synthesis of the compound S-(dichlorovinyl)-L-cysteine which upon oral administration produces a fatal aplastic anemia in young calves similar to that which we have observed with toxic trichloroethylene-extracted soybean oil meal (TESOM).

S-(Dichlorovinyl)-L-cysteine was synthesized by treating equimolar quantities of trichloroethylene (TCE) with the disodium salt of L-cysteine in liquid ammonia by a modification of the method of du Vigneaud.[2] The product precipitated on adjusting the pH to 5.0 with acetic acid and was crystallized from water–ethanol, 60–70% yield; m.p. 155–156° (decomp.). *Anal.* Calcd. for $C_5H_7O_2NSCl_2$: C, 27.29; H, 3.27; N, 6.48; S, 14.84; Cl, 32.82. Found: C, 27.83; H, 3.29; N, 6.47; S, 14.9; Cl, 32.8. *Ultraviolet absorption* in water: λ max. 210 mμ, $\epsilon = 8600$; λ max. 258 mμ, $\epsilon = 3200$. *Titration.* Neut. equiv., calcd. 216; found, 216; pI′, 5.4. *Paper chromatography.* 70:30 1-propanol–H_2O on Whatman No. 1, R_f 0.72; positive ninhydrin, 4-(p-nitrobenzyl)-pyridine (4-NBP),[3] ultraviolet and iodoplatinate tests.

Preliminary data indicate that the compound is S-(1,2-*trans*-dichlorovinyl)-L-cysteine.

The biological response of young calves to oral administration of S-(dichlorovinyl)-L-cysteine was studied by the methods established for the toxicity assay of TESOM.[4] The assay results are shown in Table I. The 500 and 200 mg./100 lb./day dosage levels were not tolerated by the assay calves and had to be discontinued after 5 and 7 days, respectively; however, all dosage levels tested produced the complete clinical, hematologic and postmortem picture of severe aplastic anemia of the bovine.[4]

TABLE I

BIOLOGICAL RESPONSE OF CALVES TO ORAL ADMINISTRATION OF S-(DICHLOROVINYL)-L-CYSTEINE

Dosage mg./ 100 lb./ day	Days to develop						
	Thrombocytopenia[a]	Leucopenia[b]	Lymphocytosis[c]	Elev. temp.	Fecal blood	Visible hemor.	Death[d]
500	10	9	13	13	13	11	14
200	12	10	10	11	11	13	14
50	14	19	21	21	17	19	23
20	18	22	22	25	25	22	27
10	20	27	31	51	27	26	60

[a] Platelet count below 200,000. [b] Leucocytes below 5000. [c] Over 85% lymphocytes. [d] Necropsied when moribund. Typical severe lesions of aplastic anemia.

We recently reported[5] on fractionation studies of toxic TESOM which indicated that the aplastic anemia causing entity is associated with the protein component of the meal. Analyses indicated that toxic TESOM contained 0.5 mole less sulfhydryl groups per 10^6 g. and about 25 p.p.m. more chlorine than did hexane-extracted meal from the same beans. In addition evidence that TCE would react with cysteine was obtained from sealed tube experiments. Of fourteen amino acids tested, only cysteine gave more than one ninhydrin spot by paper chromatography and one of these absorbed ultraviolet light and gave a positive 4-NBP test. Likewise reduced glutathione liberated chloride equivalent to its sulfhydryl content in sealed tube reactions and gave strong spots of R_f 0.50 and 0.70 which absorbed ultraviolet light and were 4-NBP positive. These facts and the knowledge that heat is required for the apparent interaction of TCE with soybean flakes to form toxic TESOM suggested the attempt to interact TCE with cysteine on a larger scale suitable for characterization and assay of the product.

Oral administration of S-(dichlorovinyl)-L-cysteine at the 20 and 10 mg./100 lb./day levels produces the typical syndrome of aplastic anemia in calves consuming levels of toxic TESOM'S ranging from $^3/_4$ to $^1/_5$ lb./100 lb./day and to samples of our isolated toxic protein at levels ranging from $^3/_8$ to $^1/_{10}$ lb./100 lb./day.

Paper chromatograms of fractions from a proved toxic pancreatic digest of TESOM's protein show ultraviolet absorbing 4-NBP and S positive spots with an R_f 0.45 and 0.70 with 70–30 1-propanol–H_2O on Whatman no. 1 paper. Similarities of the chemical and physical characteristics of these spots with those of S-(dichlorovinyl)-L-cysteine and its derivatives (TCE + glutathione) plus the observation that S-(dichlorovinyl)-L-cysteine pro-

duces in calves the typical TESOM toxicity syndrome, suggest that S-(dichlorovinyl)-L-cysteine may be related in structure to a part of, or may possibly be, the toxic principle of TESOM. Attempts to isolate sufficient toxic material from TESOM for chemical characterization are under way at the present time.

THE MAGNETIC SUSCEPTIBILITY OF MOLTEN NICKEL(II) COMPLEXES

Sir:

The paramagnetism exhibited by the bis-N-methylsalicylaldiminenickel(II) complex, diamagnetic in the solid state, when dissolved in "non-coördinating" solvents such as benzene and chloroform, has been interpreted as being due to the conversion of a proportion of the molecules of the complex from a planar to a tetrahedral configuration.[1] A similar behavior is observed for complexes of the series from bis-N-ethyl- to bis-N-amylsalicylaldiminenickel(II).[2]

The electric dipole moment measurements made on such complexes dissolved in dioxane and benzene have afforded evidence against such a view.[2] On the other hand, the hypothesis that paramagnetic octahedral disolvated complexes are formed, although improbable in the light of the investigations by Basolo and Matoush[3] on the coördinating tendencies of the methylbenzenes, cannot be ruled out.[4] In fact the existence of a silver perchlorate–benzene complex[5] shows that benzene and metal atoms may bind together.

In order to determine whether or not benzene molecules do coördinate with these nickel(II) complexes to yield paramagnetic solutions, magnetic measurements have been made on bis-N-alkylsalicylaldiminenickel(II) complexes, from bis-N-ethyl- to bis-N-decyl-, in the molten state. The magnetic susceptibilities of the molten compounds were measured between 80 and 200° by the Gouy method. In order to have samples of a lower melting point, mixtures of two complexes in the molecular ratio of 1:1 also were used.

Complexes which are diamagnetic in the solid state are paramagnetic with moments ranging from 0.8 to 1.15 B.M. in the molten state. Graphs of the magnetic moment *vs.* temperature for all of the complexes examined have very similar shapes and sometimes coincide. In the case of complexes or mixture of complexes melting below 100°, the curves have a minimum near 120°. Since the paramagnetism of bis-N-methylsalicylaldiminenickel(II) in benzene and chloroform, as measured by Clark and Odell,[1b] decreases steadily with increasing temperature from −16 to 43°, magnetic measurements have been also made on solutions of the complexes in dibutylphthalate which permits measurements up to 200°.

Curves of the magnetic moments of these complexes dissolved in this solvent likewise show a minimum. For the bis-N-methyl- complex this minimum falls near 120°. Beyond this point the magnetic moment rises steadily with increasing temperature. This suggests that the mechanism of the transition from diamagnetism to paramagnetism is the same for solutions as it is for the molten systems. The results of this investigation also show that the presence of solvents is not necessary to give rise to paramagnetism in these complexes, their diamagnetism being a property peculiar to the solid state only.
